The Isthmus of Panama is in that portion of the globe where the influence of convection is very great, but where cyclonic disturbances are almost absent. Currents due to convection of heat are nearly vertical, and moisture evaporated in a region exposed to these con-

ditions will largely be precipitated before being carried far away. Increased evaporation, therefore, will be followed by increased rainfall, and any change that increases or decreases the former will be followed by a corresponding change in the precipitation. Wherever there are mountain ridges the slopes of which obstruct and deflect upward the prevailing winds, there also will be found a well-watered country and perennial streams. So effective is this cause in producing rainfall that it is of frequent occurrence to find luxuriant vegetation on the windward side of a mountain range while the leeward side is dry and parched, and with meager growth. Although not to extremes, such conditions as these are found in the Canal Zone, with its 72 in. of

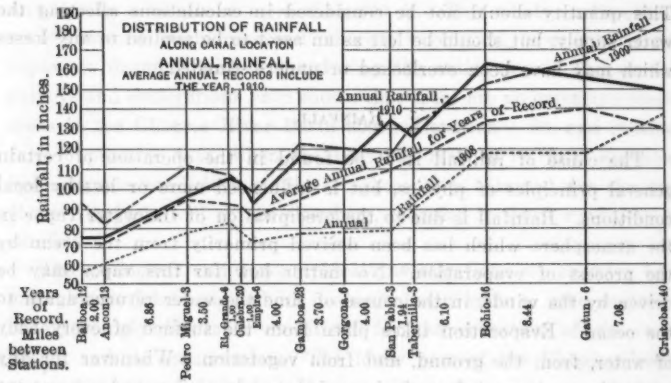

FIG. 14.

precipitation on the Pacific Coast and its 130 in. on the Atlantic, which are averages of long-period records.

The conditions of rainfall following excessive evaporation in this region are best shown in the basin above Alhajuela. There, on the high mountains, the moisture-laden winds from the north and west are forced to drop their loads. Along the Canal Zone and to the southwest, the ridges are of much less elevation, and therefore do not so much disturb the direction of the wind. The results of these conditions are found in the run-off at Alhajuela, with its well-sustained flow, and at Trinidad and Caño, with the opposite conditions.

The distribution of rainfall across the Isthmus is shown by Fig. 14. Culebra, with its annual average of 91 in., is at the limit of the wind-

ward slope, and its rainfall, averaged with that of Cristobal and Gatun, gives a rough approximation of the rainfall conditions north of the divide and over the area in which will lie Gatun Lake and its drainage area. On the southerly or leeward side of the ridge the rainfall averages about 80 in. annually, or less than three-fourths of that on the windward side. Due to other local conditions, however, the actual rainfall on the Gatun Basin is larger than these mean values and more nearly approaches a ratio of 3 to 2.

Records of rainfall have been kept on the Isthmus of Panama in the vicinity of the Canal Zone for long periods at several of the stations. Table 6 gives the stations which have been in operation for 6 years or more, the length of record, and the probable accuracy of the record as a basis for prediction of the average conditions which may be expected in the future.

TABLE 6.—RAINFALL STATIONS IN CANAL ZONE.

Station.	Length of record, in years.	Probable error. Percentage.	Station.	Length of record, in years.	Probable error. Percentage

Bohio	16	4.50	Gorgona	6	14.00
Albajuela	13	7.00	Rio Grande	6	14.00

The figures in Table 6 for probable deviation from the actual average agree substantially with those given by Mr. A. R. Binnie, and quoted by Mr. Rafter.*

In his report on the "Influence of Forests on Stream Flow," Lieut.-Col. Edward Burr, M. Am. Soc. C. E., Corps of Engineers, U. S. A., states as his deduction that 60 years or more of climatic records are necessary from which to draw satisfactory conclusions, and that those drawn from records of 40 years or less will probably be misleading or incorrect. Col. Burr's conclusions regarding length of records necessary for basing estimates are therefore substantially in accord with the similar deductions of Messrs. Binnie and Henry, mentioned previously. From an examination of the curve, Fig. 15, it appears, however, that the probable variation from normal, in records of from 35 to 40 years, is of such small amount that errors due to observation and

the application of the data from a few stations to a large area may somewhat offset the accuracy presumed for longer records.

Fig. 16 shows graphically the annual rainfall for five stations having the longest records, and Fig. 19 shows the comparative monthly distribution for several stations, including those recorded on Fig. 16. Table 7 gives the mean monthly and accumulated quantities for each station.

Of the 31 rainfall stations now operated, 17 are supplied with rain gauges of the U. S. Weather Bureau standard pattern, 11 have automatic gauges of the tipping-bucket type, and 3 have 14-day automatic gauges of Dutch make. The latter are located in isolated positions, where daily attendance is impracticable.

The Weather Bureau standard rain gauge consists of a hollow metal cylinder, 8 in. in diameter and 20 in. high, made in two sections, a receiver for catching the rainfall and an 8-in. overflow tank for storing any water that may accumulate in excess of the quantity required to fill the measuring tube. The receiver leads by a funnel to the copper measuring tube, approximately 2½ in. in diameter, placed inside the

8-in. cylinder. When the measuring tube has become filled, the water is allowed to overflow into the larger cylinder, whence it is drawn off later and measured. The two cylinders are proportioned so that the measuring tube has exactly one-tenth of the cross-section area of the receiving cylinder, therefore $\frac{1}{10}$ in. in depth in the measuring tube represents 0.01 in. of rainfall. The quantity of rainfall is obtained by measuring the depth in the smaller cylinder with a graduated stick, turning back into the smaller cylinder any rain which may have overflowed into the larger one.

The tipping-bucket gauge is of more complicated design. It is composed of a metal cylinder, 12 in. in diameter, open at the top, and about 30 in. high over all. Inside the cylinder, a brass bucket is balanced, having two compartments of the same size and shape. The bucket is adjusted to tip when a quantity of water equal to $\frac{1}{100}$ in. over the area of the receiving cylinder has accumulated, and spill the contents into the cylinder, where it can be measured with a stick as a check. The bucket is connected electrically with a register on a revolving drum on which is wrapped a sheet of paper graduated in

hour- and five-minute periods. Every tip of the bucket is registered on the paper by a pen or pencil, and as each mark represents $\frac{1}{100}$ in. of rainfall, an automatic record is obtained of the time the storm begins and ends, and the number of marks gives the total quantity and the rate of downpour in a given time.

The Dutch gauges are of somewhat similar construction, except that there is no electrical connection, the entire gauge and recording devices being contained in the same case. On account of direct measurements, the standard 8-in. rain gauge is considered the most reliable indicator of the quantity of precipitation. In order to obtain

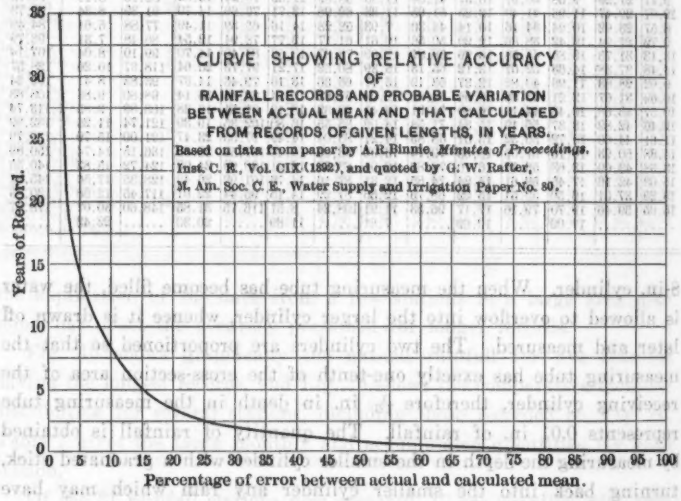

FIG. 15.

some idea of the reliability of the automatic gauge, a standard gauge (8-in. diameter) and an automatic gauge (12-in. diameter), were located side by side and daily readings were taken during August and September, 1910. During August, 95% of the measurements in the two gauges agreed exactly, and the remaining 5% were only slightly at variance with each other. The total monthly rainfall by stick measurement was the same in both gauges. During September, 93% of the measurements agreed exactly, while the total monthly rainfall by the standard gauge equalled 101% of the total by the tipping-bucket

FIG. 16.

gauge. It appears that the records from these two gauges agreed about as closely as would the records of two gauges of the same type if exposed side by side.

Like all automatic devices, however, the records are only reliable when the instruments receive proper care and attention, and when their peculiarities are known and accounted for. Some investigation was made of the relation between the quantity recorded by the register

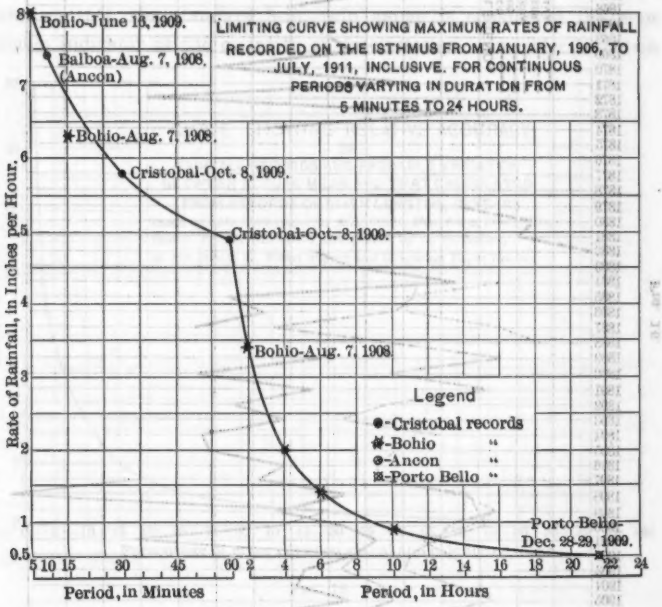

FIG. 17.

and the actual collection as indicated by stick measurement. It was found that the ratio depended largely on the quantity and character of the rainfall. For light and slow rains, the automatic registration accorded closely with the stick measurement, but for heavy rains, a marked deficiency of record appeared with the automatic registers. This loss was due to an appreciable quantity of water which pours into the tipped bucket while it is tipping. Each bucket, therefore, is over-filled, and, as only $\frac{1}{100}$ in. is recorded for each tip, all the water

flowing down the funnel is not measured. The deficiency in the automatic record was found to vary from less than 1% to as much as 8 or 10%, in exceptional cases. There are other factors, also, which contribute to defective registration, among which are lack of care in leveling up the gauge when setting, insufficient lubrication of the moving parts, weak battery power, and poor contacts in the electrical connections. The records in Table 8 are given as an indication of the foregoing conditions.

The trouble in the Balboa and Empire gauges was investigated and removed. In the latter case it was due to improper adjustment of the ratchet wheel; in the former it was due to defective leveling. These errors are not the fault of the instrument, but carelessness, inattention, or ignorance would fail to detect them, and the records would be misleading. On this account the total quantity of rain caught by the gauge is always measured by stick, and this reading is used in the records. The automatic record is used only to find the time the shower began and ended, and determine the rates of downpour during various periods.

As it was desirable to get rainfall records from isolated locations, where daily attention was not practicable and where the expense of a long-period gauge was not warranted, some investigation was made

as to the loss by evaporation from a standard rain gauge if the readings were taken at intervals of 2 weeks or longer. During November, 1910, the rainfall was allowed to accumulate in the standard rain gauge at Culebra, measurements being made on the 15th and 30th of the month. The total monthly rainfall by standard gauge showed a quantity slightly in excess of the total by the tipping-bucket gauge, which was close by, the collections in which were measured daily by stick before dumping. In other words, the nightly accumulation from dew and fog in the standard gauge more than equalled the evaporation during the day. It seems, therefore, that semi-monthly measurements of the accumulation in a standard rain gauge during the rainy season will give the total monthly rainfall with a fair degree of accuracy. On account of the construction of the standard rain gauge, its contents are well insulated from the effects of solar radiation until the inner tube is filled, the capacity of the latter being equivalent to 2 in. of rainfall, and, therefore, it seems that fairly reliable results may be obtained during the dry season by visiting the gauges only if necessary two or three times a month.

In regard to the collection from dew and fog, an appreciable quantity of moisture is gathered by night over the receiving surface of a rain gauge. This, however, enters only occasionally into monthly tables, because, if there has been no rain during the night, the moisture which has gathered in the automatic register is thrown out by the observer in the morning unmeasured. The only time this quantity does appear is when rain has fallen, and then it is impossible to separate the precipitation from the two sources. The nightly accumulations from fog and dew are greatest during foggy and clear nights and least during cloudy nights. The quantities range from zero to as much as 0.01 in. for a night. The average for the rainy season is estimated to be about 0.005 in. per night, or 0.15 in. per month. This, of course, does not mean that there is an equivalent of 0.15 in. of rainfall over the whole land surface from fog and dew; it merely means that the thin metal surface of the rain gauge has cooled rapidly by outward radiation, that the warmer air coming in contact therewith has been suddenly cooled, and the vapor condensed and precipitated on the surface of the gauge.

In order to get information concerning rainfall conditions at the heads of streams, three 14-day automatic rain gauges, manufactured in

Holland, were purchased. These gauges have now been in operation more than one year, and the following notes are submitted regarding their value in securing automatic rainfall records at interior points which cannot be visited except at infrequent intervals.

The clocks which actuate the drums on these registers were designed to run 14 days without rewinding, but experience has shown that they cannot be depended on in this climate for periods of more than 10 days. Thus it has been found necessary to visit these gauges at least three times a month.

The drums are driven at such a slow speed that during heavy rains, so frequent in tropical countries such as the Canal Zone, the bucket tips so fast that the record is blurred and the individual tips cannot be counted. The blurred and indistinct character of the record makes it always difficult and at times impossible to determine accurately the quantity of rain falling during heavy showers.

Certain parts of the registering apparatus have been found to get out of order readily, and various parts deteriorate rapidly from rust and other causes when exposed to the climatic conditions obtaining on the Isthmus. When parts of these gauges become worn or broken, it is very difficult, if not impossible, to secure new parts to replace them, as neither the gauge nor any of its parts are manufactured in the United States. If, however, a standard gauge is placed by the side of the 14-day automatic gauge, as a check, it is possible to get daily automatic records of dependable accuracy.

Long-continued rain storms extending over a large area are of infrequent occurrence in the Canal Zone. The rainfall is usually in the form of showers of limited extent, and it has been found that the topography and the location of the rain gauge are most important factors in getting correct results. To investigate this matter somewhat, records from a set of four gauges located in Empire were compared. These gauges are placed almost in a straight line northeast and southwest, and across the valleys of the Obispo and Camacho Rivers from hill to hill. No. 1 is on the east side of the Canal not far from the Empire suspension bridge, at about Elevation 190. No. 2 is the permanent gauge from which the official records are taken, and is about 1 000 ft. southwest of No. 1, and on top of a hill, Elevation 330, on the west side of the Canal, not far from the Division Office. No. 3 is about 2 600 ft. southwest of No. 2, and is in the corral yard, Elevation 220,

a most excellent exposure. No. 4 is at Camacho Reservoir, Elevation 370, and is about 4 600 ft. southwest of No. 3. Gauges Nos. 1 and 3 are in the valleys, while Nos. 2 and 4 are on the hills, but the extreme difference in elevation is not more than 200 ft. Table 9 shows the records, in inches per month, obtained from these gauges:

TABLE 9.—Records of Rain Gauges at Empire.

Month.	No. 1.	No. 2.	No. 3.	No. 4.
June	7.98	5.98	6.43	4.62
July	6.44	4.00	5.94	6.62
August	6.96	5.98	8.50	7.98
September	5.97	5.46	6.20	6.97
October	15.37	14.97	18.05	18.81

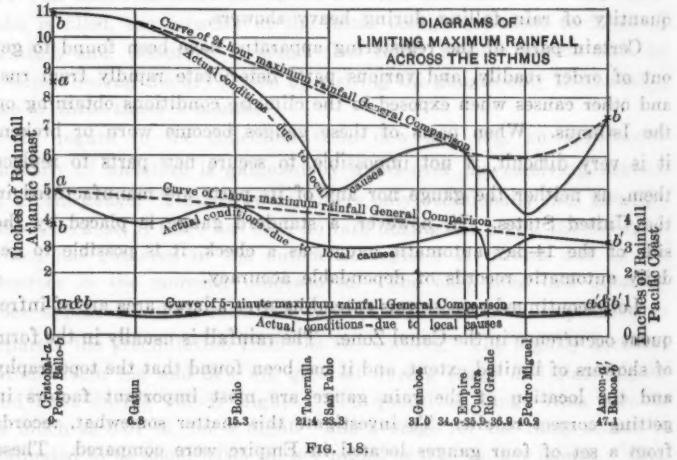

Fig. 18.

From inspection, it seems possible that the annual rainfall hitherto recorded at Empire may be from 12 to 15% too low. Table 10 gives information of a similar character, but mostly illustrating the limited extent of some of these tropical downpours. The records were obtained from Gatun and stations in the vicinity during a heavy rain on May 23d, the distances given being in an air line from Gatun Evaporation Station No. 2. (Gatun Evaporation Stations Nos. 1, 2, and 3 are located on the surface of the water in Gatun Lake.)

The diagram, Fig. 19, shows the frequency of heavy downpour on both sides of the Isthmus. It will be seen that the heaviest rains occur on the Atlantic side, and that there, too, are to be found the least number of days without any rain at all. This diagram represents average conditions.

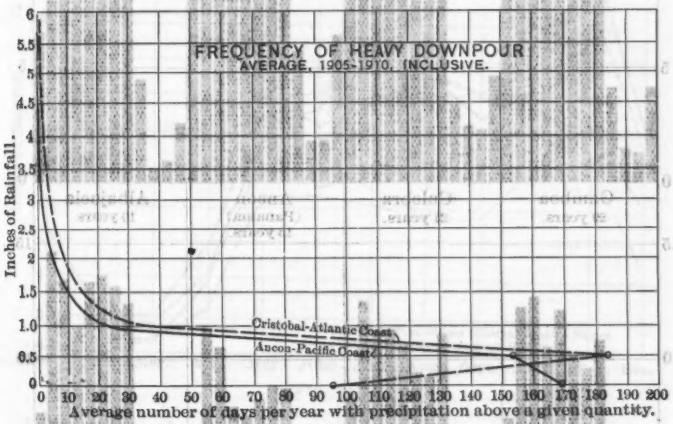

FIG. 19.

Storms giving a greater precipitation than 6.00 in. on the Atlantic or 4.50 in. on the Pacific side in 24 hours are of infrequent occurrence. During the past five years (June, 1906, to July, 1911), there have been 78 storms in which the precipitation has exceeded 4.00 in. Of these, 41 have had a precipitation of not more than 5.00 in., and 70 not more than 7.50 in. The rainfall in each of the remaining storms was: one not more than 8.00 in., one not more than 8.50 in., four not more

than 9.00 in., and two not more than 11.00 in. During this period the rainfall on the Pacific side has exceeded 4.50 in. at one or more stations on six different dates, or an average of a little more than once each year. On the Atlantic side the rainfall has exceeded 6.00 in. at one or more stations on fifteen different dates, or an average of about three times per year. It appears, therefore, that a rainfall of 6 in. in 24 hours is of not infrequent occurrence during the year, and that twice in 5 years a downpour of from 10.50 to 11 in. may be expected. Fig. 17 is a graphical representation of the extreme maximum limits of rainfall during the years of record.

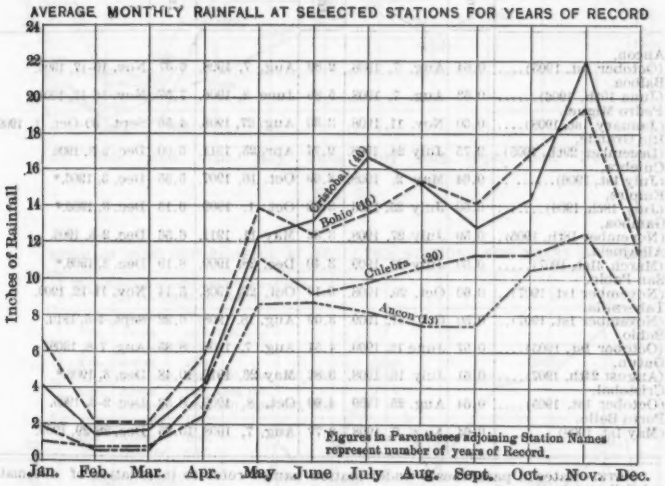

FIG. 21.

Fig. 21 shows the average monthly rainfall at four stations having long-time records. These stations indicate such conditions as are found from ocean to ocean across the Isthmus, and show that even in the so-called dry season there is an appreciable quantity of rainfall. The diagrams, Figs. 22 and 23, show, respectively, the maximum and minimum monthly precipitation for the years of record for the stations mentioned above. The greatest quantity recorded in the Zone was at Colon in November, 1862. Quantities exceeding this, however, were recorded at Porto Bello in 1909, where 45.03 in. fell in November and

58.17 in. in December. The total annual rainfall for this station in 1909 was 237.28 in., which is the maximum of record on the Isthmus.

NOTE.—Dates in parentheses under station names refer to installation of automatic rainfall registers.

*No automatic record on these dates. Total for 24 hours ending at noon.

†Maximum rainfall for any 24 consecutive hours.

In Table 11 may be found the record of the maximum rainfalls in the Canal Zone, October 1st, 1905, to June 30th, 1911, for periods of 5 min., 1 hour, and 24 hours. The curves on Fig. 16 show the relative distribution of excessive precipitation with relation to geographical location. Table 12 gives the periods of maximum rainfall for Cristobal, Gamboa, and Bohio.

Table 13 is compiled from the reports of the U. S. Weather Bureau, and is given for the purpose of showing the mean monthly rainfall

FIG. 23.

at selected stations covering geographically the whole of the United States. It is commonly believed that the rainfall on the Isthmus and in the tropics generally is very much heavier than in the United States and the temperate zone. There are several areas, however, in different parts of the United States, where the average annual rainfall equals or exceeds that on certain parts of the Isthmus, and this is especially noticeable when compared with the Ancon (Panama) records. The average and maximum annual rainfall records at a few selected stations are given in Table 14.

The line between the dry and rainy seasons is neither constant nor clearly marked. In some years the dry season begins as early as the middle of December, and in others not until toward the end of January. The dry season usually begins early on the Pacific side, and on the Atlantic side it has a tendency to lag considerably behind. This accounts for some of the freshets in the Chagres during January and February, when conditions in the interior do not seem to warrant their occurrence. During the first 6 months of the rainy season, the rain comes in heavy local showers, and the downpour is usually of short duration. In November and December, rains of a more general character occur, which cover wide areas and at times have a duration of 24 hours or more. The intensity of precipitation, however, is much less than that of the local showers of the preceding months.

Summarizing partly, from Table 11, "Maximum Rainfall in the Canal Zone," Table 15 shows the stations which recorded the extreme limits.

As has been stated previously, severe rainstorms of general distribution are not frequent on the Isthmus. The storm of December 2d and 3d, 1906, was the heaviest of record in the Canal Zone. This storm produced one of the greatest of the Chagres River freshets, and interrupted work for a very considerable period, besides bodily damaging the railroad and other works. The quantities recorded are given in Table 16.

Table 17 shows that, as a rule, the heavy downpours are of an extremely local character, and an examination of the records indicates this condition during showers of recent occurrence.

In connection with what has been stated regarding the quantity of rainfall, it may be interesting to note that the location of the heaviest known rainfall in the world is in the district of Assam,

* Evaporation Station No. 2.

Run-Off.

All the water that flows in a stream comes from the rainfall, but by no means all the rainfall finds its way into the stream. What proportion ultimately does appear depends on many conditions and combinations, the principal factors of which are elevation, topography, geology, and vegetation. The proportions of the rainfall ordinarily found running in northern streams may be seen in Table 18, abstracted from the Report of the Board of Public Works, Philadelphia, Pa.

TABLE 18.—Average Annual Yields of Sundry Water-sheds to October 1st, 1908.

Water-sheds.	Period covered, in years.	Area, in square miles.	Average rainfall, in inches.	Average rainfall flowing off, in inches.	Percentage flowing off.	Average yield, in cubic feet per second per square mile of drainage.	Average yield, in cubic feet per second per square mile of drainage area, for each inch of rainfall.
Perkiomen, at Frederick	25	152.0	47.179	23.276	49.313	1.7104	0.0360
Neshaminy, below Forks	25	189.3	48.113	23.111	48.033	1.6979	0.0350
Tohickon	25	102.2	48.751	27.264	55.920	2.1963	0.0450
Schuylkill	10	1 915.0	48.139	21.564	44.800	1.5842	0.0330
Sudbury, Mass.	33	75.2	45.99	22.387	48.680	1.6451	0.0380

It appears that, in streams of the character of those in Table 18, from 45 to 55% of the rainfall is ordinarily collectable, and that the yield may be taken as from 1.5 to 2.2 cu. ft. per sec. per sq. mile of drainage area. In the case of the Isthmian streams, for the past 10 years, the ratio of average annual run-off to rainfall has been more than 60%, and the average annual yield per square mile of the Chagres

River has averaged between 5.75 and 6.06 cu. ft. per sec., with some monthly averages of nearly twice as much.

For the purpose of measuring the discharge of the rivers and streams, gauging stations have been maintained at Gatun, Bohio, Gamboa, and Alhajuela, all on the Chagres River proper. River stage stations have also been maintained at Lagartera, on the Trinidad River, and at Monte Lirio, on the Gatun River, where several gaugings per month are usually taken. Besides this, a hydrographer makes regular trips to the principal secondary streams for the purpose of gauging, the intention being to get measurements at different gauge heights. On account of back-water from the lake, the Trinidad and Gatun River stations were abandoned in April, 1911, and December, 1910, respectively, after records had been obtained for about 4 years at each place. Bohio was abandoned as a gauging station in October, 1910, but is still maintained as a river stage station. Automatic water stage registers are in operation at all the regular stations, and a continuous record of river heights has been obtained since gaugings were begun.

A meter-rating station is maintained at Bohio, and all meters used on the work are rated and adjusted as nearly as possible at regular intervals.

The regular field work is carried on by the hydrographers in charge of the several stations, and after being worked up, the data obtained are sent to the central office for checking and filing. Gaugings are made frequently, and at as many different elevations as possible, in order to check the discharge curves. This course is necessary on account of the continuously changing cross-sections of the river bed, due to the shifting gravel bars. Cable stations are maintained at Gatun, Gamboa, and Alhajuela, and the gauging is done from cars, except in very low water, when wading or a boat is resorted to. All other gaugings are made by wading, under ordinary conditions, and by estimate of quantity passing under bridges, in times of freshet.

At Gatun the entire run-off from the Chagres Basin has passed through the spillway since April, 1910, and gaugings have been made regularly. Up to the dry season of 1911, and before the installation of the cable, gaugings were made from a boat. During periods of extremely low water, it was possible to work in the spillway itself, where, on account of the even flow and the shape of the concrete sec-

tion, very good measurements of the minimum discharge of the stream in 1911 were obtained. At the same time simultaneous gaugings were made at the cable station below, and from comparison with the spillway gaugings, it appeared that the results at the regular station were satisfactory.

Tables 19 to 30, inclusive, give the discharge measurements in various units for the Chagres River at Alhajuela, Gamboa, Bohio, and Gatun. Unless otherwise noted, the quantities are from actual gaugings—floats previous to 1907, and current-meter work subsequently.

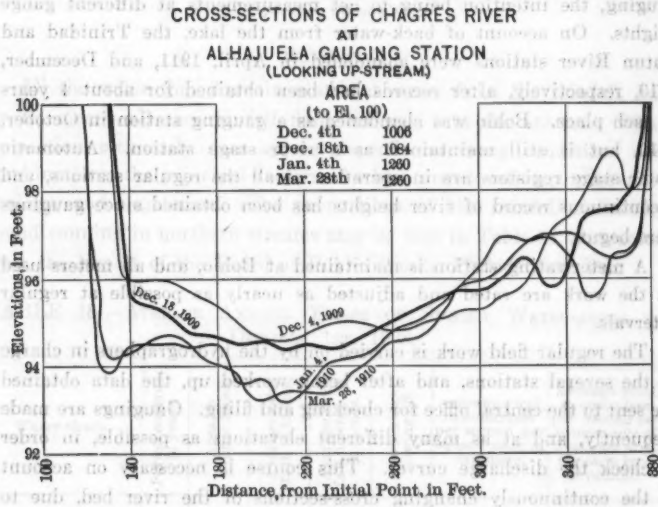

FIG. 24.

The discharge measurements for the stations on the Trinidad and Gatun Rivers for the years of record are given in Tables 31 and 32.

The Chagres River above Bohio has a constantly changing bed, and in order to get reliable measurements and estimates of the flow it is necessary to be constantly on the watch for changes in cross-section. After every freshet there is a change, and oftentimes of a most remarkable character. Some idea of this condition, perhaps, may be found from the fact that from one bar the Panama Railroad dredged some 60 000 cu. yd. of gravel in 1909, 90 000 cu. yd. from the same place in 1910, and about 95 000 cu. yd. in 1911. This gravel is dredged and stored during the dry season to be used as ballast on the new

railroad location. In spite of the removal, the pit is filled again during early flood season by most excellent gravel of various sizes, and, of course, cleanly washed. The cross-sections shown by Figs. 24 to 27, inclusive, were taken at the several stations, as required by the gauging work, and show the variations in area due to freshet scour. This action is perhaps best illustrated by comparing the cross-sections taken on December 18th, 1909, and January 4th, 1910, before and after one of the largest freshets recorded on this river. This rise began at Alhajuela on December 26th, and in the 9 days intervening, up to Jan-

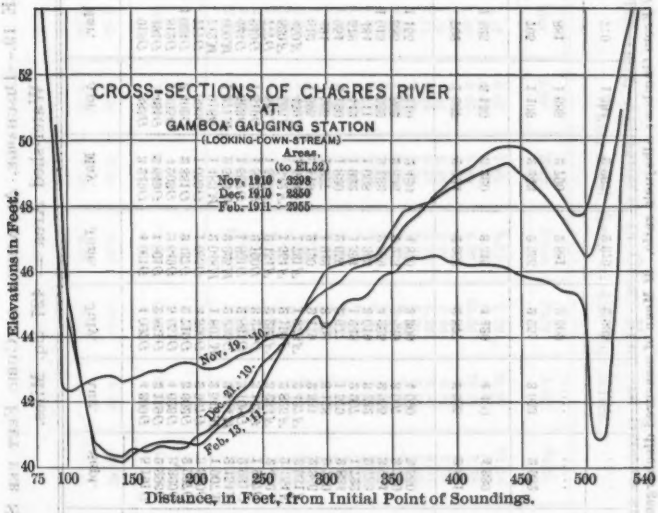

FIG. 25.

uary 4th, when the cross-section was taken, there had been a change in area of 176 sq. ft. below Elevation 100. The Gamboa station was not in operation at this time, but between December 21st, 1910, and February 13th, 1911, there was an increase of 95 sq. ft. in section at this station, due to a smaller freshet which caused high-water conditions for about 12 hours. The relation of change in cross-section is illustrated by the curves of area, velocity, and discharge for Gamboa shown by Fig. 28. These curves are made up from actual gaugings, and the change in cross-section producing the change in discharge can be seen by inspection of Fig. 25.

At Bohio the conditions are very different from those in the upper river. Here the river bed has very little slope, and the material carried along by the flood is alluvium and fine sandy clay. Besides this, the conditions are greatly modified by the large quantity of material from the canal excavation, which is dumped directly into the river and carried down stream. This has resulted in filling the bed to a greater extent than would otherwise have been the case. The changes in cross-section due to the various causes are shown by Fig. 26, the maximum change being about 200 sq. ft. below Elevation + 3 during the period between May 24th and December 23d, 1909. Since April, 1910, back-water conditions, and consequent lessening of the current, have resulted in a comparatively rapid filling of the bed at this point. On account of construction work at Gatun, it has been rather difficult to find a permanent gauging section at this station. Although the conditions of bottom and flow were not ideal, the best location seemed to be in the spillway channel below the concreted portion. Here the bottom was rather rough, and a little back-water was found near shore on each side. The eddies, cross-currents, and waves, which were found farther up in the concreted portion, due to bridge piers and other obstructions, were absent at the site chosen, and this location seemed to have the most advantages. A profile of the bottom, taken on February 28th, 1911, and the horizontal velocity curves taken on February 14th, 21st, and 28th, at different elevations of the lake surface, are shown by Fig. 27.

During the 21 years of record and estimate, for which the discharge tables have been made up, Alhajuela, Gamboa, and Bohio had the maximum discharge year in 1909, and Gatun in 1910. This condition was brought about by the fact that the rainfall and consequent run-off which took place in November and December, 1909, was especially large during the latter part of December, 1909. This caused an excess of flow at the upper stations for the last part of the calendar year, 1909, but much of the water was not delivered at Gatun until the following January, thus appearing to bring up the average of the calendar year, 1910. The river year, 1909-10, however, was the year of maximum run-off at all stations. The year of minimum run-off was 1905 at all stations, and the year of minimum dry-season run-off was 1908. The interrelation of these periods of discharge, as compared with each other and with the mean discharge for the period, is shown by Figs. 29 to 32, inclusive. From these it may be seen that the ratio

of the annual minimum and maximum discharge at Alhajuela is about 3.25, at Gamboa 3.40, at Bohio 2.56, and at Gatun 2.50, decrease down the river being due to the regulation of the flood discharge by flowage and storage in the swamps and low areas. All the diagrams show the influence of the heavy rainfall during November and December, 1909. Figs. 33 and 34 show the conditions of discharge duration for the period used for Alhajuela and Gatun, together with the mean discharge of the several months placed in order of dryness. Comparing the diagrams, it is seen that the discharge of the three dry months at Alhajuela is about one-half that of the whole drainage basin, while the average discharge at Gatun is about three times that at Alhajuela, which is about the same as the ratio of the respective drainage areas. These conditions of minimum and average discharge, when considered with relation to the character of the country in the upper and lower portions of the drainage basin, offer additional evidence of the harmful effect of swamps, as far as conservation of water is concerned, although their value as flood regulators has been indicated.

The critical period in maximum discharge appears to be a space of about 1 month in the case of Gatun; that is, a fairly uniformly increasing discharge can be expected for about 11 months of the year, with the rate in the twelfth month greatly in excess.

At Alhajuela this period of excess flow is of shorter duration, being only about 10 months out of the 252 recorded, or an average of about 15 days per year.

Fig. 35 shows the interrelations of discharge at the four main stations on the Chagres River.

Figs. 36, 37, and 38 show the cycle of monthly average discharge, or the average hydrograph, for the years of record. From these and the preceding diagrams the probable quantity of water available for power is easily seen. For the design of spillway and discharge channels, absolute maximum conditions are required, and these may be found in Table 35.

December 31st.....	9 A. M.	17.7	60 000	57 000
February 13th.....	4 P. M.	15.7	38 860	21 520

Floods are of frequent occurrence in the Chagres Basin, and from 1879 to 1906, General Abbot* records eight rises having a maximum discharge of more than 40 000 cu. ft. per sec. at Gamboa. Subsequent to this period, there have been other similar floods—those of November and December, 1909. That is, there have been eleven great floods in the Chagres in 30 years, or an average of about one every 3 years. The most important recent flood, and the one which gave the maximum recorded gauge height, was that of December 26th, 1909. This was accurately observed in all its conditions, and the data and results are believed to be the most reliable record of any flood on the Chagres River. The flood was the last of a series of three, all of which can be classed as great, and their occurrence between November 11th and December 31st, 1909, is an indication of the conditions for which it is necessary to provide in tropical water supply. During the period,

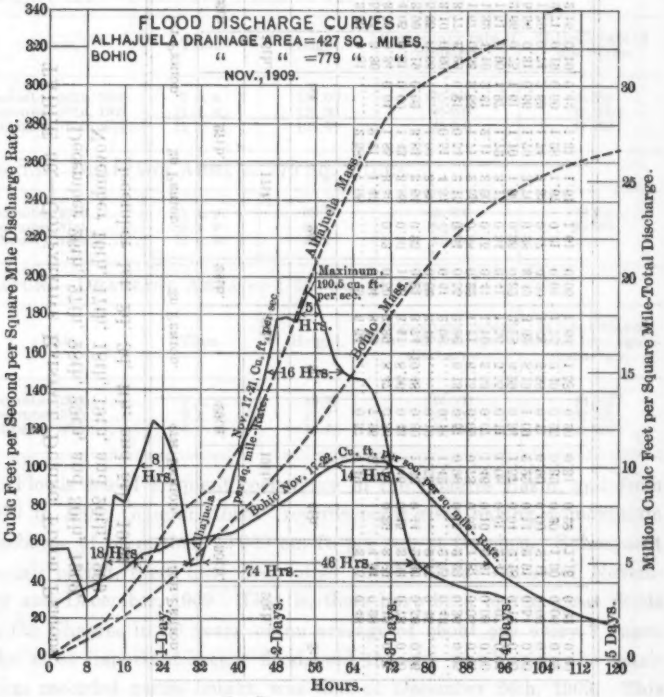
it is estimated that 128 000 000 000 cu. ft. of water were discharged past Gatun. This quantity, if delivered under the present conditions of Gatun Lake (water surface + 15) and with no outlet, would fill the lake to about Elevation + 73, or to within 14 ft. of maximum lake level (+ 87). Hydrographs of two of these floods and mass-curves of discharge are shown on Plates XXIX and XXX. These hydro-



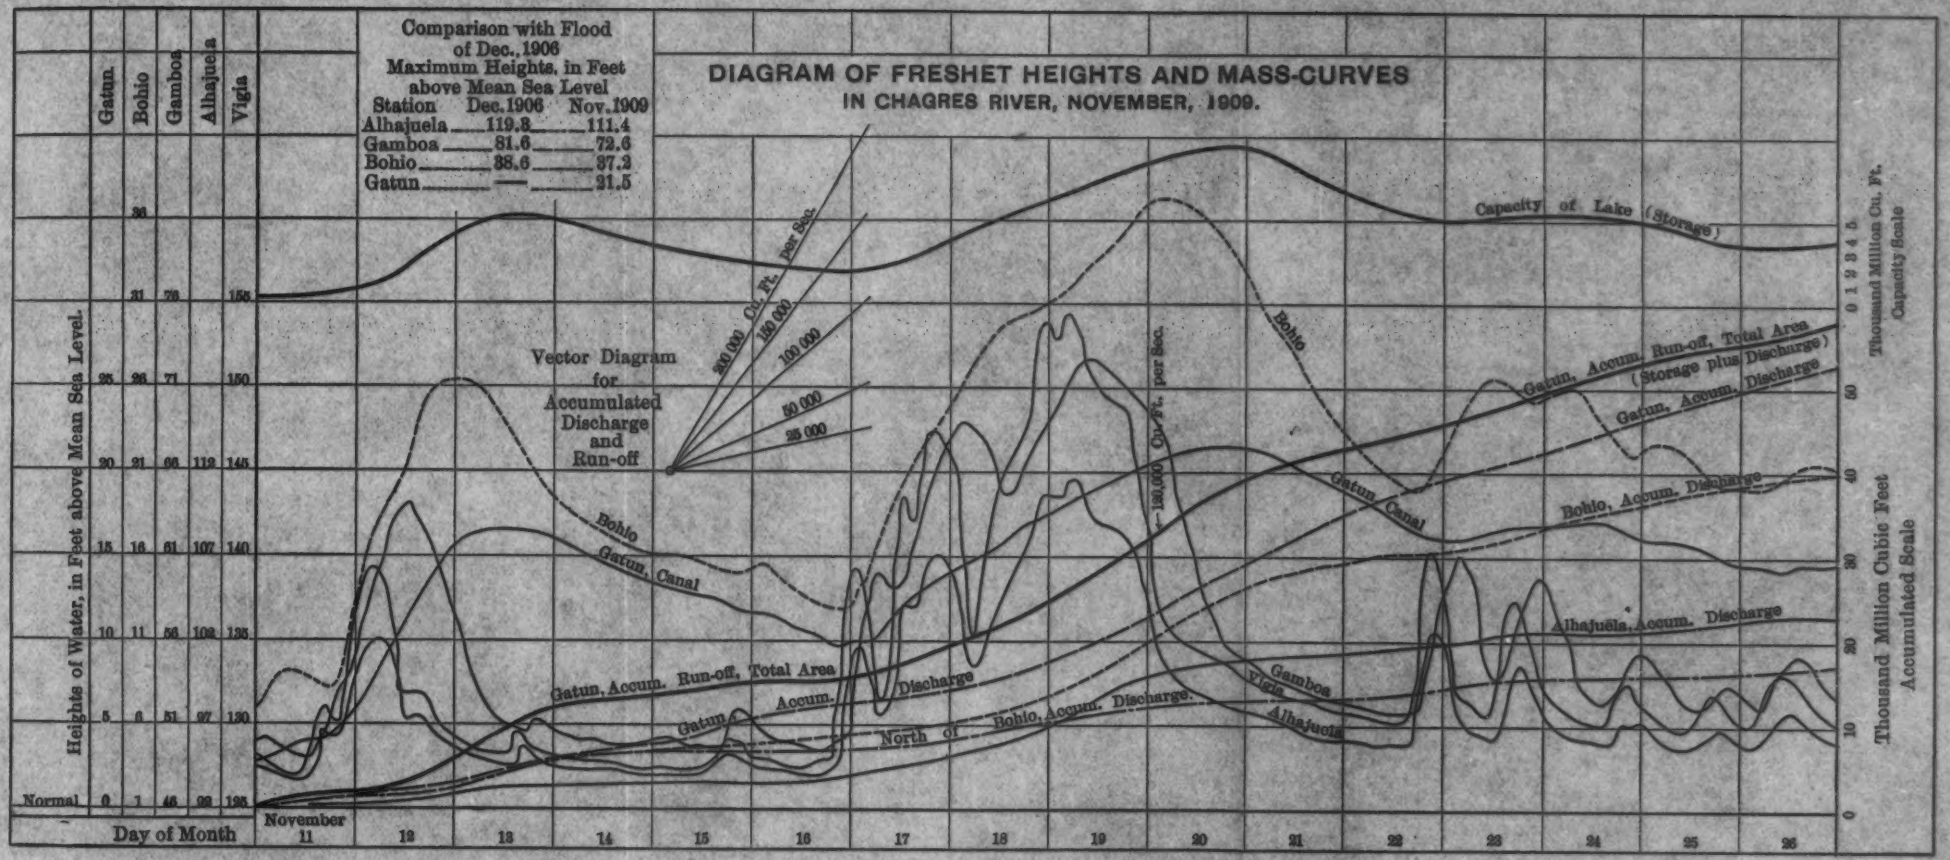


FIG. 39.

graphs are typical of the Chagres River freshets, and a study of them presents some very interesting facts. Figs. 39 and 40 show these conditions, and indicate two distinct types of freshet discharge which are probably of not infrequent occurrence in a long term of years, although they have been unusual during the period in which authentic records are available. The freshet of November, 1909, was of com-

PLATE XXIX.
TRANS. AM. SOC. CIV. ENGRS.

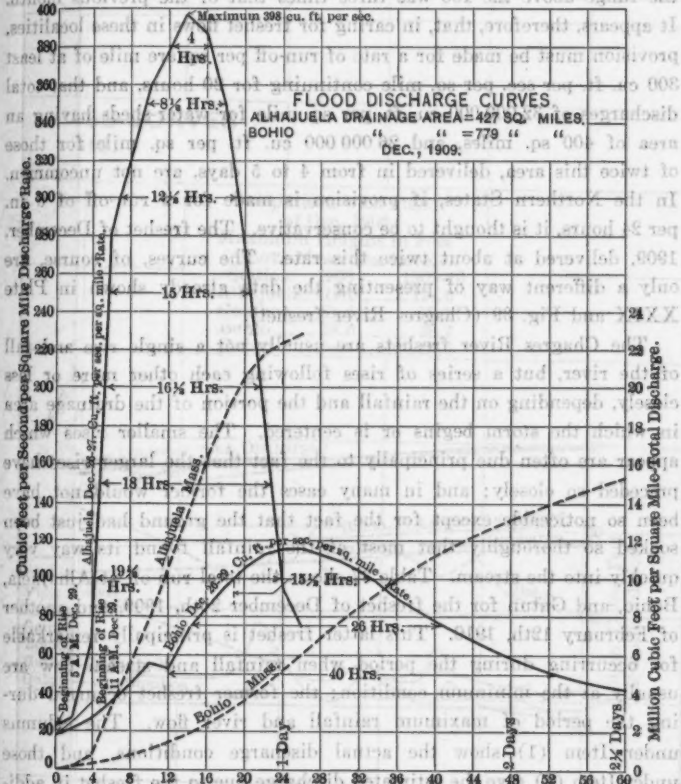
SAVILLE ON
HYDROLOGY OF THE
PANAMA CANAL.

paratively longer duration and of more widely distributed rainfall than that of the succeeding month, although the crest height at all stations was less than that of the December freshet. For the November rise, however, the discharge past Gatun was nearly 50% more than that of



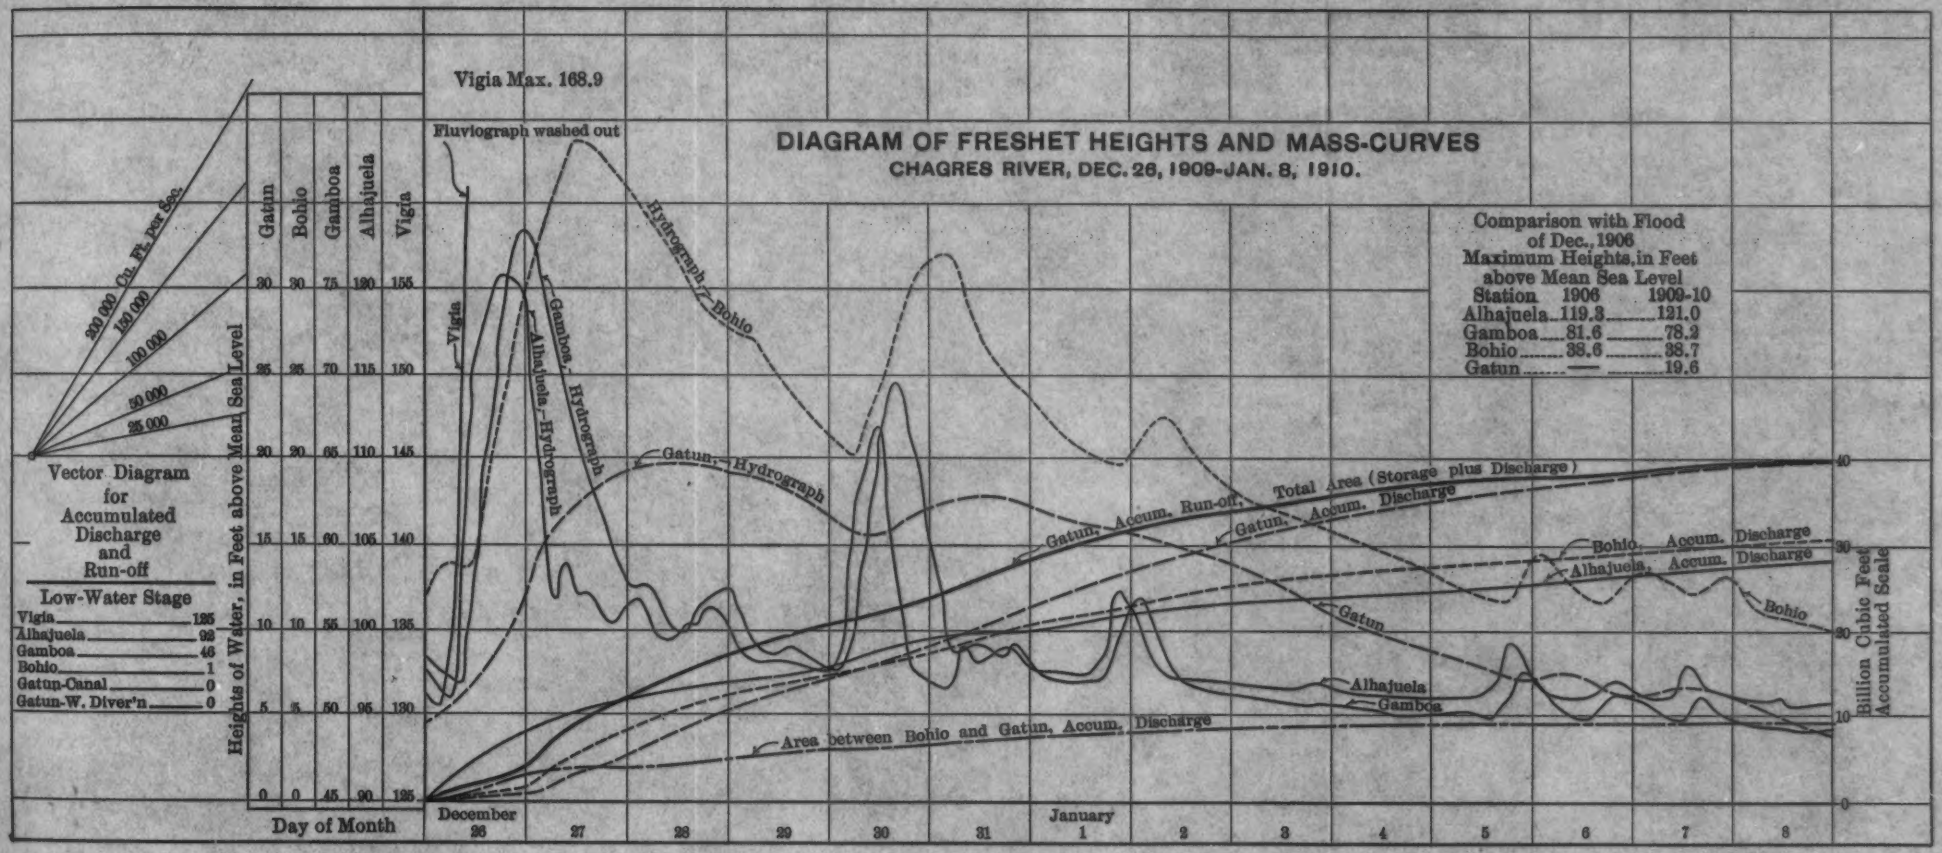


FIG. 40.

December. The duration of those extensive flows is a matter of considerable interest, and the length of time the rate of run-off equalled or exceeded a given rate is shown by the figures on the horizontal lines included between the discharge lines.

On comparing these two curves on this basis, it is seen that in November the flow was more than 100 cu. ft. per sec. per sq. mile for 40 hours, and in the case of the December freshet this rate was equalled or exceeded for only 19½ hours. During this time, however, the range above the 100 was three times that of the previous month. It appears, therefore, that, in caring for freshet flows in these localities, provision must be made for a rate of run-off per square mile of at least 300 cu. ft. per sec. per sq. mile continuing for 20 hours, and that total discharges of 32 000 000 cu. ft. per sq. mile for water-sheds having an area of 400 sq. miles, and 26 000 000 cu. ft. per sq. mile for those of twice this area, delivered in from 4 to 5 days, are not uncommon. In the Northern States, if provision is made for a run-off of 6 in. per 24 hours, it is thought to be conservative. The freshet of December, 1909, delivered at about twice this rate. The curves, of course, are only a different way of presenting the data already shown in Plate XXIX and Fig. 39 (Chagres River freshet).

The Chagres River freshets are usually not a single rise and fall of the river, but a series of rises following each other more or less closely, depending on the rainfall and the portion of the drainage area in which the storm begins or is centered. The smaller rises which appear are often due principally to the fact that the larger rises have preceded so closely; and in many cases the former would not have been so noticeable except for the fact that the ground had just been soaked so thoroughly that most of the rainfall found its way very quickly into the stream. Table 37 shows the total run-off at Alhajuela, Bohio, and Gatun for the freshet of December 26th, 1909, and another of February 12th, 1910. This latter freshet is principally remarkable for occurring during the period when rainfall and stream flow are usually at the minimum condition; the former freshet occurred during the period of maximum rainfall and river flow. The columns under Item (1) show the actual discharge conditions, and those under Item (2) give the estimated discharge due to the freshet in addition to the normal river flow, estimating the latter from the gauge height just before and after the rise. In the absence of rain gauges on the area above Alhajuela, the rainfall seems to be best estimated by taking the average of the Porto Bello and Alhajuela records. In the freshet of December 26th, this rainfall was about 19.50 in., and the discharge due to the particular conditions at this time was about

SAVILLE ON
HYDROLOGY OF THE
PANAMA CANAL.

17.18 in., showing that nearly this entire rainfall was discharged during the period of 4 or 5 days succeeding. An inspection of Table 36 will show that the rise of December 26th-27th was due to rainfall which was quite general over the basin, and that of the 20th was due almost entirely to rainfall in the extreme eastern part of the territory, in the neighborhood of Porto Bello. This latter condition was also true in the freshet of February, 1910, when 4.38 in. of rain fell at Porto Bello, 1.62 in. at Alhajuela, and less than ½ in. elsewhere in the whole basin.

The freshet of December 26th gave the greatest momentary discharge at all gauging stations, and that of November gave the greatest quantity of water. The comparative relations of the former are given in Table 38.

TABLE 38.

	Maximum Discharge for Short Period.		Ratio to Mean Discharge.		
	Cubic feet per second.	Cubic feet per second per square mile.	December.	Annual.	Minimum month.

Fig. 41 shows the hydrograph and discharge curves for the "dry season" freshet of February, 1910, and it is interesting to note that the total run-off at Gatun was about one-fourth of the discharge of the "wet season" freshet of December, 1909. Figs. 42 and 43 show the surface slope of the Chagres River during freshet periods, with the crest at various places. The time the crest passed the gauging stations

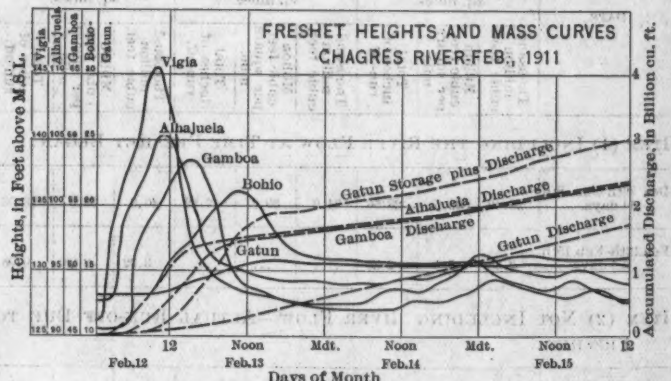

Fig. 41.

is given on Fig. 42, and from this it is possible to note the progress of the crest down the river. Table 39, for the freshet of December 26th, 1909, shows these data in concrete form.

The Gamboa station had not been established in December, 1909, but the flow past the station at Alhajuela had a mean maximum velocity of 13.57 ft. per sec., or more than four times that with which the crest moved down stream. In the lesser rise of February, 1911, the

The foregoing facts are of especial interest in the study of river hydraulics, and appear to indicate: (1) That flood crests move down stream with about the same velocity, irrespective of gauge height, due to the configuration of the average cross-section and the meanderings of the stream. (2) That the actual mean stream velocity is absolutely dependent on the gauge height. In the high rises in the Chagres River, the maximum current velocity at any point may be more than four times that of the crest, and gradually decreases in rate with the gauge height until, on the low flows, the two velocities practically coincide.

Run-off or stream flow depends, not only on the quantity of precipitation, but also on its distribution throughout the period under consideration. In the case of the Chagres River freshets, it has been shown that after a period of heavy rainfall the ground has become so thoroughly saturated that nearly all of a subsequent storm may pass quickly to the stream. On the other hand, after a period of drought and dry weather, oftentimes very little of the rainfall finds its way to the stream, or else it comes so slowly as to be unnoticed. Though excessive downpours of short duration may be disastrous to small reservoirs in some cases, as a general proposition, they are so local in their happenings as to be of interest mainly in combination with the design of sewers and drains. The effect of such conditions, therefore, is best studied on small areas. The Rio Grande Reservoir and water-shed have offered opportunities for such investigation. This reservoir is about 1 mile south of Culebra, at the extreme head-waters

of the Rio Grande. The top of the spillway is at Elevation 235.2, and the surface of the lake can be raised 3 ft. by the use of flash-boards. At the latter elevation the area of the reservoir surface is about 0.09 sq. mile, and the total area of the basin above the dam and including the reservoir is 3.15 sq. miles. The land area is wholly uninhabited, is covered with tropical vegetation and second growth, and is representative of the ordinary woodland conditions which obtain in the greater part of the river basins on the Isthmus.

Though there are several small brooks running directly into the reservoir, most of the area is tributary to the main stream for quite a distance above high water. A short distance above this point a river stage register was established, the area tributary from above being 2.36 sq. miles, or about 78% of the total land area. There is an automatic rain gauge on the shore of the lake, about ¾ mile east of the register station. A gauging section was established near the register, and a sufficient number of gaugings were made to fix the discharge curve and rating table. In Table 40 are shown the record and distribution for some of the most severe storms which have occurred since the station was established. Attention is called particularly to the

progressive increase in the ratio of run-off to rainfall, Column 10. Near the end of the dry season there had been only 3.34 in. of rain since February 15th, and 2.38 in. of this had been in a sudden downpour. The ground, therefore, was parched and dry, and the vegetation eager for moisture. On April 25th, 3.12 in. of rain fell in 3 hours 15 min., but only 5% appeared as run-off in the stream. As the rains became more frequent and the depleted ground storage became filled, a progressively greater quantity appeared in the stream flow until about July. A ratio of about 45% had been reached then, and the percentage of run-off afterward oscillated above and below this mark, depending on the rainfall and the quantity of water stored in the ground. The ratio of 72% appearing from the storm of May 13th is due to the heavy rainfalls just previous, which had not fully been cared for either by storage or surface flow. The data concerning the storms of July 21st and 23d are also of interest as an indication of the almost complete loss of a considerable quantity of water to stream flow and water use. This condition is due to the excessively dry period of June and July, when the rainfall was considerably below normal. It is indirect proof of the large water requirements of vegetation, and may be considered as a total loss to the lake. A study of the ground-water conditions showed that little, if any, of this rain appeared as run-off, although the run-off probably benefited indirectly by a lessened demand on the ground reservoir for vegetation.

The storm of May 25th was rather notable for the quantity of rain falling in a short time, and the conditions of run-off are those which ordinarily obtain from storms of this character. It occurred at a time when the ground reservoir was considerably filled and the demands of vegetation would not be out of the ordinary. Certain facts concerning this storm are shown by Fig. 44. The total rainfall was 2.73 in., of which a little more than 2 in. fell in 1 hour. The rain began at 12.12 P. M., and 0.29 in. fell in 26 min., no run-off being appreciable on the river gauge. The rain again began at 2.54 P. M., and at 4.32 P. M. 2.44 in. had fallen. At 3 P. M. the river gauge registered a flow of 1.3 cu. ft. per sec., and at this time the discharge began to increase. The maximum flow came at 4.15 P. M., the gauge showing a rise of 5.31 ft. and a discharge at the rate of 380 cu. ft. per sec. The stream flow did not return to its original discharge until 3 P. M. of May 30th, a period of 5 days. From 4.30 P. M. of the 25th to 3 P. M. of May 30th,

0.18 in. of rain fell between 2 A. M. and 10 P. M. of the 26th. As the 0.15 in. of rain that fell on May 25th, prior to the principal downpour, did not affect the stream flow, it is probable that the 0.18 in.

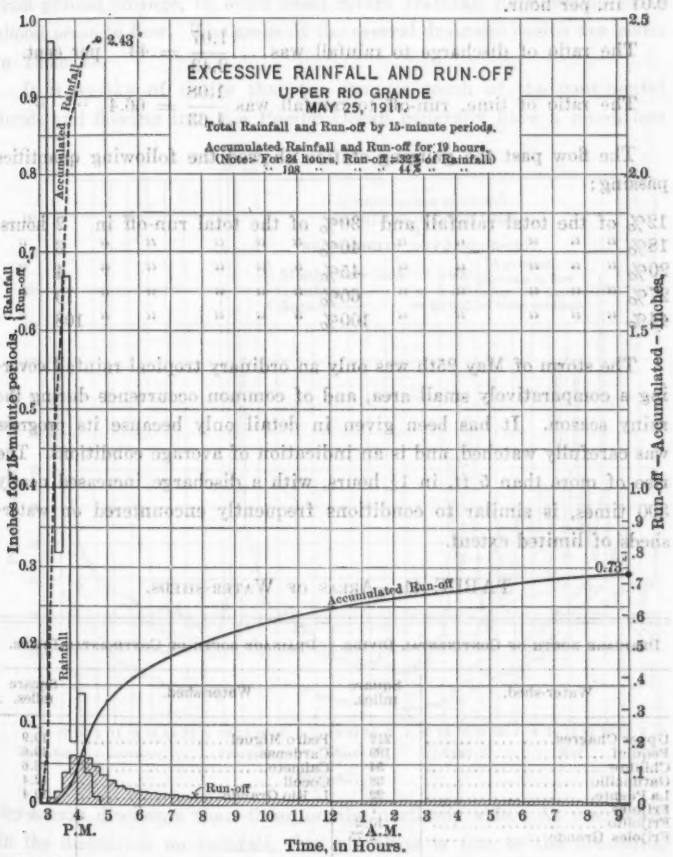

FIG. 44.

falling 9½ hours later also had so little effect as to be negligible. Assuming this condition, the rainfall between 2.54 P. M. and 4.30 P. M., May 25th, caused a run-off, which, beginning at 3 P. M., May 25th, reached a maximum at 4.15 P. M. of the same day, and its effect was

noted in the stream flow up to 3 A. M. of May 30th. That is, 2.43 in. of rain falling in 1 hour 38 min., at an average rate of 1.76 in. per hour, caused a run-off of 1.07 in. in 108 hours, at an average rate of about 0.01 in. per hour.

The ratio of discharge to rainfall was.... $\frac{1.07}{2.43} = 44$ per cent.

The ratio of time, run-off to rainfall was $\frac{1.08}{1.63} = 66.4$ " "

The flow past the gauging station showed the following quantities passing:

12%	of	the	total	rainfall	and	30%	of	the	total	run-off	in	2 hours.
18%	"	"	"	"	"	40%	"	"	"	"	"	3 "
20%	"	"	"	"	"	45%	"	"	"	"	"	4 "
27%	"	"	"	"	"	60%	"	"	"	"	"	10 "
44%	"	"	"	"	"	100%	"	"	"	"	"	108 "

The storm of May 25th was only an ordinary tropical rainfall covering a comparatively small area, and of common occurrence during the rainy season. It has been given in detail only because its progress was carefully watched, and is an indication of average conditions. The rise of more than 5 ft. in 1½ hours, with a discharge increased nearly 300 times, is similar to conditions frequently encountered on water-sheds of limited extent.

The relation between the rainy- and dry-season discharges of streams is particularly interesting in its bearing on water supply, and the use to which it can be put in regard to stream flow and reservoir storage. Figs. 45, 46, and 47 show these conditions graphically, and

little description seems necessary. It appears that the extreme low flows last for comparatively short periods, and though in many cases the discharge of the stream through the dry months is very well sustained from ground storage, in other cases rivers draining considerable areas almost cease to flow. The areas of the several drainage basins are given in Table 41.

It is worthy of notice that the streams south of the continental divide and flowing into the Pacific Ocean generally have a much less

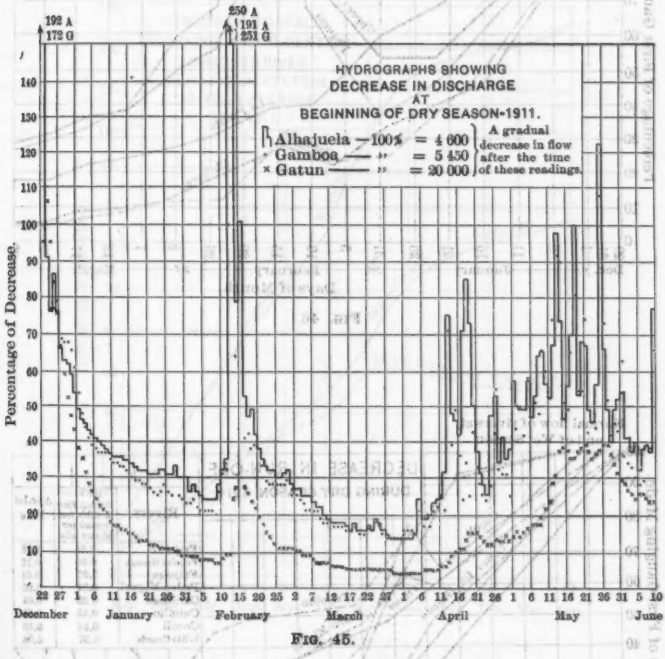

FIG. 45.

dry-season discharge than those on the northerly side. As mentioned in the discussion on rainfall, this condition is due to the prevailing winds and to the fact that the northerly side is the windward side of the cordillera.

The relations of rainfall and run-off in the basin seem to be best presented in diagrammatic form. The run-off, as measured and estimated at the several principal stations, has been given in Tables 19

to 32, inclusive, and the rainfall or record in Tables 7 to 11. Figs. 48 to 53, inclusive, show the run-off in the Chagres Basin for the average year and for other critical periods at Alhajuela and Gatun. Before studying the river relations, it was necessary to have the quantity of rainfall on the area considered. An estimate of this, based on the actual records from the stations, weighted for their relative influence, have been prepared. The values are given in Tables 44 and 45.

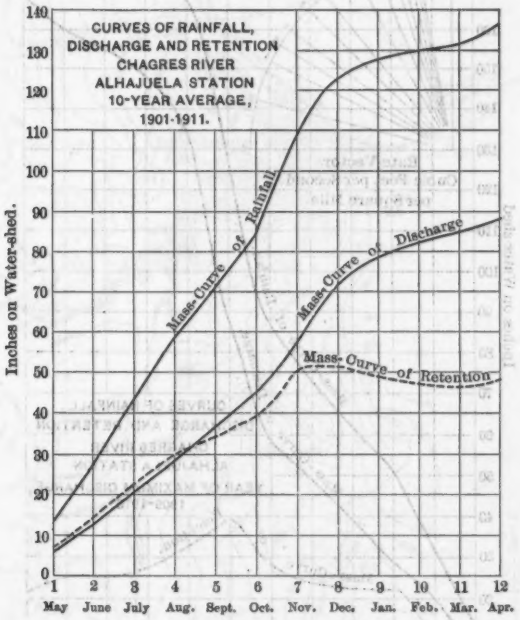

FIG. 48.

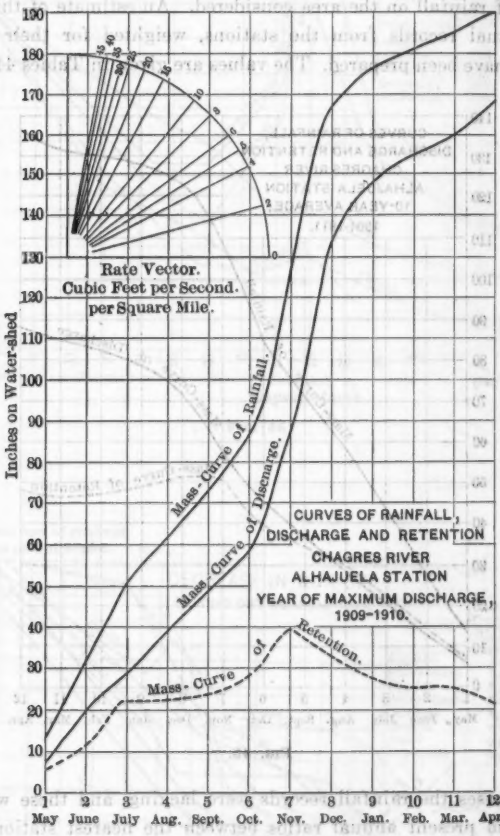
In many cases the rainfall records were lacking, and these were estimated from present annual ratios between the nearest station with a long-time record and the station where a value was required.

Attention is called to the fact that, although the run-off is a function of the rainfall, and would in time absolutely cease if the latter should stop, the quantity of the former does not vary directly with the quantity of the latter. During comparatively short periods of

little or no rainfall the run-off is many times in excess of the precipitation, and for longer periods the run-off decreases with the rainfall. This decrease, however, is not directly proportional, but is in some more complex ratio, depending on the character of the water-shed and



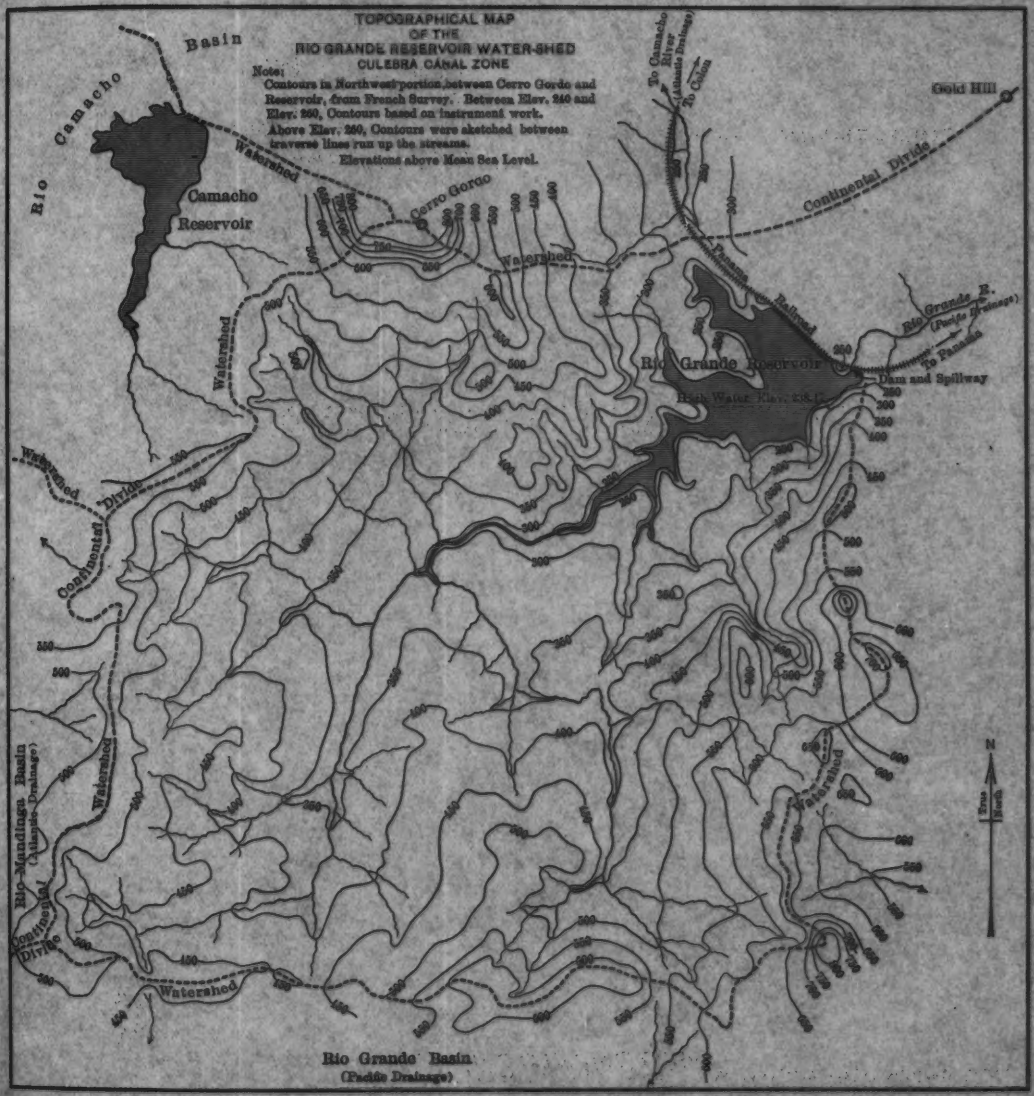


FIG. 49.

its vegetation. For example, a rainfall of 25% less than normal will produce a certain run-off during the year, under certain conditions, but a rainfall of 50% of the normal for this period would probably yield much less than 50% of the normal run-off. For this reason, it

is very unsafe to base calculations of yield on short-time observations, and apply the relation thus established to minimum conditions of rainfall existing at some former period. For the purpose of illustrating these conditions, Tables 42 and 43 and Fig. 53 are given for the whole area of the basin above Gatun (1 320 sq. miles), and for the area above Alhajuela (427 sq. miles).

The year of lowest rainfall in this decade is 1902-03, with 93.38 in. The river discharge for this year was 48.87, or 52.4 per cent.

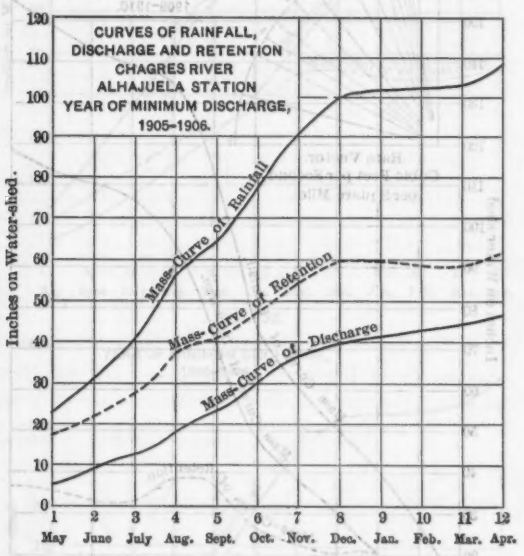

FIG. 50.

April, 1905, was quite dry, and the heavy rainfall of 20.22 in. in May produced only a moderate run-off, although it increased considerably the total rainfall for the year.

A comparison of the retention curves and discharge tables given in this paper indicates in some degree the quantity of water required by vegetation. In the year of plenteous rainfall, besides actual precipitation, the air contains more water vapor, which, being absorbed by the leaves and grasses, gives them a supply of moisture in lieu of actual rainfall. In the years of less rainfall these demands must be met from

ground storage, and thus a large quantity of actual precipitation must be taken, to the consequent detriment of stream flow.

In the year of heavy rainfall the subterranean reservoir is kept full, and rainfall reaching the surface of the ground, having no opportunity to delay, is delivered quickly to the stream with minimum loss.

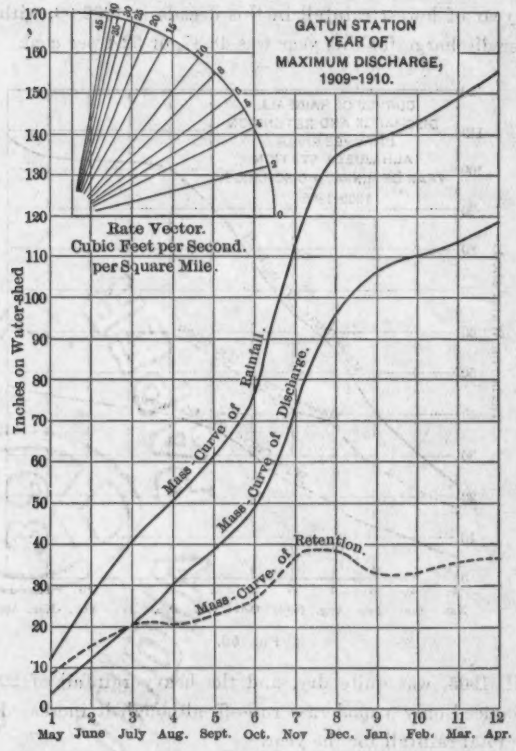

FIG. 51.

What proportion of the stream flow is due to sub-surface flow is a complex question, and each water-shed has a coefficient of its own that must be applied to any general statement. The quantity depends on the character of the soil, the underlying strata, the topography, and the surface cover of vegetation. That considerable quantities of

water are received in this way is an undisputed fact. Table 46 shows some conditions that have obtained on the Rio Grande water-shed. No attempt is made to discuss the subject in this paper, the intention being to make further study before presenting conclusions. The data thereon, however, are applicable to some extent to conditions of the proposed Gatun Lake, and indicate a considerable increase in supply other than that due to surface conditions. Figs. 48 to 53, inclusive, present graphically the conditions of rainfall, run-off, and retention which obtain in the basin above Alhajuela and over the entire drainage area above Gatun. The large quantity unaccounted for in minimum years, and the relatively small quantities "lost" in years of maximum rainfall, are, of course, what would be expected.

Hydrography of Gatun Lake and the Panama Canal.

Gatun Lake, which will be formed by the big earth dam across the Chagres River at Gatun, is one of the largest artificial bodies of water in the world, if not the largest. There is no similarly made body of its size in the Western Hemisphere, the nearest approach being the proposed Bear Lake Reservoir, in Utah, with a surface of 108 sq. miles, and it is probable that Egypt alone in the Eastern Hemisphere has a lake comparable either in area or capacity.

TABLE 47.—Areas and Volumes of Gatun Lake.

90	4 835	173.44	205 911	1 540 211	4 727 056

At Elevation + 87 Gatun Lake has an area of 167.4 sq. miles, of which about 90 sq. miles are within the Canal Zone and the remainder in Panamanian territory. The shore line, not including islands, is about 1 010 miles in length, of which about two-thirds are without the Zone.

Table 48* is given for purposes of comparison. The reservoirs listed therein are either built or projected.

TABLE 48.

Belle Fourche, S. D.	9.35	Jarpen, India	2.69
Wachusett Dam, Mass.	8.40		

Total area, Gatun Lake Drainage Basin	1 320	sq. miles.
Land " (Lake surface El. 87 M. S. L.)	1 152.6	" "
Water " " " " 87 " " "	167.4	" "
Ratio of water to land surface	14.52	per cent.

The top of the upper miter-sill at the locks has an elevation of + 37.33 above mean sea level, and the bottom of Culebra Cut will be at Elevation + 40, referred to the same base. The largest vessel yet built is the *Olympic*, which, when loaded to full capacity of 60 000 tons, is said to have a draft of 37.5 ft. If the minimum lake level is assumed at Elevation + 80.33, this vessel would have about 5 ft. of water under her keel when passing over the miter-sills and more than 2 ft. when passing through Culebra Cut. The heaviest United States war vessel is the *Utah*, recently in commission, and she, when loaded, is said to have a draft of 28.5 ft.; that is, at the minimum lake level assumed above, the *Utah* could pass through Culebra Cut with at least 11 ft. of water under her keel.

A storage depth of 6.67 ft., or 80.04 in., is equivalent to 11.624 in. distributed over the land area at Elevation + 87; that is, a run-off of 11.624 in. from the total land area, would raise the surface of the lake 80.04 in. This quantity, therefore, is required to make good the loss in storage when the lake surface is drawn down to the minimum, or

* Abstracted in part from Wilson's "Manual of Irrigation Engineering," Schuyler's "Reservoirs for Irrigation, Water Power and Domestic Water Supply," Buckley's "The Irrigation Works of India," and Barrois' "*Les Irrigations en Egypte.*"

the reservoir will stand this much depletion without reaching a surface level below that taken as a minimum. Reducing to equivalents, 1 in. on the land surface equals 0.574 ft. of lake storage. It is evident that, after considering the several unavoidable and continuous losses, such as maintenance, power, seepage, etc., the remainder is the quantity available for lockage.

TABLE 49.

Condition.	Elevation.	Area, in square miles.	Storage capacity in cubic feet.
Extreme high water	+87.00	167.4	192 246 000 000
Extreme low water	+80.33	154.0	161 864 000 000
Difference	6.67	13.4	30 382 000 000

The continuous draft or loss to lake storage was placed by the original Consulting Board of Engineers as:

Power, light, etc.	275	cu. ft. per sec.
Leakage at gates	275	" " " "
Seepage and other losses	85	" " " "
	635	" " " "

and these figures have been used in the following investigation, although it has been stated that recent experiments on the Stoney gates in place have demonstrated that the leakage on that account was exceedingly small, and it is probable that the figures given above will be greatly in excess of actual conditions.

The total requirements for seepage, maintenance, leakage, etc., of 635 cu. ft. per sec. are equivalent to 3.793 cu. ft. per sec. per sq. mile of lake area, which, converted into inches, gives the results in Table 50 for the several months.

TABLE 50.

Month.	Equivalent Depth, in Inches.

31-day	4.37	0.634

The rainfall on Gatun Lake surface has been estimated from the records at the stations in this area, and gaps in the record have been filled by using the observed ratios between the given stations and those in the vicinity where the records were continuous. After completing the monthly periods, from 1901 to 1911, inclusive, for the several stations to be used, the quantities from these stations were given proper weight in making up the final table.

The yearly totals are for the run-off year beginning May 1st. The average monthly rainfall over Gatun Lake was computed from the following records:

Station.	Weight.
Monte Lirio	11
Trinidad	53
Bohio + Alhajuela ÷ 2	42
Bohio + Gatun ÷ 2	61

The lowest annual rainfall of record at Colon was 86.50 in., during the calendar year of 1884. The rainfall at Gamboa for the same year was 96 in.

The weights given are the numbers corresponding to the area of lake surface that appeared to be represented by this particular station. It may be noted that the average of the Bohio and Alhajuela rainfalls of record is very close to that of Gamboa, which is nearly in the center

of this district. It is realized that nothing is added to the accuracy of the records by the interpolations for supplying missing data, either in rainfall or run-off tables. On the other hand, no more reliable data are at hand, and the intention in extending these tables has been to afford a basis for comparison extending over a similar term of years in all cases. The tabulations thus made are given as the best available, in the judgment of the writer, and do not purport to be a record of conditions that have existed. From close personal observation for the past 4 years, the writer is of the opinion that the results which are based on these estimates are within reasonable limits of error.

Besides the rainfall and the unavoidable demands for water, there is a very considerable loss to storage due to evaporation. The records and a discussion of this phenomenon have been given previously. From

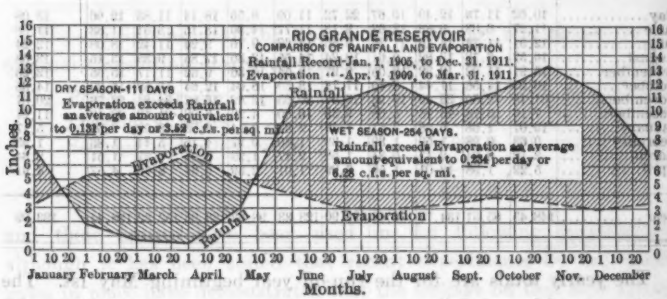

FIG. 54.

these records, the diagrams on Plate XXXII and Figs. 53 to 55, inclusive, have been prepared to show the relations that exist between rainfall and evaporation on water surfaces on the Isthmus, and also to show an application to the surface of Gatun Lake. In many of the estimates there has been no allowance for the gain due to rainfall on the lake surface. The evaporation figure usually has been taken as equivalent to maximum conditions, and this has been applied flat throughout the year without reference to the rainfall. Fig. 53 and Plate XXXII give the actual conditions which existed during the calendar year, 1910, on Rio Grande and Brazos Brook Reservoirs. Fig. 54 shows the estimated evaporation from the surface of Gatun Lake had it been in existence during 1902-03, the year of minimum rainfall at Cristobal and that of estimated minimum on Gatun Lake.

PANAMA CANAL.

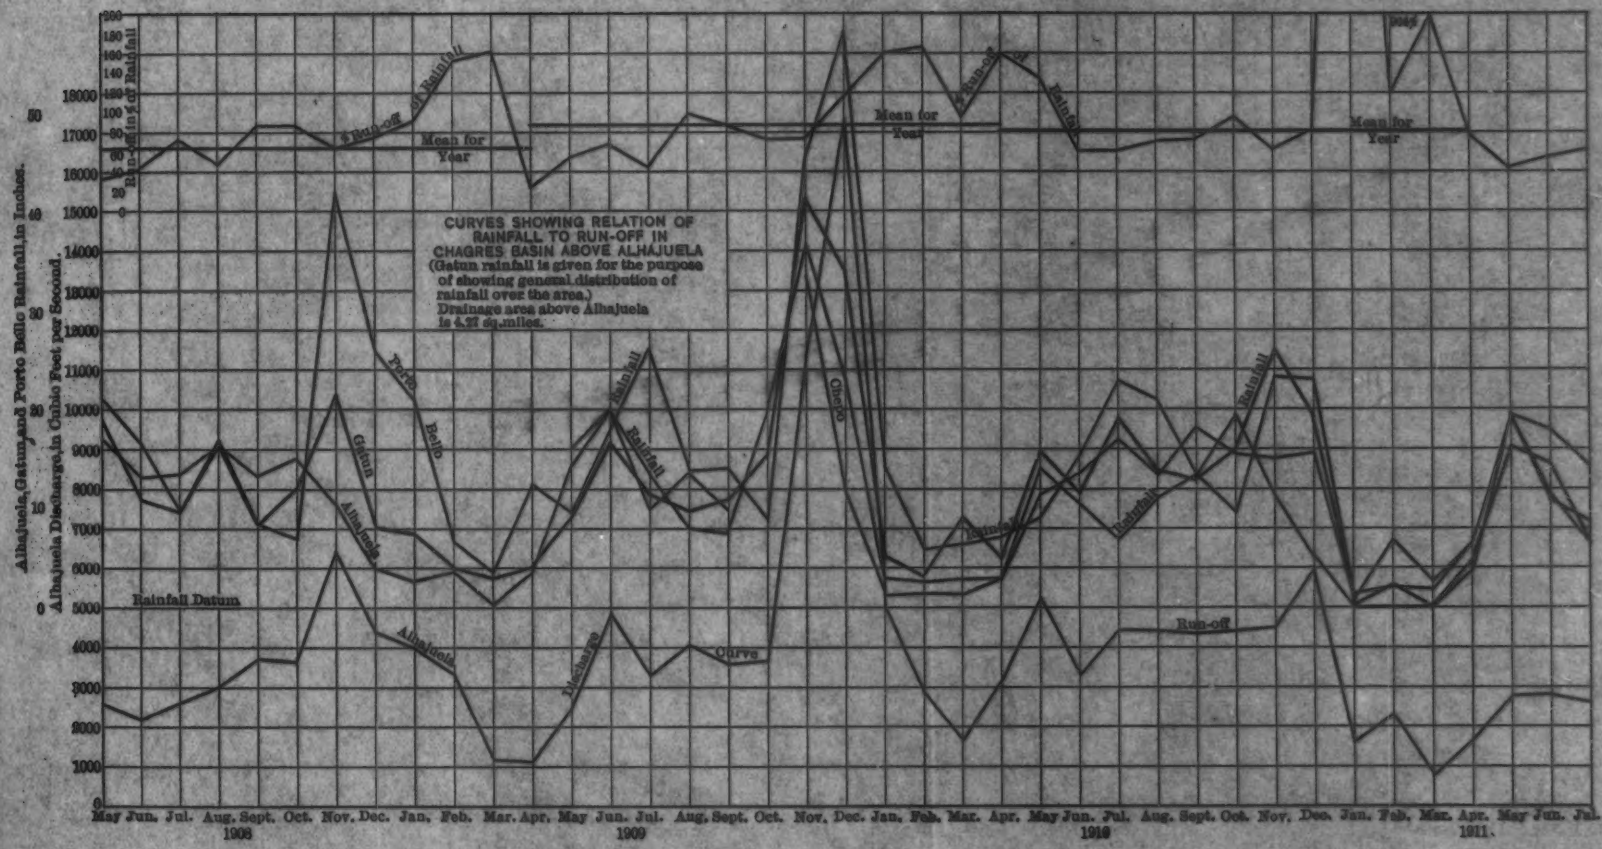

Fig. 55 shows the probable average conditions which would have existed on Gatun Lake during the past 10 years, had the lake been then in existence. These diagrams, together with that on Fig. 8, appear to indicate that the period of excessive daily evaporation is extremely limited, and that the apparent considerable losses to water surface during the so-called dry months are in reality greatly modified by the rainfall, which is especially persistent on the Gatun Lake area during this period. For investigations concerning water supply and storage conditions, the so-called mass-diagram presents a very satisfactory and simple solution of many problems, and a study of the character of the various curves brings out facts which might otherwise be overlooked. Desmond

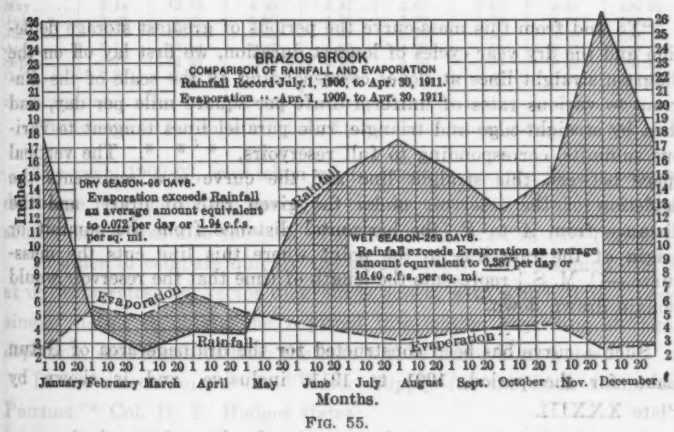

FIG. 55.

FitzGerald, Past-President, Am. Soc. C. E., was probably the first to use this method in the United States, and it appears in his report on the "Capacity of the Sudbury River and Lake Cochituate Water-Sheds in Time of Drought," 1887. Mr. FitzGerald credits the use of this diagram to Mr. W. Rippl.* John R. Freeman, M. Am. Soc. C. E., has made the most extended use of this method in working up the probable yield of the Croton water-shed.† A very clear description is given therein of the construction and properties of this curve, and Theodore Horton, M. Am. Soc. C. E.,‡ has gone into the matter in

* *Minutes of Proceedings*, Inst. C. E., Vol. 71, p. 270.
† "Report on New York's Water Supply," Freeman, 1900, pp. 226-228.
‡ *Engineering Record*, July 31st, 1897.

considerable detail. Briefly, the mass-curve is the accumulated run-off of the drainage area (in this paper reduced to flow per square mile of land area) corrected for the rainfall and evaporation on the water surface, if a pond or reservoir is included in the area, and including the known constant withdrawals. Given this mass-curve of supply and the available storage capacity of the reservoir reduced to the same unit as the mass-curve, it is readily seen that, by projecting straight lines representing uniform rates of flow, it is possible to read directly from the diagram either the maximum draft that can be counted on during various seasons, or to find what will probably be the reservoir's depletion under various drafts. To quote Mr. Freeman:

"To find from this mass-curve the periods of greatest storage depletion and the dry year cycles of longest duration, we first lay off on the diagram straight lines at slopes corresponding on the scale of the diagram to various rates of uniform draft per square mile per day, and then by straight-edge and triangle, rule parallel lines tangent to various summits, corresponding to full reservoirs, * * *. The vertical space between this straight line and the curve now represents the depletion of the reservoir under the given rate of draft; and the distance from *A* to *E* [the horizontal distance from the summit or origin of the rate line to the point where this line cuts the mass-curve.—C. M. S.] represents the length of time that the reservoir would remain drawn down."

Such a curve has been constructed for the drainage area of Gatun Lake for the period, 1901 to 1911, inclusive, and is shown by Plate XXXIII.

In order that its construction may be clearly understood, the computations for the year 1902-03 are given in Table 52.

In Table 52: Column 2 is the run-off past Gatun (see Table 30). Column 3 is the estimated rainfall on the Lake (see Table 51). Column 4 is the mean evaporation for the past 2 years at Brazos Brook Reservoir, which, on account of its location, appeared to approximate most closely the conditions on Gatun Lake. Column 5 is the constant draft of 635 cu. ft. per sec., reduced to an equivalent in inches on the lake surface. Column 7 is the yield of the water surface of the lake in terms of the land surface; that is, Column 6 $\times \left(\frac{167.4}{1\,152.6}\right) = 14.52$ per cent.

Oct.....	7.89	11.44	4.17	4.37	2.90	0.42	8.31	174.94

The quantity for November in Column 9 is the sum of Column 8 from May, 1901.

The year, 1902-03, was taken as an example because its dry-season discharge was one of the lowest of the decade (1908 being about the same), and it was also the year of minimum rainfall in this period.

In order to compare quickly the given supply with assumed drafts at uniform rates, the vector diagram is added, with which it is a very simple matter to obtain the required information regarding storage, depletion, and length of time the lake will be below high water.

In his discussion on the "Water Supply for the Lock Canal at Panama,"* Col. H. F. Hodges states:

"With these assumptions [previously given.—C. M. S.], and taking into consideration the saving in water which can be effected by cross-filling, the total average consumption for one passage per day, *i. e.*, for two prisms of lift each day, is 44.2 cu. ft. per sec. Neglecting any advantage to be derived from cross-filling, it is 51.9 cu. ft. per sec."

In the following computation regarding the number of lockages possible per day, as far as water supply is concerned, it is taken as 51.9 cu. ft. per sec., or about 0.04503 cu. ft. per sec. per sq. mile of land area.

For converting cubic feet per second per square mile into inches

* *Transactions*, Am. Soc. C. E., Vol. LXVII, pp. 105-106.

depth on the tributary area, the following relations are convenient, 1 cu. ft. per sec. per sq. mile being equivalent to:

Period in days.	Inches.	Logarithms.
1	0.03719	$\overline{2}$.5704262
28	1.04132	0.0174507
29	1.07851	0.0330214
30	1.11570	0.0476642
31	1.15289	0.0618292
365.25	13.58380	1.1330164

The factors in the construction of the rate diagram are given in Table 53.

From inspection of Plate XXXIII it is evident that the critical periods, as far as storage is concerned, are to be found in 1903 and 1908. In order to study these conditions better, the diagram, Fig. 58, has been prepared, covering these same periods, but on a larger scale.

The construction of these diagrams is such that any measurement on the vertical scale represents inches depth per square mile of land area, and any measurement on the horizontal scale represents time in months. It is also to be remembered that the available lake storage is equivalent to 11.624 in. over the land surface. Therefore, direct measurement of the number of lockages* per day that can be made is possible, considering that the lake is full at the beginning of each dry season, and is not to be drawn below Elevation 80.33. The lake will be full at the beginning of the dry season if the line representing the required number of lockages does not in any year pass above the yield summit of the next following year.

* Wherever the word "lockage" is used in this paper, it means one complete passage of the canal; that is, the expenditure of water required for passing a vessel from one ocean up one slope and down the other to the ocean on the opposite side of the Isthmus.

PANAMA CANAL.

RATE VECTOR. LOCKAGES PER 24 HOURS.

MASS-CURVE

FOR DETERMINING THE PERIOD OF LEAST YIELD OF THE GATUN LAKE WATER-SHED FOR 1901-11, SHOWING MAXIMUM DEPLETION THAT WOULD HAVE OCCURRED WITH VARIOUS RATES OF LOCKAGE.

In the case of the left-hand diagram of Fig. 58, the distance, 11.624 in., measured up from F, comes just above the line, BC, representing 55 lockages per day; and in the case of the right-hand diagram on Fig. 58, the distance up from K is a little above the line, GH, representing 55 lockages per day. Therefore, 55 lockages per day is

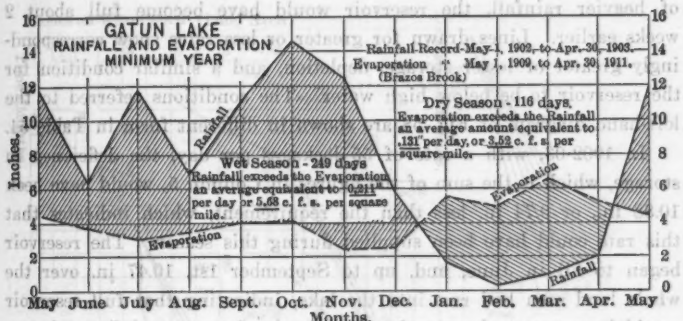

FIG. 56.

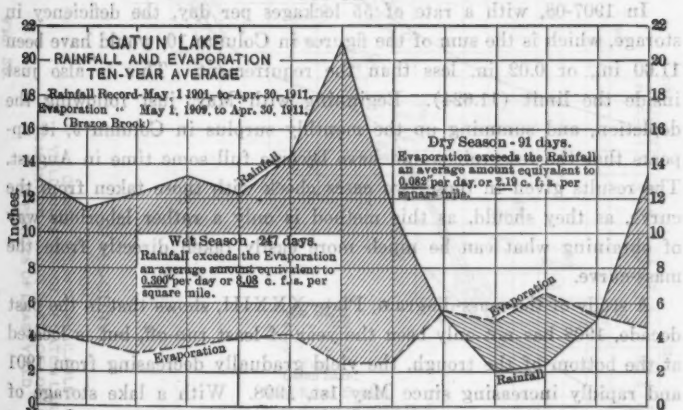

FIG. 57.

the maximum that can safely be counted on with present conditions of storage. On the horizontal scale each small subdivision represents a month. In the left-hand diagram, the line, BC, beginning January 1st, cuts the mass-curve a little after September 1st. With 55 lockages per day, the lake would begin to drop about January 1st, reach

its minimum elevation about May 1st, would then begin to fill, coming to high-water mark during the first part of September, and then wasting until the beginning of the next dry season. From the right-hand diagram it is seen that in 1908 similar conditions would have been experienced with the same number of lockages per day, but, on account of heavier rainfall, the reservoir would have become full about 2 weeks earlier. Lines drawn for greater or less rates show correspondingly greater or lesser storage, depletion, and a similar condition for the reservoir to be below high water. The conditions referred to the left-hand diagram of Fig. 58 are shown in different form in Table 54.

In 1902-03, with a rate of 55 lockages per day, the deficiency in storage, which is the sum of the figures in Column 5, would have been 10.88 in., or 0.74 in. less than the requirement, which indicates that this rate could have been supplied during this season. The reservoir began to fill in June, and, up to September 1st, 10.47 in. over the whole land area had run into the lake, indicating that full reservoir would have occurred some time during the first part of September.

In 1907-08, with a rate of 55 lockages per day, the deficiency in storage, which is the sum of the figures in Column 10, would have been 11.60 in., or 0.02 in. less than the requirement. This is also just inside the limit (11.624). Beginning with May, just following the depletion, and summing up the monthly surplus in Column 9, it appears that the reservoir would have become full some time in August. The results given in these two cases check with those taken from the curve, as they should, as this method is only a rather laborious way of obtaining what can be much more easily taken directly from the mass-curve.

A study of the mass-diagram, Plate XXXIII, shows that in the past decade, 1908 has not only been the year of least run-off, but is located at the bottom of the trough, the yield gradually decreasing from 1901 and rapidly increasing since May 1st, 1908. With a lake storage of a little more than 12 ft., or a limiting minimum lake elevation of + 75 instead of + 80.33, even during this period of low run-off, the lake would have been capable of caring for about 100 lockages per day. It appears, therefore, that under the present conditions of high-water elevation and storage it is possible to take care of 100 complete lockages per day without drawing the lake surface below Elevation + 75. Even with this rate of draft, the reservoir would have

filled by January 1st, 1909. The general trend of the mass-curve indicates that the rate of 100 lockages per day is the reasonable maximum capacity of the canal, as far as water supply is concerned. Below this rate the storage lies in the present lake, provided Elevation + 75 can be allowed for the minimum surface elevation. For more than 100 lockages per day, the storage requirement increases so rapidly that it could be developed only at a considerable expense.

With practically unlimited storage during the past decade, the run-off would have been sufficient to have provided for about 125 lockages per day. To do this would probably mean additional storage reservoirs on tributary streams to conserve water which, under present conditions, will waste during the rainy months.

The rainfall on the Isthmus since January 1st, 1911, has been light, and below normal at many stations. The run-off for the tributary area has been affected, and the monthly flow past Gatun is the lowest of record (either by measurement or estimation) since 1890. Comparisons of the rainfall records in the drainage area for this period with the normals for the years of record are given in Table 55.

Table 56 is a comparison of the run-off at Alhajuela and Gatun for the present period, and the average of the monthly records of these stations for 1890-1911.

The run-off past Gatun is affected constantly by two conditions which do not obtain in the basin above Alhajuela:

1.—Extensive swamp areas with a cover of vegetation that require large quantities of water; and

2.—Evaporation from Gatun Lake surface, which was not experienced in former years.

In addition to the foregoing, the greatest factor contributing to the large proportional quantity of run-off per square mile above Alhajuela, compared with that of the basin as a whole, probably is to be found in the greater precipitation on the former area. This condition is found in Tables 44 and 45, from which it appears that the annual average rainfall from the whole basin for 10 years was 125.04 in.; for the portion below Alhajuela, 118.90 in.; and for the portion above that station, 136.36 in. In other words, the rainfall on the area above Alhajuela is about 9% greater than the average on the basin as a whole, and 14.5% greater than that on the basin below that station.

TABLE 57.

Month.	Mean lake elevation.	Mean area of lake surface, in square miles.	Evaporation, Brazos Brook, in inches.	Evaporation in cubic feet per second, per square mile. September	14.48	20.45	4.10	3.56	73	596

The figures in Column 5 of Table 57 should be added to the monthly discharge of Table 28, since April, 1910, in order to compare these 3 months with the discharge of previous months of the same name.

Table 58 is given to show what would have been the effect on the lake and its usefulness had it been in operation during the period since January 1st, 1911.

Table 58 shows that, even with the low rainfall and similar conditions of run-off since January 1st, 1911, the lake would have handled 55 lockages per day, and the surface then would have been above the limit by 2.38 ft., equivalent to 4.15 in. in land surface.

From that which has preceded, therefore, it appears that the water supply of Gatun Lake is sufficient for any probable demands of commercial or other navigation; and the use of the canal is limited only by the capacity of the locks and the requirements of practical operation.

DISCUSSION

Gen. Abbot.

HENRY L. ABBOT, ESQ.* (by letter).—Mr. Saville has made an interesting and valuable contribution to the technical literature of the Panama Canal. He has had a prominent part in directing the meteorological and hydraulic investigations, and the results set forth in detail in this paper will command general attention. Such records, covering one more of the greatest known floods of the Chagres, would have been of great service in the studies which determined the character of construction to be adopted—whether with lake and locks, or at sea level. The contours of the bed of the lake and the area of the watershed were then known only approximately, and the statistics as to rainfall and evaporation were much less complete than at present. It is pleasing to note that the new data confirm the conclusions and plan finally adopted, and set at rest any doubts as to the sufficiency of the water supply for all the operating needs of the Canal; and this without resort to the expedient of a reservoir above Alhajuela, to conserve the excess of flow in the rainy season which otherwise might go in part to waste over the spillway.

It may be interesting to note that such a reservoir formed an essential element in the plan adopted by the New French Company, in order to augment the water supply afforded by the lake to be formed by the proposed dam at Bohio, a lake storing a much smaller volume than Lake Gatun, but which financial reasons compelled the Company to adopt, as the Old French Company had already excavated a sea-level canal to the vicinity of Bohio. There is a favorable site for a masonry dam a short distance above Alhajuela, of which the cost was estimated at about $2 500 000, and Mr. Saville's surveys and observations in the Upper Chagres Basin have confirmed the opinion that a large volume of water may be stored there, if it is ever found to be desirable.

There are two reasons why such an addition to the present plan may be found to be advisable ultimately. The sudden and violent freshets which characterize the regimen of the Chagres will attain the canal route near Gamboa, where the narrow arm of Lake Gatun turns nearly at right angles to the direction followed by shipping. The channel here, for about four miles, is only 500 ft. wide, and it is not impossible that these sudden but brief rushes of water may prove to be more or less annoying. The largest freshets of record at Gamboa have carried maximum volumes ranging from about 65 000 to 79 000 cu. ft. per sec., with an average flow during 24 hours falling but little below 60 000 cu. ft. per sec. Their annual frequency, as well as the amount of rainfall on the Isthmus, seems to be subject to a progressive variation, ranging at Gamboa during the last 40 years from about 10 to about 35 annually, with a corresponding duration, including large

*Brigadier-General, U. S. A. (Retired).

and small freshets, ranging from about 75 to about 650 hours. A dam above Alhajuela would regulate this variable flow perfectly and eliminate all objectionable currents from the route for shipping. The second reason why an Alhajuela dam may become desirable is that, in these days of water-power development through the agency of electricity, it may be found convenient to augment the quantity of water available on the Isthmus by conserving the flow which otherwise, at such times, might run to waste over the spillway. Whether there will be such a demand can best be decided when the Canal is opened to traffic. Gen. Abbot.

W. E. FULLER, M. AM. SOC. C. E. (by letter).—This paper contains interesting information on the flood discharge of the Chagres River. The flood at Alhajuela, on December 26th, 1909, with a maximum rate of discharge of 170 000 cu. ft. per sec., on a catchment area of 427 sq. miles, ranks high among the floods of which the writer has record. Mr. Fuller.

By applying the writer's formula,

$$Q = KA^{0.8}\,(1 + 2\,A^{-0.3}),$$

to this flood, a value of $K = 1\,010$ is obtained. The greatest floods of the eastern portion of the United States give values of $K = 300$ to 360. For floods giving values of K similar to that for the Chagres at Alhajuela, the writer has only found records on a few rivers in India and in Saxony. It seems probable from the limited data that similar floods occur on some rivers on the Pacific Coast, but no records of such maximum rates are available.

It is interesting to note that in all three floods mentioned by the author the maximum rate of discharge was greater at Alhajuela (catchment area, 427 sq. miles) than at either Bohio (catchment area, 779 sq. miles), or Gatun (1 320 sq. miles). It would be interesting to know whether other floods indicate similar results, and if so, whether the conditions of temporary storage below Alhajuela satisfactorily account for the difference.

Although the data are not very complete, those for the floods at Gamboa give an indication of the frequency of flood occurrence. An application of the writer's formula,

$$Q\,(\text{Max.}) = C\,A^{0.8}\,(1 + 2\,A^{-0.3})\,(1 + 0.8 \log.\ T),$$

to the data given by the author, and by General Abbot in his discussion, gives a probable value of C for Gamboa of 170 to 200. The floods at Bohio and Gatun indicate values somewhat smaller, and those at Alhajuela indicate a value of from 350 to 450.

Values of C, for streams in the eastern part of the United States, seldom exceed 100, with 65 as an average; it appears, therefore, that this tropical river produces floods from three to five times as great as those rivers.

Paper No. 1261

A SUGGESTED IMPROVEMENT IN BUILDING WATER-BOUND MACADAM ROADS.*

By J. L. Meem, Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. F. G. Frink, C. H. Sweetser, W. W. Crosby, J. C. Meem, Arthur H. Blanchard, and J. L. Meem.

In this era of vast road building throughout the country, it has seemed to the writer that there is too much variance in the specifications, especially in those for water-bound macadam roads, and this paper describes what is believed to be an improvement in such road construction.

By way of explanation, it may be stated that water-bound roads are those in which the only binder is water, and this is used very plentifully in the process of building the road. There is no other foundation than the rolled earth; the standard depth of loose rock ordinarily used is 9 in., and when this has been thoroughly rolled, a theoretical depth of 6 in. of finished roadway is obtained. The ordinarily accepted specification for placing this rock calls for 6 in. of No. 1 stone (the largest size) varying from 1½ to 3 in. in diameter; then 2½ in. of No. 2 stone, varying from ½ to 1½ in. in diameter, and the top course is finished off with stone ½ in. and less in diameter, usually called "screenings," including the material resulting from the dust of fracture. Assuming, then, a depth of loose rock of 9 in. as a standard, the writer describes herein a method of proportioning this rock which he has used successfully and is using at the present time on an 8-mile section of the Memphis-Bristol Highway, in Tennessee.

* Presented at the meeting of February 19th, 1913.

All road builders, both engineers and contractors, will probably agree that the difficult and essential thing to obtain in a water-bound road is the bond, and the method herein described attains this result at probably less cost than any other, and certainly at very much less cost than any the writer has ever tried.

The method consists in separating the screenings into two sizes, one size being from ½ to ¼ in. and the other the dust of fracture, and putting these two sizes on the road in separate operations, and the writer wishes to suggest the adoption of the following specifications for building a water-bound macadam road, both as to the method of proportioning the rock and as to sprinkling:

(*a*) The sub-grade shall be thoroughly rolled until it is firm and compact, with the proper crown of ¾ in. per ft.

(*b*) On this shall be placed 6 in. of No. 1 grade rock, ranging in size from 1½ to 3 in. This shall be spread uniformly and rolled dry until the rock does not creep before the roller, or creeps just enough to set it in place without crushing.

(*c*) Then 2 in. of stone of No. 2 grade, ranging in size from ½ to 1½ in., shall be spread uniformly, sprinkled, and rolled thoroughly into the voids of the No. 1 grade.

(*d*) Then ¾ in. of the coarse material from the screenings, consisting of sizes from ¼ to ½ in., shall be spread uniformly, sprinkled, and rolled thoroughly into the voids of the No. 2 grade.

(*e*) Finally, ¼ in. of the dust from the screenings shall be spread (preferably by hand from shovels), thoroughly soaked, and rolled to a finish.

This method gives a surface which is virtually impervious to water, and is less affected by automobile traffic than any with which the writer has had experience; in fact, it has been a matter of great surprise to him to see how well roads built by this method withstand automobile traffic without "raveling" or showing signs of deterioration.

From the contractor's point of view, as an economical method of building macadam roads, the writer finds that on the Memphis-Bristol Highway he is able to care for 100 cu. yd. of rock per day with one 10-ton roller, where previously, before the change was made, there was some difficulty in rolling properly one-half this quantity and getting the proper bond therein, in spite of the fact that it requires

one more operation to put on the extra course of stone. This is very much more than balanced by the quicker method of obtaining the required bond, and the final results as stated are so much more satisfactory than those obtained by using only three grades of rock and not separating the dust from the screenings that it would seem to be a material improvement in the method of road building, and should appeal to both engineers and contractors. It is only fair to say that the specification under which this section of the Memphis-Bristol Highway is being built called for the placing of the macadam in three operations, as originally stated, but that the change has been approved by the engineer in charge who now highly endorses the method.

This work requires a standard screen with a "dust jacket" (½-in. perforations) over the ⅝-in. screen.

The writer, who is a member of the contracting firm which is building this section of the road, is interested both from the standpoint of the engineer and the contractor. He has never before seen this method advocated publicly, and invites discussion and criticism from other road builders.

DISCUSSION

Mr. Frink.

F. G. FRINK, ASSOC. M. AM. SOC. C. E. (by letter).—It is hoped that Mr. Meem will publish such information in regard to topography, climate, sub-grade, kind of stone, expected traffic, etc., as will show the range of adaptation of the design presented. In this way costly experiments may be avoided.

The writer's experience leads to the conclusion that the "variance in specifications," deplored by the author, is really one of the most encouraging features in the development of road building, as it implies a recognition of the widely differing conditions to be met, The use of a design, because it has been a success in some other locality, may result in loss of time and money.

For example, experience teaches that a road constructed with such a base as the one cited would probably fail in a section where, by porosity of the soil and seepage from higher land, the sub-grade was saturated for extended periods. In this case the base must be rendered as nearly impervious as possible by using fine material at the bottom to fill the voids.

Bearing in mind Macadam's insistence on the use of small fragments, the writer would suggest the query: Is a road ever the better for having large stone, say, greater than 1½ in., in any part of its section?

Mr. Sweetser.

C. H. SWEETSER, M. AM. SOC. C. E. (by letter).—The method of separating the screenings into two sizes, as suggested by Mr. Meem, and used successfully on the Memphis-Bristol Highway, in Tennessee, seems to be an improvement over the usual specification for the application of the binder course. The writer has obtained a quicker bond by applying the screenings in small quantities until the required bond was obtained. When the dust of fracture is applied, together with the coarse material in the screenings, the dust when wet seems to "ball" up and prevent the coarse material from filling quickly the voids in the macadam. From the experience on the Memphis-Bristol Highway, the suggested improvement would seem to hasten the obtaining of a proper bond.

A few words on water-bound macadam and the automobile may not be out of place. Engineers should hesitate, and consider local conditions very carefully, before specifying the construction of water-bound macadam highways. With the improvement of the highway, automobile traffic is sure to increase, and it soon becomes necessary to construct a surface which will withstand this traffic. In the majority of cases the most economical time to do this is when the improvement is first made. Mr. Meem states that the suggested improvement is

Mr. Sweetser.

"less affected by automobile traffic." Why not construct at once, so that it will not be affected at all?

In spite of knowledge gained through the experience of road builders, both in the United States and Europe, there are miles of water-bound macadam roads being built in America where some other form of pavement should have been specified.

Mr. Crosby.

W. W. CROSBY, M. AM. SOC. C. E. (by letter).—The author refers to the "bond" of the road, apparently meaning the cemented condition brought about by the action of water on the stone dust. If this deduction is correct, the writer cannot agree with one of the author's premises, namely, that such a "bond" is "the difficult and essential thing to obtain in a water-bound road."

If, however, the "bond" is, as the writer understands the term, the interlocking of the angular particles of stone with each other, supplemented by the cementing of the fine material, then the writer is prepared to agree with Mr. Meem to a certain extent. The qualification he has in mind is that such a bond, while always essential, is only difficult to secure with proper stone where the sub-grade for any reason is inclined to churn up into the macadam stone and by its intrusion prevent their proper compaction. Such a bond, of course, costs something to secure by rolling, but this does not seem to the writer to be a real "difficulty."

The method of construction proposed by Mr. Meem has been tried by the writer on various occasions, but without his becoming favorable to it. In one or two instances, where "granolithic" or "grit" (the chips between the $\frac{1}{4}$- and $\frac{1}{2}$-in. screens) was in demand for other purposes, the crusher product was robbed of a part of this portion and the remainder was used as described by the author in two applications, without other benefit than securing in this way some "grit" for another use.

It seems to the writer that probably the superiority of results, stated by Mr. Meem as secured by his method, comes from the application of the screenings in two relatively thin layers with thorough rolling between them.

Too many roads are built where, after rolling the second course (or "No. 2" stone), the screenings are applied heavily in one coat an inch or more thick, and rolled and watered until the surface seems to be cemented. Such roads seldom wear well, raveling shortly and continually. The cementing thus secured is superficial, and the macadam beneath is porous. If, however, the screenings are applied in thin layers, and each layer is flushed and rolled into the voids of the "No. 2's," then the macadam will be more dense and less likely to ravel. In the writer's opinion, with the latter method, it makes very little difference how the screenings then are made up as to sizes,

unless they come from limestone. In the latter case a sufficient quantity of coarse particles or non-cementitious material must be added, by mixing or by separate application, to offset the extreme tendency of the fine limestone material, by forming a paste on the surface, to prevent the proper filling of the voids in the macadam. Mr. Crosby.

The writer's specifications, in this particular, have been as follows:

"THIRD COURSE.

"Material.

"173.—The third course of the macadam construction shall consist of trap rock screenings varying in size from dust to 1-inch pieces. Other material than trap rock screenings may be used if approved by the Engineer. Limestone screenings shall not be used with a limestone second course, unless approved in writing by the Engineer, or unless clean sand, approved by the Engineer, is used in substitution under the direction of the Engineer, for at least 50% of the limestone screenings.

"Spreading.

"174.—After the second course of No. 2 stone has been rolled and completed as above described, the screenings shall be spread, but in no case shall screenings be used until the second course has been thoroughly rolled and compacted. The screenings shall be spread dry, with shovels from piles alongside the road or from dumping boards; but in no case shall the screenings be dumped directly on the second course. The quantity of screenings used shall be such as will just cover the second course.

"Watering and Rolling.

"175.—After the screenings are spread they shall be first rolled dry and then sprinkled with water from a properly constructed sprinkling cart, and then re-rolled with a steam roller weighing not less than ten tons. The amount of water necessary shall be determined by the Engineer. The rolling shall begin at the sides and continue until the surface is hard and smooth and shows no perceptible tracks from vehicles passing over it.

"176.—If, after rolling the screenings, the No. 2 stone appears at the surface, additional screenings shall be used in such places.

"177.—The rolling and watering shall continue until the water flushes to the surface. The rolling is to extend over the whole width of the road, including the shoulders."

The closing sentence of Paragraph 174 should be noted, and this, followed by Paragraph 176, illustrates the point above made.

The writer thinks he sees one danger in the method proposed by Mr. Meem. It is that, by first partly filling the voids in the surface of the "No. 2's" through the application of the grit and by then completely filling the remaining voids in the surface by the application of the finer sizes, the penetration of the finer sizes into the voids in the body of the macadam will be obstructed or prevented. It is the

Mr. Crosby. writer's experience that the best macadam will have a maximum density, not only on or near its surface, but also well down into the macadam itself.

Mr. J. C. Meem. J. C. MEEM, M. AM. SOC. C. E. (by letter),—It would appear to the writer that a road built under the author's specifications would undoubtedly have good wearing qualities if it did not become too dry. It is suggested, therefore, that a frequent sprinkling or application of oil would insure its lasting quality in the same ratio that its original value might bear to that of a road built by the alternative method.

The presentation of this paper reminds the writer of a piece of macadam road which the author constructed on a private estate in Virginia. About 2 miles of ordinary country road were macadamized, and a highway bridge was built over a tributary of the Shenandoah River. The macadam work consisted of a 12-ft. roadway, which was "metalled" according to the specifications of this so-called improved method, with berms of earth 3 ft. wide on each side, and with under-drains outside of these, as noted later. This road is wearing very well, after 2 years of such traffic as country roads ordinarily get from heavy farm wagons and occasional automobiles; and, although no comparative values are obtainable, its good condition is believed to be due partly to the fact that under-drains, in a trench 12 in. wide and 2 ft. deep, and surrounded with broken stone, were laid to a uniform grade on each side, giving perfect drainage to the highway. The rock used was the native blue limestone, quarried and crushed on the estate.

In connection with this work, the writer designed a reinforced concrete highway bridge, which was built by the author. The question of surfacing the roadway of the bridge was an important one. It was not deemed advisable to carry the macadam over the roadway, as it was thought that its tendency to dry out and disintegrate would be much greater than in an ordinary road in contact with earth. The following method was finally adopted: The upper or compression side of the concrete was troweled to a very compact and smooth surface, and, on this, there was placed about 1 in. of lean cement mortar, over which, in turn, from $\frac{1}{2}$ to $\frac{3}{4}$ in. of sand was sprinkled before the mortar had set. The bridge has now been in use about 2 years, and this surface is apparently giving satisfaction. As this method of surfacing was in the nature of an experiment, the writer will be greatly interested in observing from time to time the wearing qualities which it develops.

Mr. Blanchard. ARTHUR H. BLANCHARD, M. AM. SOC. C. E.—Two properties of wearing surfaces which require consideration in the design of pavements are stability and density. The requisite degree of stability and density depends in part on the conditions to which the road or pave-

ment is to be subjected. The author has outlined a method for securing a certain degree of stability and density in the construction of the so-called water-bound macadam road. Mr. Blanchard.

The efficacy of the proposed method depends primarily on the traffic to which the road is to be subjected. If the traffic consists of horse-drawn vehicles not exceeding a certain number per day, the use of the type of construction advocated should result in a serviceable road. If, however, many high-speed motor cars use the highway thus built, the surface will disintegrate rapidly, as is the case with macadam roads built with a wearing surface of so-called crusher-run stone (passing over a ½-in. screen and through a 1½-in. screen), the surface of which is finished with a light coat of screenings, well rolled and watered. The difference between the former and the latter is in the arrangement of the aggregate, rather than in its composition, as is seen by a consideration of the following mechanical analysis of the wearing surface of the latter type.

Broken stone passing	⅛	in.	screen.....	1.0	per cent.
" " "	¼	"	"	2.5	" "
" " "	½	"	"	30.8	" "
" " "	¾	"	"	34.2	" "
" " "	1	"	"	23.4	" "
" " "	1¼	"	"	8.1	" "

The analysis of the author's wearing surface of 2 in. would likewise show certain percentages passing screens from ¼ in. to 1¼ in. In both cases, stone from ½ in. to 1¼ in. in diameter will usually constitute a large percentage of the top inch of the surface.

The speaker's investigations and practice have led to the conclusion that the most satisfactory type of macadam road to withstand high-speed motor-car traffic is one having a surface of broken stone, varying from 1 in. to 2½ in. in longest dimensions, which stone has been thoroughly rolled and puddled. The success attendant on the use of bituminous surfaces on macadam roads in England and France is due in part to the adoption of this type of construction. Not only does the use of the large broken stone in the surface give stability to its component integral parts, but it simplifies one essential detail of the construction of bituminous surfaces on macadam roads, namely, the cleaning of the macadam surface.

With the addition of bituminous cement, the status of the pavement, as one adaptable for use on highways subjected to motor-car traffic, is changed. The method of construction in which several courses of varying sizes of stone are used formed the basis of many

Mr. Blanchard.

of the patents covering the construction of bituminous concrete pavements granted by the United States Government during the period from 1869 to 1873. Bituminous concrete pavements of this type have given excellent results, in the United States and also abroad. At present, several foreign companies, particularly in England, are using this method of construction. The work of three of these companies is referred to in the following descriptions:

The Quarrite-Bitulithic Company of London imports from its Scotland plant bituminous-coated broken stone of various sizes for the construction of bituminous concrete pavements by the layer method. The sizes used for the courses are as follows: first course, 2 in. of 1-in. to 1¾-in. stone, rolled, with a scattering of ½ to ⅝-in. chips; second course, 1 in. of stone, varying from ½ to ¾ in. in longest dimensions, rolled; third course, a thin layer of tar-coated screenings, thoroughly rolled.

The Tarmac Company of London for many years has been mixing broken slag of various sizes with bituminous cement at its plant in Wolverhampton, and shipping from there to various points in England. The construction of one pavement of this type which came under the speaker's observation is as follows: This road was the main shore boulevard at Brighton-on-Sea, on the south coast of England. On a well-compacted gravel foundation was spread a scattering of bituminous-coated chips; the bottom layer, composed of 3½ in. (loose) of 1½ to 2½-in. slag, was then rolled; the second course, consisting of 2½ in. (loose) of ½-in. to 1½-in. slag, was next thoroughly compacted; the third course, composed of ½ in. of ¼ to ½-in. slag chips, was likewise thoroughly rolled; the pavement was finished by rolling in a top dressing of uncoated slag screenings. It may be of interest to note that a section on Madeira Drive, at this famous shore resort, was constructed in this manner in 1903. Its condition in 1910 was excellent, and an adjoining section of water-bound macadam, which was treated annually with an application of tar, rapidly disintegrated before the close of each season.

As an illustration of the practice in Germany, the work of the Deutsche Quarrite and Bitulithic-Pflaster-Gesellschaft of Berlin may be cited. In 1910 this company built a bituminous concrete pavement in Lankwitz, Germany, in accordance with the following method: On a 5-in. macadam cinder-filled foundation, the first course, consisting of 4 in. (loose) of 1½-in. stone, was spread and rolled; a thin coat of tarred chips was next spread and rolled; the second course consisted of 1 in. of ⅝-in. stone, well rolled; the final course was ½ in. of tarred chips, also thoroughly rolled; the pavement was finished with a flush coat of tar, on top of which was spread uncoated screenings.

Mr. Blanchard.

That the layer method of constructing bituminous concrete pavements in England is not of recent date is shown by the following description published in 1898:

"The hot stone, when ready for mixing, is screened into material of three sizes, 1 to 2-in. for the body, ½ to 1-in. for the intermediate coat, and ¼ to ½-in. for the top dressing. The coarsest material is used in a layer from 3 to 4 in. thick, the intermediate size forms a coat of about ¾ in., and the top dressing is used in the thinnest layer possible, with a view to filling all interstices. Afterward a dressing of ¼-in. and smaller granite screenings is scattered broadcast, and the traffic is at once allowed on the road to work this top dressing into the tarred material. Each of the layers is rolled separately with a 10-ton roller."

In conclusion, the opinion is expressed that, provided a bituminous cement is mixed with the stone for the second and third courses, the use of the principles of construction embodied in this interesting paper will produce a pavement which, under conditions for which it is suitable, will be economical in construction and maintenance.

Mr. J. L. Meem.

J. L. MEEM, ASSOC. M. AM. SOC. C. E. (by letter).—In reply to Mr. Frink the writer wishes to state that his method deals primarily with the manner of placing the different grades of stone, assuming that the sub-grade is in proper condition to receive them. He agrees with Mr. Frink that the preparation of the sub-grade, drainage, etc., are prime factors in the life of the road, but these are conditions to be controlled locally by the engineer in charge.

The writer is pleased to note that Mr. Sweetser has tried and obtained good results by this method of separating the dust from the screenings and applying them in separate layers. Mr. Sweetser says, in reference to building a road which will be affected less by automobile traffic: "Why not construct at once, so that it will not be affected at all?" The writer is not a champion of "water-bound macadam" roads, and realizes that it is the least durable form of stone pavement; but, as it is the generally accepted form of highway improvement, as adopted by the various counties, due to low first cost, he believes that any improvement in this method of construction without additional cost will be welcomed.

The writer feels that Mr. Crosby's failure to obtain good results by this method of proportioning the rock was due to the fact that he allowed a portion of the chips (¼ to ½ in. in size) to be taken for other purposes, thereby failing to fill the voids in the No. 2 stone. A section of roadway built with the foregoing proportions of rock shows practically a solid mass.

Mr. J. C. Meem's suggestion, that a frequent sprinkling or application of oil as a dust preventive would prolong the life of the road, is a

Mr. J. L. Meem.

good one. This would be of great benefit, especially during long dry periods, but having done this, we have departed from the true water-bound macadam, and Mr. Sweetser's query "Why not construct a permanent road?" presents itself.

Mr. Blanchard's interesting discussion applies to bituminous macadam rather than to water-bound macadam, as set forth in the paper.

The writer is pleased to have obtained the views of others on this simple little change in an accepted specification, and hopes it will at least have the effect of causing others to try the change.

Paper No. 1262

EXPERIMENTAL DETERMINATION OF LOSS OF HEAD DUE TO SUDDEN ENLARGEMENT IN CIRCULAR PIPES.

By W. H. Archer, Esq.

This paper presents a summary of the experimental data and computations therefrom obtained in a series of tests to determine the loss of hydraulic head due to sudden enlargement in cross-section of circular pipes. The question arose in connection with the theory of the jet pump, and its investigation as a thesis led to some interesting conclusions which are herein set forth. Observations were made during December, 1911, and January to March, inclusive, 1912, at the Hydraulic Laboratory, University of California.

Theory.

Theoretically, the determination of loss of head in liquids due to sudden enlargement in cross-section is simple and apparently exact. It is perhaps for this reason that little experimental work has been done to determine the actual losses. For convenience, this theory is here given, and is as follows:

Let v_1 = velocity, in feet per second, at outlet of smaller pipe;

a_1 = cross-sectional area, in square feet, at outlet of smaller pipe;

p_1 = pressure, in pounds per square inch, at outlet of smaller pipe;

γ = density of water, in pounds per cubic foot.

Then $\frac{p}{\gamma}$ = pressure head, in feet of water;

v_2 = velocity, in feet per second, in large pipe, at section where p_2 is a maximum;

p_2 = maximum pressure, in pounds per square inch, in larger pipe;

a_2 = cross-sectional area, in square feet, where p_2 is a maximum;

$l.h.$ = theoretical lost head, in feet of water, due to sudden enlargement;

Q = quantity of water flowing, in cubic feet per second.

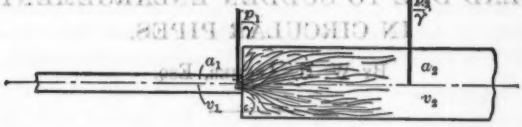

FIG. 1.

The energy relation is:

$$\frac{v_1^2}{2g} + \frac{p_1}{\gamma} = \frac{v_2^2}{2g} + \frac{p_2}{\gamma} + l.h. \quad \ldots\ldots(1)$$

or

$$\frac{v_1^2}{2g} - \frac{v_2^2}{2g} = l.h. + \frac{p_2}{\gamma} - \frac{p_1}{\gamma} \quad \ldots\ldots(2)$$

or

$$\frac{p_2 - p_1}{\gamma} = \frac{v_1^2 - v_2^2}{2g} - l.h \quad \ldots\ldots(3)$$

The momentum relation is as follows:

Force = change in momentum, or $(p_2 - p_1)\, a_2 = \frac{Q}{g}(v_1 - v_2) \ldots(4)$

By combining Equations (3) and (4) and making continuity substitutions, it is seen that

$$l.h. = \frac{(v_1 - v_2)^2}{2g} \quad \ldots\ldots(5)$$

or, in another form,

$$l.h. = \frac{v_1^2}{2g}\left(1 - \frac{a_1}{a_2}\right)^2 \quad \ldots\ldots(6)$$

The equation for the value of the actual experimental loss will probably be of the form,

$$L.H. = C\,\frac{v_1^n}{2g}\left(1 - \frac{a_1}{a_2}\right)^n \quad \ldots\ldots(7)$$

C and n being empirical coefficients, to determine the value of which under various conditions was the purpose of the work described.

Equipment Used.

Pipes.—Four sizes of commercial, smooth, brass pipes were used, ranging from 1 to 3 in. in diameter, all being $\frac{1}{16}$ in. thick and 4 ft. long. The ends were machined square and even, and burrs were removed with emery paper.

Flanges.—Connections were made with cast-iron flanges, 8 in. in diameter and $\frac{5}{8}$ in. thick, machined to make a water-tight friction fit over the ends of the brass pipe, on which they were driven until just flush. Flanges were bolted together with gaskets between.

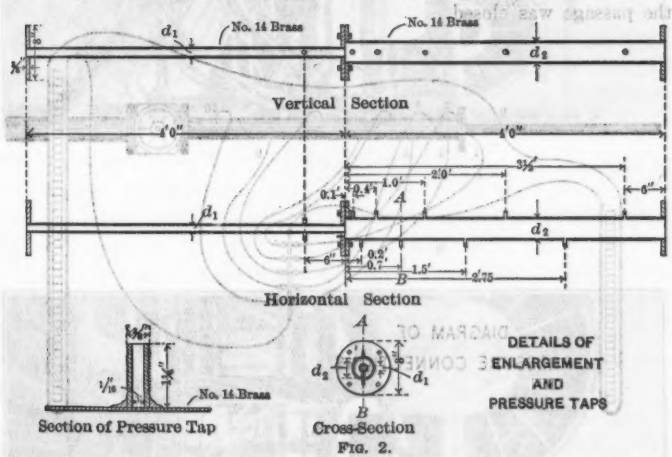

FIG. 2.

Pressure Taps.—Taps were inserted in the sides of the pipe, by which internal pressures were obtained. Taps No. 0 in the small pipe were 6 in. from the plane of enlargement and on opposite sides of the pipe. Taps in the larger pipe were 0.1, 0.2, 0.4, 0.7, 1.0, 1.5, 2.0, 2.75, and 3.5 ft. from the plane of enlargement, and were alternated, that is, No. 2 on one side, No. 3 on the opposite side, etc. Taps were made by drilling $\frac{1}{16}$-in. holes (care being taken to drill into wood so as to leave no burrs inside) and then soldering over these holes pieces of $\frac{1}{8}$-in. brass tube $1\frac{1}{2}$ in. long (Fig. 2). Rubber tubing connected these to the manifold and pressure columns.

Manifold.—The manifold consisted of twelve ¼-in. air-cocks screwed into a piece of ½-in. brass tubing 10 in. long. Five cocks were placed on each side for the connections from the pressure taps in the pipe, and one was put on each end for the pressure column connections.

Pressure Columns or U-*Tubes.*—Connections were made for using either of two U-tubes, depending on the magnitude of pressure difference. One tube, with arms about 3 ft. long, partly filled with mercury, was used for large differences in pressure. The other, having a short arm, 3½ ft., and a long arm, 5 ft. in length, was partly filled with carbon tetra chloride colored red with an aniline dye. Both U-tubes were made entirely of ¼-in. glass tubing, it being found that the carbon tetra chloride acted on the rubber, causing it to swell until the passage was closed.

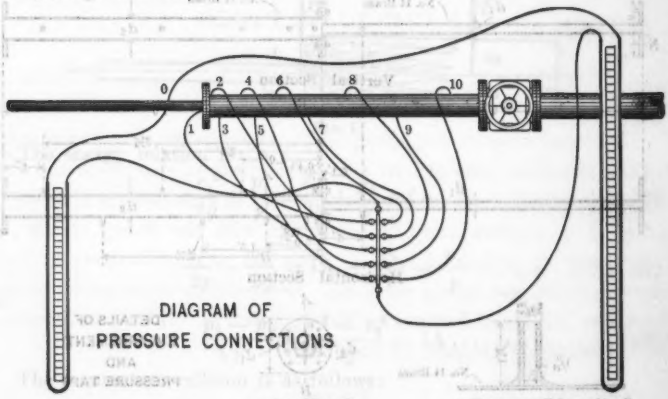

FIG. 3.

In order to obtain a good meniscus on the surface of carbon tetra chloride it is necessary that the glass be absolutely clean. This cleaning was done with a saturated solution of bichromate of potash one part, sulphuric acid three parts and then diluting with six parts of water. It was found necessary to flush all parts of the U-tube with running water to remove the cleaning solution thoroughly, otherwise a bothersome scum was formed on the surface of the carbon tetra chloride.

Bleeder cocks were placed at the upper ends of each arm of the U-tubes, to allow for the expulsion of air from the tubes and connec-

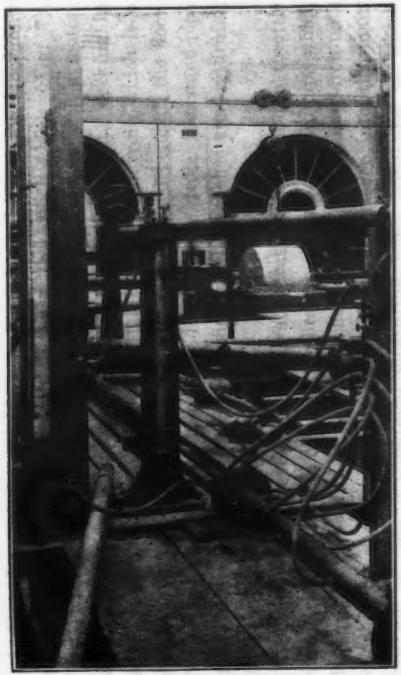

FIG. 4.—VIEW OF APPARATUS FROM OUTLET END.

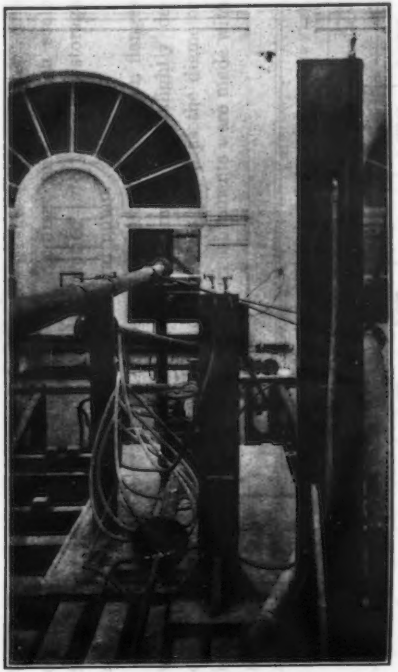

FIG. 5.—VIEW OF APPARATUS FROM INLET END.

tions. The scales between the arms of the U-tubes were graduated in inches and tenths.

Water Supply.—Water was obtained for the experiments through a horizontal 4-in. pipe about 75 ft. long leading from the laboratory stand-pipe, which is 4 ft. in diameter and 36 ft. high (Fig. 7). The height of water in the stand-pipe was maintained with a motor-driven Quimby screw pump (Fig. 6), the two cylinders working in series, and drawing water from the main storage reservoir, which is a concrete tank, 18 ft. square and 10 ft. deep, located beneath the floor. Water is kept at varying heights by overflows from the stand-pipe through any required gate in the side thereof, such water returning to the storage reservoir.

Quantity Measurements.—The water was taken from the throttle valve, at the outlet end of the large brass pipe, into a 2½-in. pipe which led to a Y. One arm of the Y discharged into a galvanized-iron tank on platform scales, and the other discharged either into the main reservoir or into a calibrated measuring tank, depending on which way the hinged piece of pipe at the end was swung.

The tank on the scales, with a capacity of about 25 cu. ft., was used for measuring small quantities of water. It was emptied into the main reservoir by a quick-opening valve.

Larger quantities were measured in the calibrated concrete tank, 7 ft. square and 10 ft. deep, using a hook-gauge. A centimeter scale on the hook-gauge was used for a few readings, and an inch scale for the remainder. This tank was also emptied into the main storage reservoir by a 4-in. motor-driven centrifugal pump.

Preliminary Observed Data.—Due to the fact that the iron flanges were driven on the brass pipes, the end diameter was slightly decreased in some cases. The central diameter is taken as the diameter before the flanges were put in place. All measurements were made with micrometer calipers.

No. of pipe.	Average Diameter, in Inches.			Average Areas, in Square Feet.		
	Inlet.	Center.	Outlet.	Inlet.	Center.	Outlet.
1.....	.....	0.992	0.982	.....	0.00545	0.00526
2.....	1.735	1.745	1.730	0.01641	0.01661	0.01631
3.....	2.488	2.495	2.486	0.03378	0.03395	0.03368
4.....	2.983	2.994	2.993	0.04855	0.04885	0.04885

Letting a_1 represent the outlet area of the small pipe and a_2 the central area of the large pipe, the following values were taken:

No. 1 $a_1 = 0.00526$; $a_2 = 0.00545$
No. 2 $a_1 = 0.01631$; $a_2 = 0.01661$
No. 3 $a_1 = 0.03368$; $a_2 = 0.03395$
No. 4 $a_1 = 0.04885$; $a_2 = 0.04885$

Specific Gravity Determination of Carbon Tetra Chloride.—The specific gravity of the carbon tetra chloride was found by taking the ratio of the length of column of water in one arm of a U-tube to the length of column of carbon tetra chloride in the other arm which balanced it.

The average value of four determinations for all the experiments was 1.601, with the exception of the 1¼ to 2½-in. combination of pipes, the specific gravity for which (average of three determinations) was 1.570.

These values were used in computing the pressure change, $\frac{p_2 - p_1}{\gamma}$, as follows:

Let S = specific gravity of liquid in U-tube;
Let U_1 = scale reading in arm of U-tube, where pressure = p_1;
Let U_2 = scale reading in arm of U-tube connected to tap where pressure = p_2.

Then:

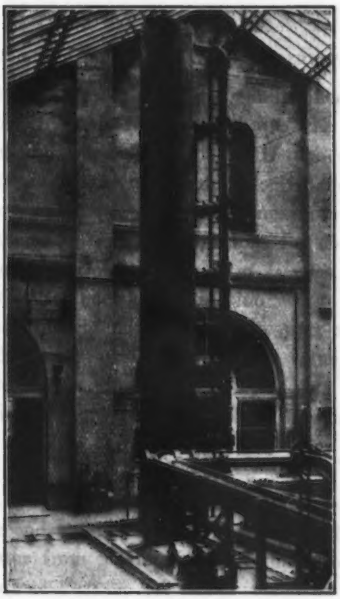
If U_1 is greater than U_2, the column of liquid of length $U_1 - U_2$ is balanced by a column of water of length $U_1 - U_2$ and by $\frac{p_2 - p_1}{\gamma}$.

Therefore:

$$\frac{p_2 - p_1}{\gamma} = (S - 1)(U_1 - U_2).$$

In all the determinations, the zero positions, U_0, of the liquid in the columns were carefully noted where $p_1 = p_2$, or when no water was flowing. Then, in most observations, U_1 only was read; and, in nearly all computations, $U_1 - U_2$ was taken as being 2 $(U_1 - U_0)$. Under the circumstances, this was considered more accurate because there was a perfect meniscus in the arm, U_1, while the surface in the arm, U_2, was broken and irregular. Some readings of U_2 were taken occasionally as a check.

FIG. 6.—QUIMBY SCREW PUMP.
HYDRAULIC LABORATORY, UNIVERSITY OF CALIFORNIA.



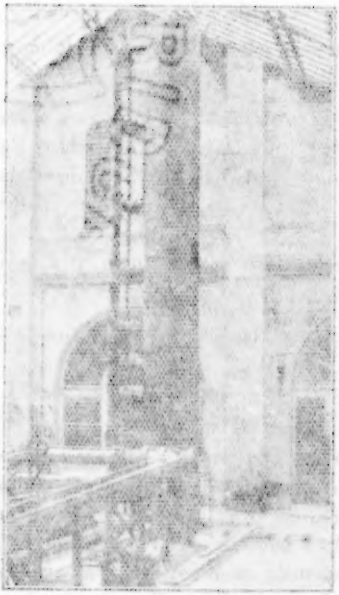


FIG. 7.—STAND-PIPE, HYDRAULIC LABORATORY, UNIVERSITY OF CALIFORNIA.

Tables 1 to 5, inclusive, show the values of $\frac{p_2 - p_1}{\gamma}$ computed from readings of U_1 and U_0, and the relation between velocity and $\frac{p_2 - p_1}{\gamma}$ at different points along the length of the large pipe is shown graphically on Figs. 8 to 12, inclusive.

METHOD AND ORDER OF TAKING OBSERVATIONS.

The Quimby screw pump was started, and, when the water was overflowing at the desired gate in the stand-pipe, the maximum range of U_1, the scale reading in the arm of the U-tube connected to the small pipe, was determined for maximum velocity and for some pressure tap in the large pipe where p_2 was near a maximum, say, Tap No. 6. Then, as it was intended to make observations for about ten different velocities for each combination, this range of U_1 was divided into ten steps, and the velocity for each determination was to be regulated by the gate-valve at the outlet end of the large pipe, so that for each successive trial, and for pressure Tap No. 6, the value of U_1 would increase by about one-tenth.

When the velocity had been thus regulated, the initial position of the surface of the water in the measuring tank was observed with a hook-gauge.

The hands of a watch were then set at some even hour, and the instant when the second hand was at 60 the swing pipe was turned so as to divert the water from flowing into the main reservoir and into the measuring tank.

While the water was flowing into the measuring tank at a constant velocity, readings of U_1 and U_2 were taken, when the various cocks in

the manifold were turned so as to connect pressure taps No. 1, No. 2, No. 3, etc., successively. Then, at the end of an even number of minutes, the water was diverted back into the storage reservoir, and the hook-gauge was set approximately right.

The adjustments of velocity for the next trial were then made while the surface of the water in the measuring tank was coming to rest. Before this was done, however, the controlling gate-valve was entirely closed and the reading U_0 taken. If the liquid in the two columns did not come to the same level, it showed the presence of air in the pressure connections, and doubt was cast on the accuracy of the previous observations. The air was then expelled by opening the bleeder cocks at the tops of the U-tube. The velocity was regulated as before, the final tank gauge reading was taken, and the next observation continued as before. Only two or three times during the experiment did the two column arms fail to balance because of the presence of air.

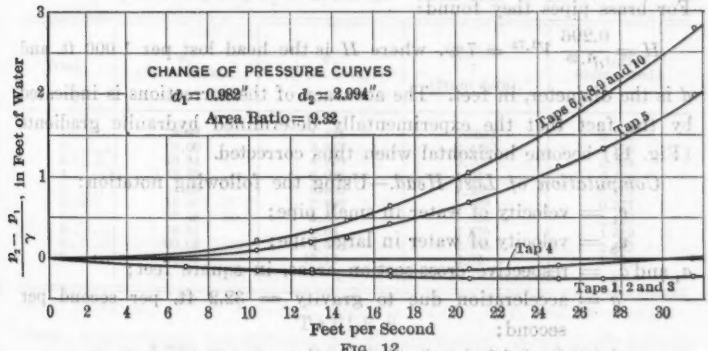

FIG. 12.

The mercury column was used but little, as nearly all the readings were within the range allowed by the long arm of the carbon tetra chloride column, and because the readings of the mercury column were subject to inaccuracy as the rubber tube leading to the U-tube came from the top of the manifold so that it would catch any air that might leak into the manifold or tubes connected thereto.

FRICTION CORRECTIONS AND COMPUTATION OF LOST HEAD.

The experimentally determined value of change in pressure head includes the loss of head due to friction in 6 in. of the smaller pipe and in the length, X, of the larger pipe, where X = the distance from the plane of enlargement to the point of maximum pressure, p_2.

To correct for this, the friction slope for each pipe was computed for several velocities, and lines were plotted on logarithmic paper showing the value of the slope for any velocity in any of the pipes used.

The formula adopted was :*

$$S^{0.54} = \frac{v}{1.32\, C\, r^{0.63}};$$

S = fall, in feet, in friction gradient per foot of length;

v = velocity, in feet per second;

C = constant, depending on surface of pipe;

r = hydraulic radius = $\left(\frac{d}{4}\right)$ feet for pipes.

The value of C given by Williams and Hazen for smooth brass pipes is from 135 to 145; 140 was taken.

This formula is based on experimental work† done by A. V. Saph, M. Am. Soc. C. E., and E. W. Schoder, Assoc. M. Am. Soc. C. E. For brass pipes they found:

$H = \frac{0.296}{d^{1.25}}\, V^{1.75} = 7\%$, where H is the head lost per 1 000 ft. and d is the diameter, in feet. The accuracy of the corrections is indicated by the fact that the experimentally determined hydraulic gradients (Fig. 14) become horizontal when thus corrected.

Computation of Lost Head.—Using the following notation:

v_1 = velocity of water in small pipe;

v_2 = velocity of water in large pipe;

a_1 and a_2 = respective cross-section areas, in square feet;

g = acceleration due to gravity = 32.2 ft. per second per second;

h = total friction head correction;

$\frac{p_2 - p_1}{\gamma}$ = measured change in pressure head;

$L.H.$ = actual experimental lost head due to sudden enlargement.

$$L.H. = \frac{v_1^2 - v_2^2}{2g} - \frac{p_2 - p_1}{\gamma} - h;$$

but

$$\frac{v_1^2 - v_2^2}{2g} = \frac{v_1^2}{2g}\left(1 - \frac{(a_1)^2}{(a_2)}\right)$$

Therefore,

$$L.H. = \frac{v_1^2}{2g}\left(1 - \frac{(a_1)^2}{(a_2)}\right) - \frac{(p_2 - p_1)}{\gamma} - h.$$

DETERMINATION OF FORMULA FOR LOST HEAD.

These values of v_1 and lost head, Tables 6 to 10, inclusive, were plotted three times, independently, on logarithmic cross-section paper.

The plotted points determined lines which were not only straight but nearly parallel, which indicated that the lost head varied as a constant power of the velocity. The value of this exponent (n) which, of course, was the tangent of the angle of inclination of the parallel lines with the velocity axis, was 1.919, and was determined by taking an average of the fifteen values obtained by the three trials of plotting of five lines each. In short, $L.H.$ varied as $v_1^{1.919}$.

Also: because, by theory, $l.h. = \frac{v_1^2}{2g}\left(1 - \frac{a_1}{a_2}\right)^2$, assume that

$$L.H. = c\, v_1^n \left(1 - \frac{a_1}{a_2}\right)^n.$$

This relation was proven to be true by plotting on logarithmic cross-section paper the values of lost head as ordinates against the corresponding values of $\left(1-\frac{a_1}{a_2}\right)$ for a constant velocity. All the points lay very close to a straight line with slope $= 1.919$.

The production of this line to the axis, where $\left(1-\frac{a_1}{a_2}\right)$ was equal to unity, and thence to such a value that v_1 was unity, gave the value of the constant, c.

From such construction, $C = 0.01705$. Hence the relationship appears to be

$$L.H. = 0.01705\, v_1^{1.919} \left(1-\frac{a_1}{a_2}\right)^{1.919}$$

or

$$L.H. = 1.098\, \frac{v_1^{1.919}}{2g} \left(1-\frac{a_1}{a_2}\right)^{1.919}.$$

RELATION OF THEORETICAL TO ACTUAL LOSS OF HEAD.

$$L.H. = \text{Actual loss} = K\, V_1^{1.919}$$

$$l.h. = \text{Theoretical loss} = k\, v_1^{2}$$

$$\frac{L.H.}{l.h.} = \frac{K\, V_1^{1.919}}{k\, v_1^{2}} = K'\, v_1^{-0.081}$$

or, if $B = K'\, v_1^{-0.081}$ where B is a variable coefficient,

$$\text{then } L.H. = B \times (l.h.) = B\, \frac{(v_1 - v_2)^2}{2g}.$$

The value of B, or the ratio of actual loss to theoretical loss at any velocity, v_1, may be shown on logarithmic cross-section paper, for any desired ratio of pipe areas, by drawing lines with slope $= -0.081$ at such positions that their intersections with lines of actual lost head for the same area ratios occur at velocities of such values that the theoretical loss for corresponding area ratios is unity. In other words, determine the value of v_1 to make the theoretical loss unity for any desired area ratio, and then the value of the actual loss at that velocity is a point on the line with slope $= -0.081$, showing the value of B for that area ratio and for any velocity. Table 11 shows the values of B for different area ratios and velocities.

Fig. 14 shows a set of gradients for a common velocity and different area ratios. The friction effect has been corrected by increasing the ordinates by an amount equal to the computed friction drop from Tap 0, or the reference pressure tap. It will be noted that the maximum change in pressure occurs when the area ratio is about 1 to 2 or 1 to 3, which is what would be expected from the theory as deduced by the application of the laws of maxima and minima.

DISTANCE OF MAXIMUM p_2 FROM PLANE OF ENLARGEMENT.

It was readily seen that this distance (call it x) would undoubtedly depend on the thickness $(r_2 - r_1)$ of the water between the stream from the smaller pipe, and the inside surface of the large pipe, or would vary as some function of $(d_2 - d_1)$.

For each of the combinations tested the value of x was determined within limits from the gradients and from inspection of the data. These limits were plotted on logarithmic paper with $(d_2 - d_1)$ in

inches as abscissas. It was found that a straight line with slope = 0.4 would pass very nearly through the average values, which would indicate that $x = K\,(d_2 - d_1)^{0.4}$.

From the line on logarithmic paper it is seen that when $(d_2 - d_1) = 1$, then $x = 1.45 = K$.

$$\text{Hence } x = 1.45\,(d_2 - d_1)^{0.4}$$

where d_2 and d_1 are diameters, in inches.

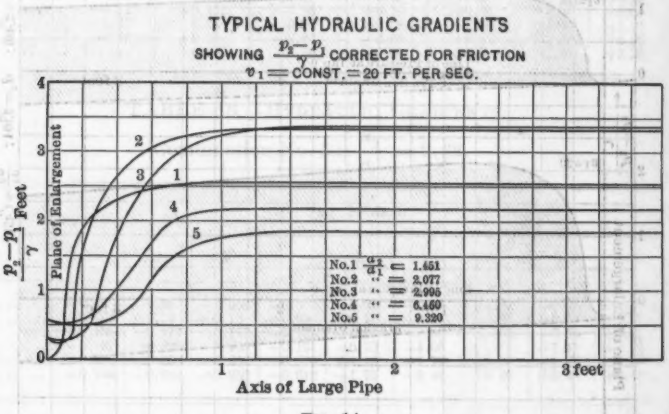

FIG. 14.

CONCLUSIONS.

The formulas thus obtained are based on data within the following limits:

v_1 from 3.82 to 31.58 ft. per sec.

v_2 from 0.07 to 11.44 ft. per sec.

$\frac{a_2}{a_1}$ from 1.451 to 9.32.

It is also worthy of note that few reliable results were obtained with values of v_1 less than 6 ft. per sec.

From the values of B it is seen that, within all ordinary limits of values of velocity and area ratios, the actual loss is less than the theoretical loss. This, at first, seems peculiar, but it is well known that velocity head may be changed to pressure head, with more or less attendant loss, by using a diverging passage to decrease the velocity

gradually and cause as little disturbance of stream lines as possible. In practice, this is accomplished by diffusers made of solid material. In the present instance, such action occurs with the dead water at the sides of the stream entering with velocity, v_1, having such diffusing effect. This explanation is borne out by the fact that the value of B decreases, or the amount by which the theoretical loss is lessened increases, as the velocity increases, or as the relative "deadness" of the side water increases. B also decreases as the area ratio increases, or as the quantity of dead water increases.

Mr. A. H. Gibson* deduces the same theoretical loss as given herein, and substantiates it with some experimental work he had done. Such results seem to agree closely with the theory, but, unfortunately, the maximum, p_2, was taken too close to the plane of enlargement, resulting in a smaller value of $\frac{p_2 - p_1}{\gamma}$ and hence a larger lost head. He used the value of $x = 10$ in., which, according to the formula, $x = 1.45\ (d_2 - d_1)^{0.4}$ should have been 1.7 ft. or 20.4 in. for maximum p_2, as $(d_2 - d_1) = 1.5$ in. The statement is made that by taking as p_2 the value obtained at a point 4 in. from the enlargement, the loss is about 20% greater than the theoretical, which agrees closely with the results herewith presented, as the actual loss decreases as p_2 increases, other things being equal. Had p_2 been taken at its maximum, losses from 0 to 20% less than theoretical, depending on the velocity, would doubtless have been observed. It is probable that the values of p_2 were taken at about the point where the loss changes from greater than theoretical to less than theoretical.

Summary of Results.—The summary of results is as follows:

(1) Lost head due to sudden enlargement = $L.H.$

$$L.H. = 1.098 \frac{v_1^{1.919}}{2g} \left(1 - \frac{a_1}{a_2}\right)^{1.919}$$

$$\text{or } L.H. = 1.098 \frac{(v_1 - v_2)^{1.919}}{2g}$$

$$\text{or } L.H. = \frac{B\,(v_1 - v_2)^2}{2g}, \text{ where } B \text{ is a variable coefficient}$$

with values given in Table 11.

* "Hydraulics and Its Applications," published in 1908.

(2) Distance of maximum p_2 from plane of enlargement $= x$

$$x = 1.45\ (d_2 - d_1)^{0.4}$$

where d_2 and d_1 are diameters in inches.

The writer takes this opportunity to thank all who helped bring this work to completion. The experimental work was done under the general supervision of Professor J. N. Le Conte, who gave many helpful suggestions in the computations as well. H. T. Cory, M. Am. Soc. C. E., also gave much valuable advice in connection with the coordination of the results and their preparation for presentation.

Paper No. 1263

ON LONG-TIME TESTS OF PORTLAND CEMENT.*

By I. Hiroi, M. Am. Soc. C. E.

With Discussion by Messrs. Chandler Davis, L. J. Le Conte, George G. Honness, and George S. Binckley.

The behavior of Portland cement in sea water has long been a subject of discussion by chemists and engineers; yet the lack of complete experimental data, on one hand, and vast amounts of material and labor placed at stake in most harbor works of magnitude relying on the durability of cement, on the other, seem to make any results of investigation on its nature a matter of ever recurrent interest, especially to those engaged on maritime works. It is under such an impression that the writer presents some of the results of his still unfinished experiments, the completion of which, however, he may not live to see.

More than 15 years ago, at a time when the writer had to give out instructions for manufacturing concrete blocks for use in harbor works, he commenced a series of tests on the behavior of the cements then in use, in order to ascertain as far as possible the reliability of the rules laid down for the execution of the works. The tests have included the quantity and quality of water used in gauging, the quantity and quality of the sand and ballast, the differences of temperature, the kind of surroundings, the modes of fabrication, and, in short, most of the important points in the manufacture of mortar and concrete considered likely to affect the strength of finished work in course of time. Most of these tests have confirmed the correctness

* Presented at the meeting of February 19th, 1913.

of the method as found in treatises relating to the subject and generally practiced in good works, so that it is hardly worth while describing here the results obtained. The durability test alone seems to be of some interest, particularly to those who have doubts as to the permanence of cement structures built in sea water.

The tests have been proposed to extend over 50 years, and although the time which has elapsed hardly covers one-third of that period, the results thus far obtained are of some value in showing the general trend of changes taking place in the strength of cement, and in forecasting in a certain measure the eventual results of the tests.

Three different kinds of cement and one hydraulic lime have been used for the various tests. In this paper only the results obtained with two kinds of cement will be considered. The chemical analyses of these two cements are given in Table 1.

TABLE 1.—CHEMICAL ANALYSES OF CEMENTS.

	CEMENTS.	
	A	*B*.
Loss by combustion	0.88	1.24
Insoluble matter	1.30	1.25
Silica	22.20	19.00
Alumina	7.55	8.35
Ferric oxide	2.90	3.90
Lime	61.77	62.17
Magnesia	1.12	1.75
Miscellaneous	2.28	2.34

In quality, the cements satisfied the following requirements:

The cement shall be so fine that the residue on a sieve of 5 000 meshes per sq. in. will not exceed 10% of the whole.

The insoluble matter contained in the cement shall not exceed 3 per cent.

The cement shall not commence to set within 1 hour of mixing with water.

The cement in setting shall not show any change in shape or volume.

Briquettes composed of 1 part of cement and 3 parts of standard sand, and immersed in sea water, shall have a tensile strength of not less than 130 lb. per sq. in. after 1 week, and gradually increasing to 170 lb. in 4 weeks, the amount of that increase to be not less than 30 lb. per sq. in.

All the briquettes for the durability test were made by hand, the mortar being gauged with fresh water and struck into the mould (with a trowel weighing 1¾ lb.) until water rose to the surface. The briquettes thus made were placed in a covered box for 24 hours, after which they were transferred to several media. The sands used for the mortar were of two kinds: (1) Coarse beach sand, with grains of all sizes up to about 0.06 in.; and (2) standard sand obtained by sifting the coarse sand between sieves with 400 and 1 400 meshes per sq. in. The briquettes kept in air were placed in an open shed, and those in water in tanks in which the water was changed once a week. The briquettes are uniformly 1 sq. in. in section, and five of them have been taken out for each single test.

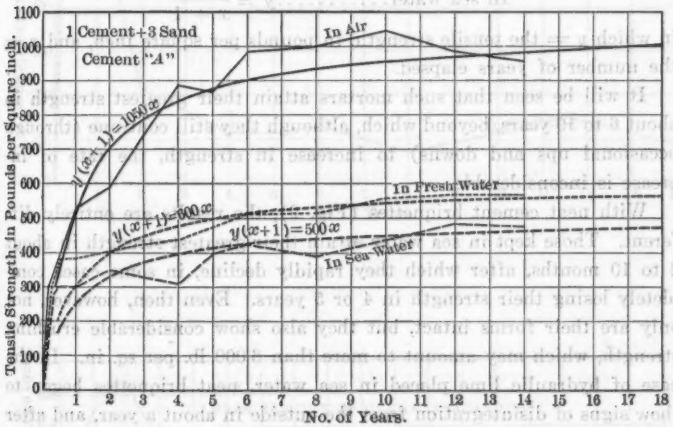

FIG. 1.

Fig. 1 shows the results of tests made with a mortar of 1 cement and 3 sand, by weight. These briquettes were placed separately in air, fresh water, and sea water, 24 hours after fabrication, in the manner already described, and remained there until tested. The strengths of briquettes made with coarse and standard sands have been found to be so nearly alike that the mean results were taken in plotting the curves. The strength attained by the use of finer sand naturally came out considerably lower. It will be seen, as might have been anticipated, that the mortar attains the greatest strength in air

and the least in sea water, the mean comparative ratio of strength attained being nearly as follows:

Air	1.00
Fresh water	0.56
Sea water	0.45

The curves of strength thus traced are approximately hyperbolic, and may be more or less closely expressed by the following equations:

$$\text{In air} \ldots\ldots\ldots\ldots y = \frac{1\,050\,x}{x+1}$$

$$\text{In fresh water} \ldots\ldots\ldots y = \frac{600\,x}{x+1}$$

$$\text{In sea water} \ldots\ldots\ldots\ldots y = \frac{500\,x}{x+1}$$

in which y = the tensile strength, in pounds per square inch, and x = the number of years elapsed.

It will be seen that such mortars attain their greatest strength in about 6 to 10 years, beyond which, although they still continue (through occasional ups and downs) to increase in strength, the rate of increase is inconsiderable.

With neat cement briquettes (Fig. 2), the results are entirely different. Those kept in sea water attain their greatest strength in about 2 to 10 months, after which they rapidly decline, in some cases completely losing their strength in 4 or 5 years. Even then, however, not only are their forms intact, but they also show considerable crushing strength, which may amount to more than 6 000 lb. per sq. in. In the case of hydraulic lime placed in sea water, neat briquettes began to show signs of disintegration from the outside in about a year, and after about 4 years even the sound core, which had been decreasing in size all that time, finally succumbed, leaving a shapeless mass. In air and fresh water, neat briquettes continue to increase in strength for 4 or 5 years, when they attain much higher strength than those placed in sea water. A comparison of the air curves on Figs. 1 and 2 shows the decided superiority, in the long run, of the use of 1 cement + 3 sand mortar over neat cement. The total loss of tensile strength in neat cement briquettes, whatever may be the medium in which they are placed, appears to be a question of time.

Fig. 3 shows another series of tests made with briquettes which had been kept immersed in fresh water for 2 months before they were finally

placed in sea water in partial reproduction of the conditions which obtain with concrete blocks used in sea water. The briquettes are of neat cement, and of mortars of 1 cement + 1 sand, 1 cement + 2 sand, and 1 cement + 3 sand, all by weight. Each curve shows the mean of the results obtained for *A* and *B* cements. Although the general form of the curves, except that for the neat cement, are (as before) approximately hyperbolic, the increase of strength is not as rapid as in the case of briquettes immersed directly in sea water, shown in Fig. 1, but the rise is more steady and continues much longer. In the case of the 1 cement + 3 sand mortar, the regular curve given by the following equation approximately coincides with the actual one through the greater part of its length:

$$y = \frac{500\,x}{x + 2.5}.$$

As far as the comparison of this equation with the corresponding one in the preceding case bears out, the strength apparently attainable by such mortar appears to have the same limitation. With neat cement briquettes, the time in which the maximum strength is attained in this, compared with the previous case, is considerably retarded, taking place in about 2 years; and the rate of decline in strength is also much less rapid.

Although the results of these tests are not yet conclusive as to the permanence of strength of cements, their indications are that, with proper selection of materials, right proportions of ingredients, and with due attention to the mode of fabrication, cement mortars used under circumstances in which engineering structures are commonly built, will continue to increase in strength for indefinite lengths of time, and thus artificial stones made with them will be as enduring as natural ones of approved qualities.

DISCUSSION

Mr. Davis.

CHANDLER DAVIS, M. AM. SOC. C. E. (by letter).—While connected with the Dock Department of the City of New York, the writer carried on a series of long-time tests of Portland cements, covering a period of 10 years. The cements used conformed to all the requirements of the Department standard specifications of 1898, the principal clauses of which were as follows:

"Slow-setting cement, gauged neat, must not set within ½ hour after being mixed with water.

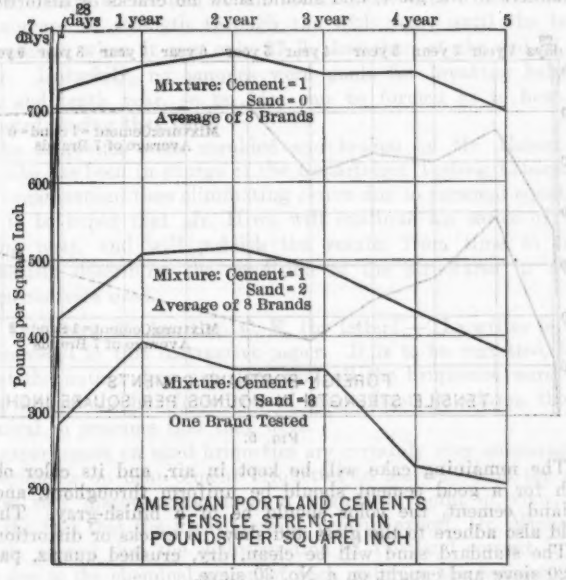

FIG. 4.

"The neat cement, after 7 days (1 day in air and 6 in water) must be capable of sustaining without rupture, a tensile strain of at least 300 lb. per sq. in.

"Mixed one part cement to two parts sand, it must, after 7 days (1 day in air and 6 in water), be capable of sustaining without rupture, a tensile strain of at least 125 lb. per sq. in.

"The neat cement, when set, must show no distortions or cracks.

"The time of setting will be determined by a wire $\frac{1}{24}$ in. in diameter, loaded so as to weigh 1 lb. The cement will be considered set when this wire is supported by the cement without showing any indentation.

Mr. Davis.

"The tests for checking or cracking and for color will be made by moulding on thin plates of glass, three cakes of neat cement, 2 or 3 in. in diameter, and about ½ in. thick in the center, and with very thin edges. One of these cakes, when it is set perfectly hard, will be put in water and examined from day to day to see if it leaves the glass, becomes distorted, or if cracks show themselves on the thin edges. Such distortions or cracks indicate that the cement is unfit for use at that time.

"The second of these cakes will be allowed to set hard in moist air, at a temperature of about 200°, for about 3 hours. It will then be placed in boiling water, and remain in boiling water for a period of from 24 to 48 hours, and, at the end of that time, the cake should still adhere to the glass, and should show no cracks or distortions.

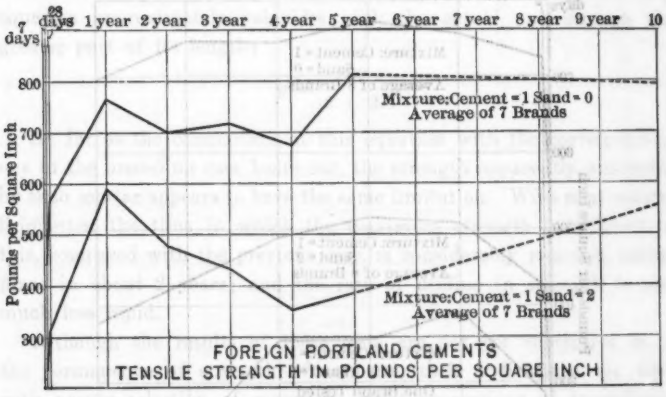

FIG. 5.

"The remaining cake will be kept in air, and its color observed, which for a good cement should be uniform throughout, and for a Portland cement, the color should be of a bluish-gray. This cake should also adhere to the glass and show no cracks or distortions.

"The standard sand will be clean, dry, crushed quartz, passing a No. 20 sieve and caught on a No. 30 sieve.

"Ordinary, fresh, clean water, having a temperature between 60 and 70° Fahr., will be used for the water mixture and immersion of samples."

All the tests were for tensile strength, and the results obtained have been plotted on Figs. 4 and 5.

The curves shown on Fig. 4 are the average strength curves of several brands of American Portland cement. The resulting curves are very irregular. The cement seems to have acquired its maximum strength at the end of the second year and then gradually decreased in strength until, after a lapse of 5 years, the tensile strength is less

than it was at the end of 28 days. The tests of the American brands were only continued for a period of 5 years. Mr. Davis.

The average results of seven brands of foreign cements are plotted on Fig. 5. Eliminating the 7- and 28-day tests, it will be seen that the neat cement reached its maximum strength at the end of 5 years, after having passed through a minimum at the end of 4 years. The strength of the cement at the end of the tenth year is only 17 lb. less than it was at the end of the fifth year. The strength curve for a mixture of one part cement and two parts sand, if the 7- and 28-day tests are eliminated, shows a maximum at the end of the first year, again a minimum at the end of the fourth year, with a continuation of the increase in strength through the fifth year, until the tenth year is reached, when it was only 37 lb. less than at the end of the first year. Unluckily, no samples were made for breaking between the fifth and tenth year, so no idea can be formed as to how the cement acted during that time.

All the briquettes were moulded and broken by Mr. Robert M. Sterritt, who has been in charge of the Department Testing Laboratory since its organization, thus eliminating errors due to personal equation.

It is to be hoped that Mr. Hiroi will continue his series of very interesting tests, and will publish the results from time to time, simultaneously describing the condition of the structures in which these cements were used.

L. J. Le Conte, M. Am. Soc. C. E. (by letter).—The writer is very much interested in this instructive paper. It is to be regretted, however, that the author does not state that all the briquettes were well protected against the hurtful effects of severe frosts in winter, though it is natural to presume that they were. Mr. Le Conte.

The experiments on sand briquettes are certainly very encouraging. The experiments on neat cement briquettes in sea water, on the contrary, are very discouraging, from a theoretical point of view. In view of the fact that the great German cement expert, Dr. Michaelis, has clearly proved that the disintegration of Portland cement in sea water is due to the chemical action of such water on the ordinary constituents of the cement, it is natural to suppose that some effect is to be expected, in the natural course of events—it being purely a question of time in any case.

Taking the worst case reported: If it can safely be assumed that the penetration of chemical action into the neat cement briquette is proportional to the loss in strength in a given time, then it amounts to approximately 0.32 in. in 4 years, and a tensile strength of 100 lb.; then, 10 years after, or 14 in all, we still have the same tensile strength, 100 lb., showing that chemical action had reached its extreme limit of penetration, namely, 0.32 in. There is certainly nothing very startling

Mr. Le Conte.

about this result, and, moreover, the concrete in all harbor works is necessarily exposed to marine growths of all kinds, such as barnacles, mussels, oysters, shell-fish, and all kinds of sea-weeds and grasses, which soon form a heavy coating over the entire water face of all the concrete work, and practically cut off all free circulation of sea water. Hence the writer does not think that the interesting results reported furnish any information which calls for serious consideration; on the contrary, the sand briquettes stand up well under the 14-year tests, much better, in fact, than one would naturally expect, theoretically.

The probabilities are that the penetration of chemical action into the sand briquettes, which undoubtedly does exist, is so very small in amount as to be completely obliterated by the general slow growth in strength. The falling off in strength of neat cement briquettes between the ages of 5 and 14 years, when kept in ordinary air, is one of the mysteries yet to be explained. It seems to be the experience everywhere. It naturally follows from the above that low-grade porous concrete may have its strength seriously affected by the chemical action of sea water.

Mr. Honness.

GEORGE G. HONNESS, M. AM. SOC. C. E. (by letter).—Actual construction seldom affords opportunity to make long-time tests of cement, consequently, such information, though valuable, particularly in this age of concrete and the growing use of reinforced concrete, should be secured by tests made by manufacturers, laboratories of technical schools, or municipal departments having the direction of engineering works.

The construction of the New Croton Dam afforded an opportunity to make long-time tests, and the writer, though not connected with that work, had access to the records, and believes them of sufficient value and interest to publish.

These records afford no opportunity to compare Mr. Hiroi's results in respect to conditions which obtain when the cement is used in salt water, but indicate the behavior of the cement and mortar under normal conditions. One brand of Portland and three brands of natural or Rosendale cement were used in this work, during the progress of which the methods of manufacture changed from the dome kiln to the rotary kiln. Practically all the testing was done by one man, which fact eliminates any inconsistency due to personal manipulation. The mortar briquettes were composed of 1 part cement to 2 parts standard sand, instead of the 1:3 mixture now prescribed; the standard sand was a crushed quartz, all of which would pass a No. 20 and be retained on a No. 30 sieve.

Table 2 shows the results of the tests, and it will be noted that they represent the average of a large number of briquettes. The dia-

Riehle Bros. 1 000-lb. testing machine used.
Cement made by dome kiln method up to 1903; afterward by rotary kiln.
Briquettes up to 3 years broken by maker. Of the 4 to 10-year briquettes, 87% broken by maker.

Mr. Honness.

gram, Fig. 6, shows the results of the tests graphically. These tests show some interesting features, the chief of which is that the natural cement mortars show a gradual increase of strength to the end of the period, and the Portland cement shows retrogression of strength, after 3 years in neat cement and after 4 years in 1:2 mortar. Another interesting feature is that after 4½ years the natural 1:2 mortar exceeds the strength of the Portland No. 1. This confirms the belief of some of the older engineers, that the lasting qualities of natural cement are superior to those of native Portlands.

The retrogression of strength shown by these tests, although it represents only one brand of Portland cement, makes one ask: Is this fall-

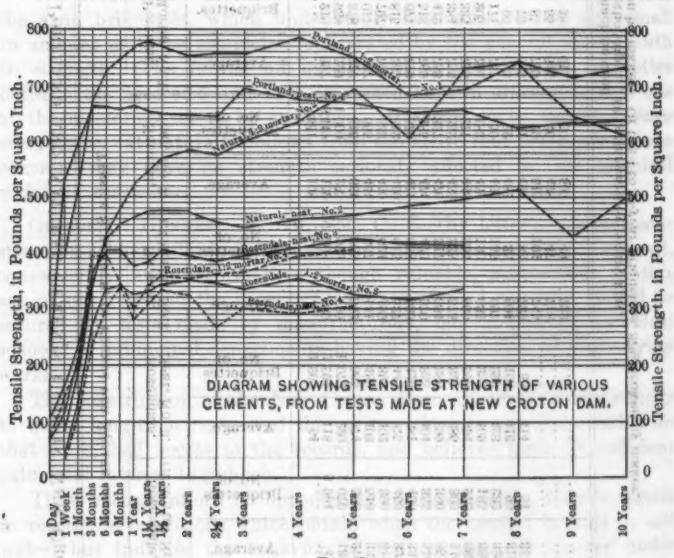

FIG. 6.

ing off of strength continuous, or when does it cease? This is of especial importance when considered in connection with reinforced concrete.

The author's experiments indicate that the brands of cement used by him continued to gain in strength after an age of 10 years. It may be that these brands have the proper combination of ingredients to assure a continual increase of strength, or at least no serious retrogression. Unfortunately, it is impossible for the writer to give the chemical composition of the Portland cement used at the New Croton Dam for comparison with the brands used by the author.

Mr. Honness.

It seems desirable that, from data of this kind now available or to become available, a determination should be made of the chemical combination in cement which would assure that the strength would not fall below a fixed minimum after a long period of years. When the proper combination has been determined, it should be embodied in all specifications for important masonry construction.

Mr. Binckley.

GEORGE S. BINCKLEY, M. AM. SOC. C. E. (by letter).—In providing a stimulating center of discussion, Mr. Hiroi's brief paper on long-time tests of cement is particularly valuable. Such data as those he presents are certainly of high importance, and the curves given by Mr. Davis, Figs. 4 and 5, are still more suggestive, especially in consideration of the conditions under which these really startling results have been obtained.

These two sets of curves present such a striking contrast between the American and foreign cements as to call for more than passing comment. They are of peculiar interest to the writer in tending to strengthen a growing suspicion that American cements lack the inherent soundness found in the best of those of foreign manufacture.

Some years ago, the writer had occasion to make a comparison between one of the best-known of the English Portland cements and a cement made in Western Canada, and in the course of these tests some very curious and suggestive results were obtained. So striking were some of these that the writer used them as the basis for a brief article published soon afterward.* In few words, these particular tests had to do with the qualities of the coarser particles in Portland cement—those passing the 100-mesh and remaining on the 200-mesh screen.

In the cements examined, this material, contrary to the commonly accepted idea, showed very considerable hydraulic properties; in fact, briquettes gave a tensile strength at 7 days of 126 lb. for the Canadian, and 220 lb. for the English briquettes; at 28 days the figures were 215 lb. for the Canadian and 353 lb. for the English briquettes. Mr. Spackman, of Philadelphia, has suggested to the writer that part of this effect was due to fine particles adhering to the coarser ones, yet he admits a certain hydraulicity in at least the superficial part of the coarse particles themselves.

Both these cements passed the standard tests successfully, the gain in strength between 7 and 28 days being 90 lb. in each. Both cements, neat, stood the accelerated tests successfully; and the Canadian cement showed a greater strength than the English at both 7 and 28 days.

When the briquettes or pats made from this intermediate material—that passing the 100-mesh and remaining on the 200-mesh screen—

* *Engineering Record*, Feb. 19th, 1910, p. 212.

Mr. Binckley.

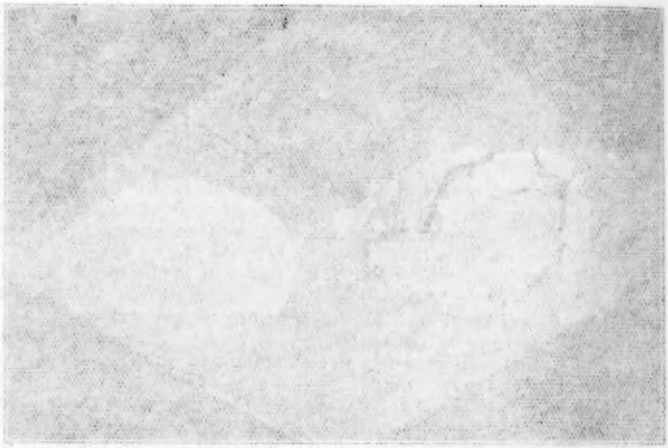
were subjected to the steam test under atmospheric pressure, however, the difference in results was startling. The accompanying photographs of these test pats and briquettes (Figs. 7 and 8) make this very clear. The English pat and broken briquette remained perfectly hard and sound, and those made from the intermediate material of the Canadian cement quickly broke down. To quote from the article previously referred to:

"Standard boiling pats were prepared and placed on the same glass plate to secure perfect identity of conditions. On account of the crumbling (noted above) of the edges of the briquettes made from the intermediate material screened out of the Canadian cement, these boiling pats were kept in moist air 60 hours before boiling to insure a perfectly fair test.

"The two pats representing the two cements investigated were then placed in cold water, which was raised to the boiling point. Boiling was continued for 2½ hours, at the end of which time the condition of the two pats may be seen by reference to the accompanying photograph. That pat made from the intermediate material of the English cement showed no deterioration whatever, adhered tightly to the glass, and was free from any sign of cracking. It in every respect indicated perfect soundness. The other pat, made from intermediate material screened out of the sample of Canadian cement, showed the first sign of breaking down 45 minutes after being placed in the water, and its integrity was completely destroyed in two hours and a half. Its condition is most graphically shown in the accompanying photograph, in which it is seen that it is cracked and disintegrated to such an extent that its interior is in a granular or sandy condition.

"These results were so striking that a further boiling experiment was made on half of one of the briquettes, the 28-day [Canadian] specimen showing a tensile strength of 215 lb. per square inch. * * * This briquette was boiled when it was 38 days old. Yet in spite of its comparatively high strength and thorough seasoning in and out of water, it broke down completely after about five hours' boiling, as shown in the photograph.

"This complete failure was a surprise, as there had been no visible sign of deterioration before boiling; yet but a short time after the water had reached the boiling point the first sign of distress appeared."



The writer considered these results highly suggestive. Here are two cements, each apparently conforming to the standard tests for soundness; yet, when one is subjected to the writer's test, it is seen to contain an element of weakness, and the other remains sound. The Canadian cement seems to contain about 20% by weight of a material inherently mischievous, but protected in such a way, under the standard tests, as to remain undiscovered. In other words, this Canadian cement—and probably a great many American cements also—contains in its coarser particles an element of weakness which evades discovery under the standard tests, but may reasonably be expected to reveal itself as the years pass. This is strikingly indicated in Mr. Davis'

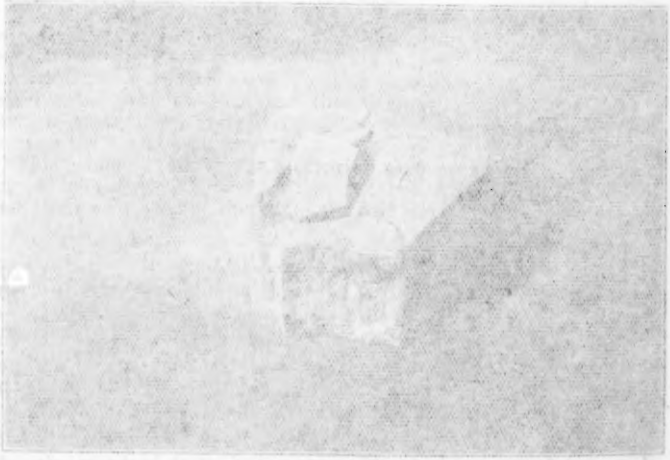


FIG. 7.—"PATS OF INTERMEDIATE MATERIAL AFTER BOILING."

FIG. 8.—"BRIQUETTE OF INTERMEDIATE MATERIAL."

curves, and, in the case of neat cements, in the curves presented by Mr. Honness (Fig. 6), and also, to a less striking yet notable degree, in Mr. Hiroi's paper. Mr. Binckley.

Though it would hardly be proper to consider the characteristics of American cements as indicated by these data as a cause of actual alarm, they can hardly be considered satisfactory. Even qualified and at least partly compensated by the better showing made by the sand briquettes, Mr. Davis shows curves representing an average of eight brands of American cement that lead one to wonder where the rapid drop in strength will stop, if at all. It must be remembered, also, that those eight brands probably represent the best cements obtainable for the works considered, as it is incredible that inferior or suspected cements would be placed under a long-time test and allowed to drag down a good average. The curve Mr. Davis gives for a single brand in 1:3 sand briquettes is rather appalling, for it has lost 50% in 4 years, and is still falling off.

The engineer cannot afford to contemplate with composure the possibility of a progressive deterioration of a supposedly permanent material of such importance. If cement is to fall under the head of materials subject to deterioration, the sooner we know it the better, to the end that its life may be calculated, replacements provided for, and means taken to prevent disastrous failures. If, on the other hand, we are to have a dependable material for all the ages, which, built into our structures will actually—as so confidently assumed—improve in strength with the years, defects must be sought out, and faulty material must be rejected without mercy. In the article previously referred to, the writer suggested the advisability of applying the test described as a ready means for the detection of inherent weakness in a cement passing the standard tests. Since that time, a still more drastic test—the autoclave test—has been advocated, but this requires special and rather costly apparatus, and is so drastic that it seems probable that few American cements would succeed in passing it. Yet the writer believes that the time will come very soon when engineers will find it prudent or even imperative to subject the cement required for works of importance to far more searching tests than those now in use; and if the cement manufacturers find it difficult or even impossible to supply cement of the required integrity under their present methods of manufacture, they will simply have to improve their methods. As soon as the certainty of eventual weakness in concrete made with any particular class of cement is established, or even a strong suspicion of concrete as a permanent material is aroused, some very strict requirements will have to be met by the cement manufacturers.

Mr. Binckley.

In the meantime, the writer suggests—even urges in cases of importance—the application of the tensile and steam tests to that part of the material passing the 100-mesh and remaining on the 200-mesh screen. This material should be made into standard boiling pats and briquettes, and carefully observed. Everything else being apparently equal, as between rival cements, this test will certainly give a definite indication of relative soundness that should fix one as superior.

Paper No. 1264

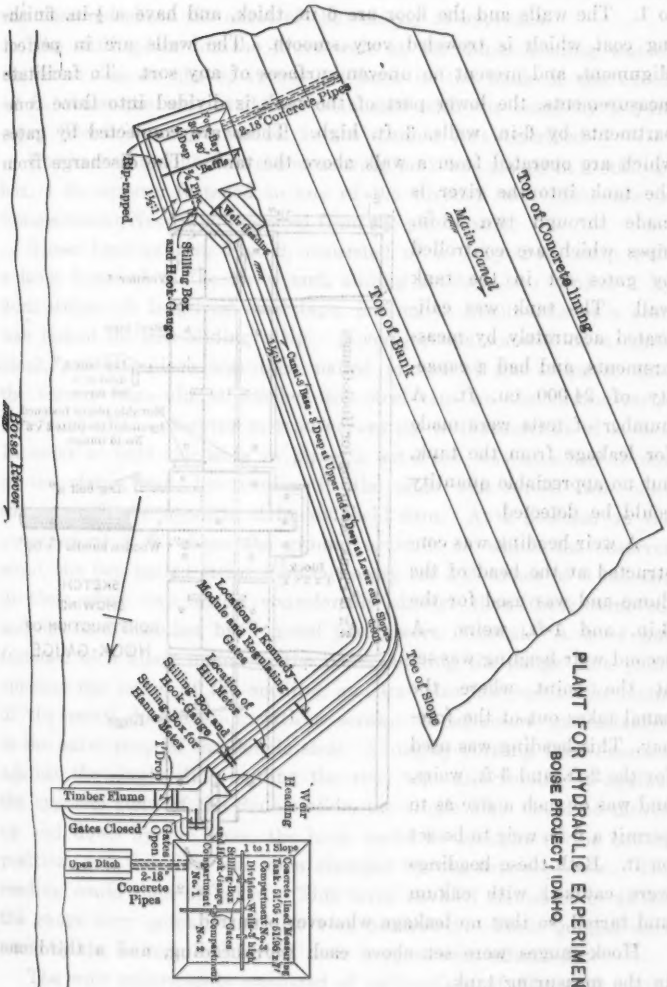
EXPERIMENTS ON WEIR DISCHARGE.

By W. G. Steward,* Esq., and J. S. Longwell,† Jun. Am. Soc. S. E.

With Discussion by Messrs. C. H. Pierce, Francis F. Longley, W. G. Steward and J. S. Longwell.

The experiments discussed in this paper were made by the writers at the experiment station of the Boise Project of the United States Reclamation Service during 1911, in connection with duty of water investigations for the project. The project experiment station is on the main canal of the Boise Project, near Boise River, at a point about 8 miles above Boise, Idaho, and was built in the fall of 1910.

The water used for this station is diverted into a forebay from the main canal by a double turn-out consisting of two 18-in. concrete pipes, each controlled separately by gates on the bank of the main canal, as shown by Fig. 1. The forebay or weir pool is 30 ft. square on the bottom, 4 ft. deep, and has side slopes of 1½ to 1. The bottom of this bay is 12 ft. below the bottom of the main canal. An adjustable baffle-board divides the forebay into two parts. The sides of the pool above the baffle are rip-rapped with large stones in order to prevent the water from washing the banks as it issues from the turn-out. Below the baffle the water is quiet, and no rip-rap is needed.



* Asst. Engr., U. S. Reclamation Service, Boise Project, Boise, Idaho.
† Junior Engr., U. S. Reclamation Service, Boise Project, Boise, Idaho.

A canal having a bottom width of 8 ft. carries the water about 318 ft. from this forebay to the upper end of a timber flume, 8 ft. wide and 3 ft. deep. This flume section extends for 12 ft. and then divides into two sections of equal width at right angles with each other and located so that the center line of each makes an angle of 45° with the center line of the main flume. The left branch leads to a concrete measuring tank; the right branch leads to Boise River, and acts as a wasteway. A set of gates in each branch controls the flow of water, diverting it into the tank or into the river, as may be desired. There are two gates in each set, a large one hinged to a vertical post set just enough off center to cause the water pressure to keep it closed, and a small water-tight one hinged to the floor and held in a vertical position by a hinged brace fastened to one of the cross-pieces on top of the flume. A water-proof canvas is nailed to the sides and floor of the flume and to this gate, with enough extra material in the ends, so that the gate can be operated without difficulty. The large gate serves to stop most of the flow, thus making it easier to operate the small one. The closing of one set of gates requires from 1 to 2 sec. There was no difficulty in operating the gates, and they proved very satisfactory and efficient.

This gate heading was caulked and coated with a tar preparation, and no leakage could be detected, either through the flume or the gates. The upper portion of the flume, between the gates and the weir, acted as a storage basin for the water between the time of closing one set and the opening of the other. The weir was set high enough above the flume floor so that the water which backed up between the shutting and opening of the gates did not cause any submergence on the weirs. In the case where the weirs were set at the upper heading, the flume and canal acted as the storage basin, and there was no effect on the weir discharge.

In obtaining the intervals for the various runs, the time was recorded at the closing of the gates in the wasteway at the beginning of the run and the closing of the opposite set at the end of the experiment. Thus the only possible error that might enter into the results would be the difference in times required for closing, which at the most was about ½ sec.

The concrete measuring tank is set into the ground 7 ft. The

PLANT FOR HYDRAULIC EXPERIMENTS
BOISE PROJECT, IDAHO

FIG. 1

bottom is 51.95 ft. square, and the side slopes are on a batter of 1 to 1. The walls and the floor are 6 in. thick, and have a ½-in. finishing coat which is troweled very smooth. The walls are in perfect alignment, and present no uneven surfaces of any sort. To facilitate measurements, the lower part of the tank is divided into three compartments by 6-in. walls, 3 ft. high. These are connected by gates which are operated from a walk above the tank. The discharge from the tank into the river is made through two 18-in. pipes which are controlled by gates set in the tank wall. The tank was calibrated accurately by measurements, and had a capacity of 24 000 cu. ft. A number of tests were made for leakage from the tank, but no appreciable quantity could be detected.

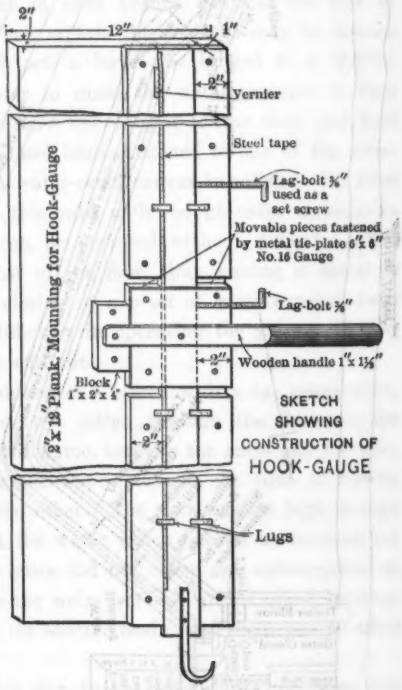


FIG. 2.

A weir heading was constructed at the head of the flume and was used for the 6-in. and 1-ft. weirs. A second weir heading was set at the point where the canal takes out of the forebay. This heading was used for the 2-ft. and 3-ft. weirs, and was of such a size as to permit a 6-ft. weir to be set on it. Both these headings were caulked with oakum and tarred, so that no leakage whatever occurred.

Hook-gauges were set above each weir heading, and a third one in the measuring tank.

In the case of the upper heading at the forebay, a stilling-box, 1 ft. square, was set back into the bank, with a ¾-in. pipe leading out into the forebay about 15 ft. above the weir. The hook-gauge was

attached to the inside of the stilling-box, and the head on the weirs was observed above the effect of the velocity of approach.

The stilling-box for the lower weir at the flume heading was of the same size as above; it was set back in the bank of the canal, 10 ft. above the weir, and was connected with the canal by a ¾-in. pipe. The hook-gauge was set in the manner just described.

The hook-gauge used in the measuring tank was placed in a stilling-box, 1 ft. square, fastened to one of the division wall buttresses in Compartment No. 1 and operated from the plank walk.

These hook-gauges, Fig. 2, consisted of a 1 by 2-in. strip with a hook fastened to the lower end, sliding between two similar 1 by 2-in. strips. A length of steel tape, reading to hundredths of a foot, was tacked on this sliding strip. A vernier was screwed on a small block, and the block was then nailed to one of the strips so that the vernier edge almost touched the steel tape on the sliding strip. This enabled the observer to read accurately to thousandths of a foot. In order to hold the slide in place, a set-screw was attached to one of the strips, and, by turning it, the slide was forced into close contact with the opposite strip and held firm. At a position on the gauge about 3 ft. above the ground or walk on which the observer stood, the two nailed strips were cut away for a distance of 6 in., and in their place two strips, considerably shorter than those removed, and fastened together by a metal plate, were inserted. A lever was fastened to a block nailed to the plank holding the gauge at a point opposite the center of the opening, and was also fastened to the metal of the small double slide with a screw. A set-screw was attached to the outer strip of the double slide. Thus, by turning this set-screw against the single slide holding the steel tape and forcing it against the opposite strip of the double slide, the single slide could be moved up and down by the lever, the hook could be brought to the proper position, and the slide was then clamped by the first set-screw. The reading could then be taken. This lever enabled the observer to set the gauge very quickly and also very accurately. These gauges were made by the writers, and served their purpose very effectively.

The weir experiments consisted of calibrations of 6-in., 1-ft., 2-ft., and 3-ft. sharp-crested Cippoletti and rectangular weirs with full contraction. The experiments on sharp-crested Cippoletti and rectangular weirs were made, not with the idea of obtaining new general formulas

for weirs, but for the purpose of testing the general weir formulas and ascertaining whether they are applicable to the weirs on the Boise and other projects of the Reclamation Service, and, if necessary, of preparing rating tables for the weirs tested and a formula or table by which accurate discharges might be obtained for a range of weirs and heads above the limits of previous experiments.

The crests of all the weirs were set about 1 ft. above the canal bottom. The 6-in. and 1-ft. weirs were located in the center of the 8-ft. canal at the flume heading. The 2-ft. and 3-ft. weirs were located at the head of the canal, and took the water directly from the 30-ft. forebay. The gauges were set far enough above the weirs to be free from the effect of velocity of approach. At the flume heading, baffles were placed in the canal just below a regulating gate, and planks were laid on the water to do away with any surface disturbances. A very even and uniform flow resulted, with no appreciable velocity of approach except in one or two high heads on the 1-ft. Cippoletti weir. In the case of the weirs used on the upper heading, the regulation was obtained with the gates in the main canal. Very little trouble was experienced after the water had settled in the pool. The water in the main canal was from 4 to 5 ft. in depth over the gates, and any slight variation in head did not affect the discharge of the pipes appreciably. The hook-gauges above the weirs were read every 30 sec. throughout the length of runs, which varied from 5 min. to 1 hour, depending on the head. The average of the readings gave the gauge height for each particular run. The different compartments of the tank were used as the discharge increased. For the low heads and smaller weirs Compartment No. 1 was used. As the head increased, Compartments Nos. 1 and 2 were used, and, for the large heads, the entire tank was utilized. No trouble was experienced in reading the gauges to thousandths of a foot.

Cippoletti Weirs.—The experiments on Cippoletti weirs are divided into five parts: (1) calibrations of the 6-in. weir; (2) an attempt to determine the shape of the 6-in. weir to discharge according to the Cippoletti formula; (3) calibrations of the 1-ft. weir; (4) calibrations of the 2-ft. weir; and (5) calibrations of the 3-ft. weir.

In the 6-in. weir, twenty-four runs were made with heads ranging from 0.161 to 0.945 ft. The maximum variation in gauge height during any run was 0.024 ft. No appreciable velocity of approach

existed during this experiment, and the end contractions and the shape of the nappe were not disturbed in any manner. Compartment No. 1 of the measuring tank was used entirely during the calibrations of this weir.

Plate XXXIV shows the gauge height and discharge curve, and Table 2 gives the actual discharge for each $\frac{1}{100}$ ft. of gauge height. Plate XXXVI is a logarithmic discharge curve from which it will be

WEIR DISCHARGE EXPERIMENTS.

seen that three distinct parabolas exist as the discharge curve, instead of one. This logarithmic curve was used in determining the proper plotting of the gauge height discharge curve. The equations of the different parabolas were determined as shown in Table 7, also the gauge height at which the change of equation takes place, and the proportional part that this gauge height is of the crest length.

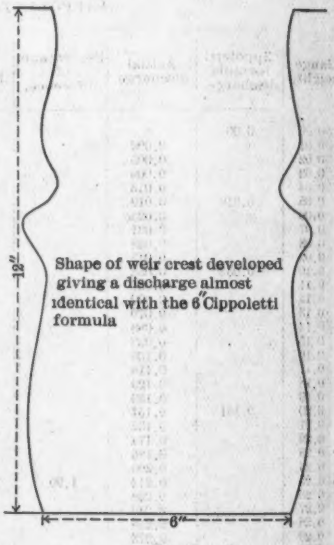
A number of runs were made to determine the shape of a weir that would discharge according to the Cippoletti formula. Plates were screwed on the face of a 6-in. Cippoletti weir, and a general shape was determined. The shape obtained, Fig. 3, was a series of reverse curves or waves, and seems to be of no practical value.

The 1-ft. Cippoletti weir was placed on the flume heading, and the flow was regulated by special gates. The gauge heights on this weir ranged from 0.138 to 1.978 ft., with a maximum variation of gauge height of 0.019 ft. for any run. No corrections were made for velocity of approach, as the maximum correction was only 0.002 ft. for the highest head of 1.978 ft. over the weir. The effect on the lower heads was not appreciable. In all cases there was full contraction and a free nappe. A gauge height discharge curve, also shown on Plate XXXIV, was plotted with the assistance of a logarithmic curve, as described for the 6-in. weir. Table 3 gives the discharge for each $\frac{1}{100}$ ft. of gauge height. Compartment No. 1 in the tank was used for the lower heads, and Nos. 1 and 2 for the higher ones.



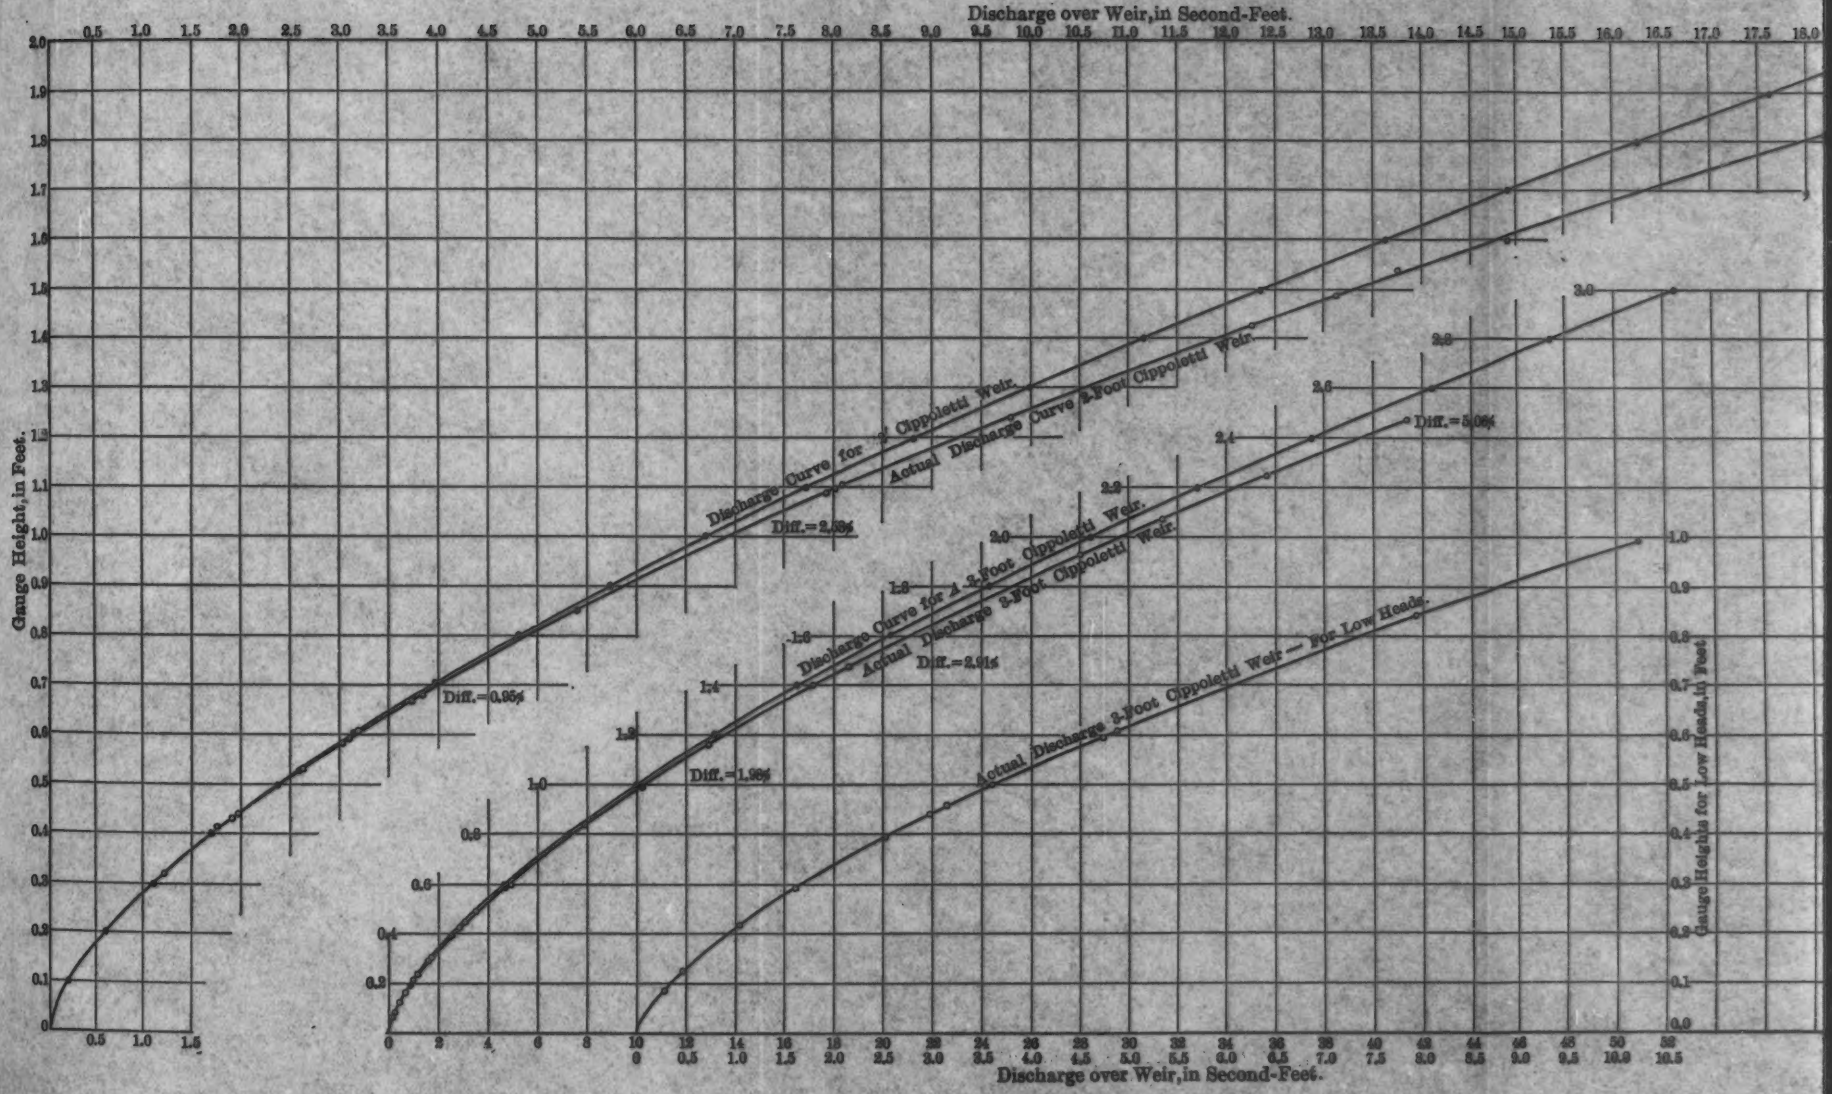


FIG. 3.

The 2-ft. and 3-ft. Cippoletti weirs were set at the head of the canal, taking the water from the 30-ft. forebay. No velocity of approach existed, as the gauge was set to give the elevation of the water in the forebay above the effect of the weirs. For the 2-ft. weirs, the heads ranged from 0.034 to 1.987 ft., with a maximum variation of head of 0.017 ft. for any run. For the 3-ft. weir, the heads varied from 0.082 to 2.415 ft. The greatest variation of head was 0.009 ft. The contraction in both weirs was entirely full, and the nappes were perfectly free from any disturbances. Compartment No. 1 of the measuring tank was used for the low heads, Nos. 1 and 2 for interme-

diate heads, and the entire tank for the high heads. The discharge curves are shown on Plates XXXV and XXXVI, and Tables 4 and 5 give the details.

Plates XXXIV and XXXV show the discharge curves for the actual discharge of the Cippoletti weirs and the theoretical discharge by the Cippoletti formula. It is observed that in every case the actual discharge curve follows the Cippoletti curve to a gauge height of approximately one-third of the length of the crest. After this point, the actual discharges for the gauge height become larger than indicated by the formula. Tables 2 to 5 give the actual discharge for each $\frac{1}{100}$ ft. of gauge height, the formula discharge for each $\frac{1}{10}$ ft. of gauge height, and the percentage that the actual discharge is in excess of the formula discharge for each $\frac{1}{10}$ ft. of gauge height. At a gauge height of 1 ft. on a 6-in. weir, the difference is 30.36%, at 2 ft. on a 1-ft. weir it is 29.65%, showing that at a gauge height equal to twice the length

of the crest the actual discharge is approximately 30% in excess of the formula discharge. The gauge heights were not carried up to this proportion on the 2-ft. and 3-ft. weirs, but it will be observed that the percentage of difference for the same proportion of gauge height to length of crest agrees fairly well for the different weirs.

Plate XXXVI shows the logarithmic discharge curves for each Cippoletti weir. For the 6-in., 1-ft., and 2-ft. weirs, it is observed that there are three distinct straight lines for each weir. For each succeeding larger weir, the points plot in less decided breaks, and for the 3-ft. weir, there are only two curves. The equation of each of these separate divisions was taken, and the gauge height at which the change in equation takes place was observed, also the proportional part that each of these gauge heights is of their respective lengths of crest. These are given in Table 7. It will be observed that, for the 6-in. and 1-ft. weirs these breaks occur at gauge heights which are approxi-

mately one-half the length of the crest and equal to the length of crest, respectively.

For the 2-ft. weir, the heads are not high enough to obtain the break at the length of crest, but the break at about one-half that length is quite evident. This weir makes a change in equation at a lower

proportion than the other two, at approximately one-tenth of the length.

For the 3-ft. weir, there are only two equations, the break occurring at a proportion of gauge height to length of crest of about one-tenth.

Table 1 gives the results of the experiments as recorded, and also, in each run, the value of C in the formula, $Q = Clh^{\frac{3}{2}}$, the customary weir formula.

Table 6 gives the gauge heights of the experiments, arranged in the order of their value, and the corresponding values of C. This table shows that the values of C increase with the gauge height, and that the exponent, $\frac{3}{2}$, or the slope of the logarithmic curve, is not correct, as is also shown by the logarithmic curves of actual discharge.

Table 8 gives the gauge heights for every $\frac{5}{100}$ ft. up to a height of 2.45 ft. These gauge heights are accompanied by the corresponding discharges for each of the four Cippoletti weirs tested. From this table it is seen that the discharges by formula are practically correct up to a gauge height of one-third of the length of the crest. Above this point, however, the use of a new formula or discharge table is essential to accuracy. This table also shows that, above the limits of the formula, the weirs do not discharge in proportion to their length of crest, and that this difference increases with the gauge height. It will be observed that the discharges of the 2-ft. and 3-ft. weirs are more in proportion to the length of the crest than any of the others.

Table 9 shows the values of C in the weir formula, $Q = Clh^{\frac{3}{2}}$ for all the Cippoletti weirs. The values were prepared for each $\frac{5}{100}$ ft. of gauge height, up to a head of 0.3 ft., and for every $\frac{1}{10}$ ft. above that point. The values of Q in the formula were taken from the prepared discharge tables. This table shows that above a gauge height equal to one-third of the length of the crest, C increases very rapidly in each case, and that this increase is not uniform for all the weirs, but is more nearly in proportion to the ratio of gauge height to length of crest.

The foregoing tables and plates show that the Cippoletti weir formula may be used with reasonable accuracy for depths up to one-third of the length of the crest. Above this gauge height, it will be necessary to use tables prepared carefully from actual ratings. The

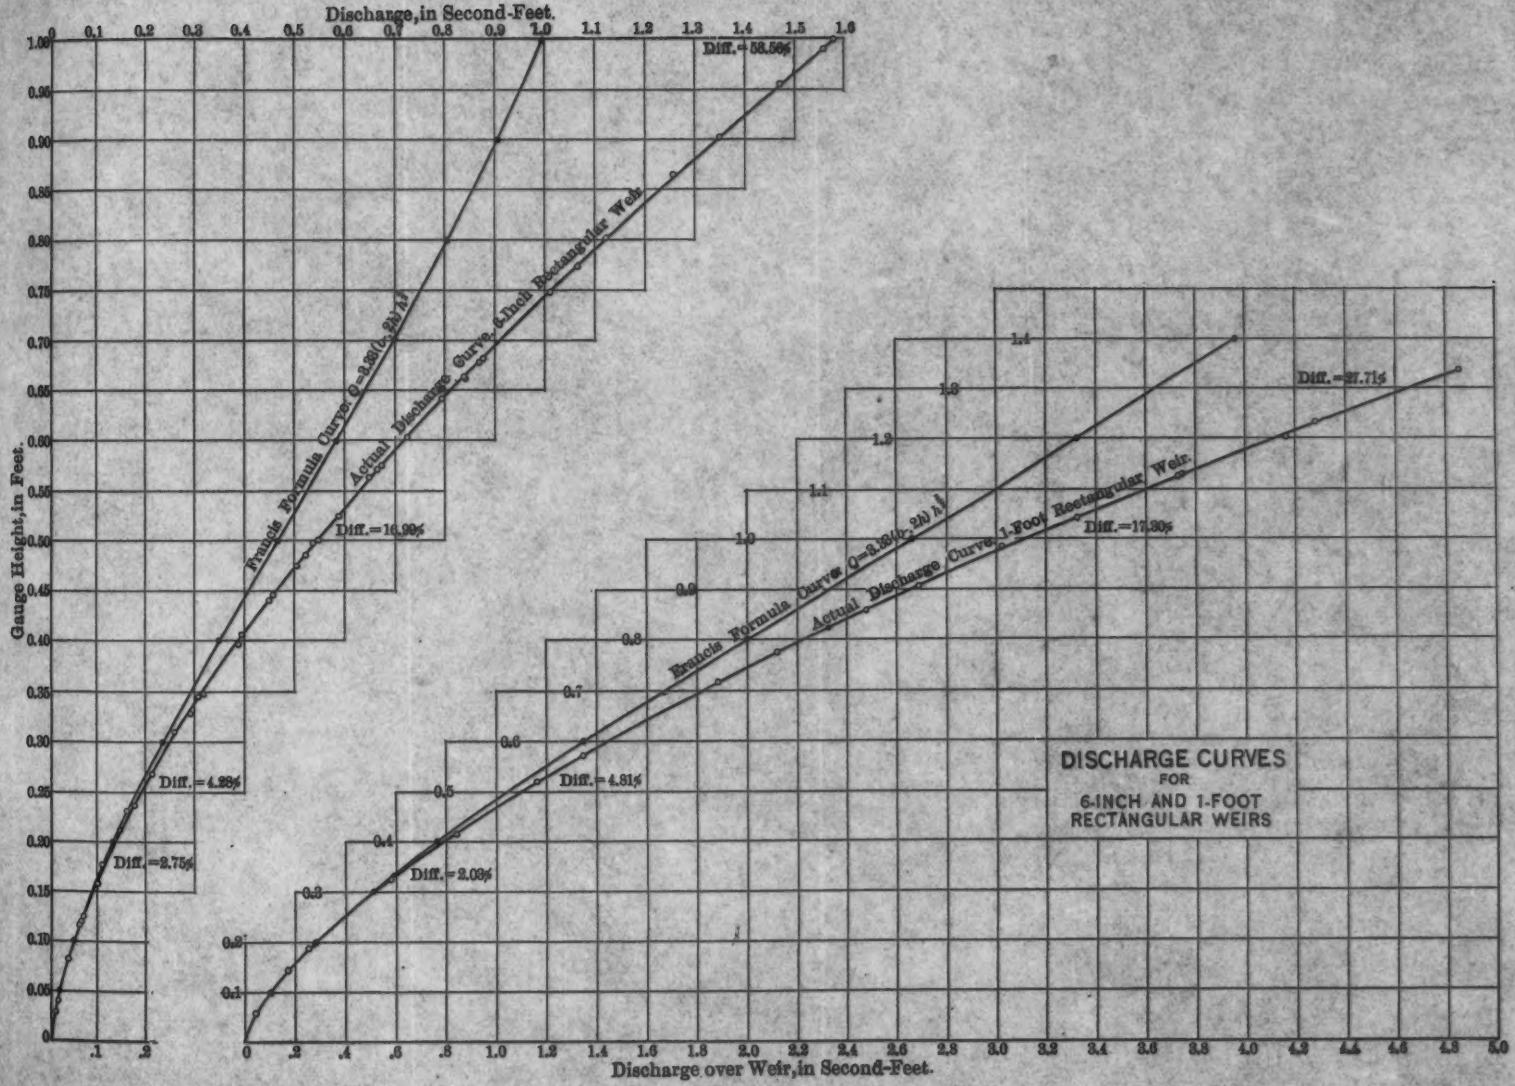
results show that the discharge curves of smaller weirs above a gauge height of one-third of the length of the crest are not a single section of a parabola, but a series of short sections of parabolas. This series of parabolas, however, seems to become less evident as the weirs increase in length, and it will be assumed that the logarithmic curve for the 3-ft. weir above a gauge height of 0.444 ft. is a good representative of the behavior of the larger weirs, and that it may be used with reasonable accuracy up to a depth equal to the length of the weir crest. Thus, in the use of Cippoletti weirs, the formula will be taken as correct up to gauge heights of one-third of the length of the crest. Above this point, for 3-ft. weirs and smaller, the tables given here-



with are recommended, and for weirs of greater length than 3 ft., for gauge heights of more than one-third of the length of the crest, the formula, $3.435\ lh^{1.526}$, should be used. In this manner accurate results are assured for all reasonable gauge heights.

Rectangular Weirs.—The experiments on sharp-crested rectangular weirs were made on the same sizes as were those of the Cippoletti type, namely, 6-in., 1-ft., 2-ft., and 3-ft. These were tested and calibrated at the same headings and in the same manner as the

Tables and plates similar to those for the Cippoletti weirs were prepared for this type. The Francis formula for rectangular weirs was used, and in each case the percentage of difference between the actual and Francis discharges was tabulated.

Table 10 gives the actual experimental data for each weir, together with the corresponding values of C in the formula, $Q = Clh^{\frac{3}{2}}$.

Tables 11 to 14 give the actual discharges corresponding to each $\frac{1}{100}$ ft. of gauge height, up to the limit of the experiments. The discharges, computed from the Francis formula, $Q = 3.333\ (l - 0.2h)\ h^{\frac{3}{2}}$, are tabulated for each $\frac{1}{10}$ ft. of gauge height, and the percentage of difference between this and the actual discharge is recorded as shown. It is seen that the formula is only fairly correct for very low heads.

Table 15 gives the value of C in the formula, $Q = Clh^{\frac{3}{2}}$, for the gauge heights of the various experiments, arranged in the order of their value. It will be observed that these do not show the marked variation characterizing the Cippoletti weirs. Table 16 gives the equations of the different parabolas, the gauge height at which the equations change, and the proportion that these gauge heights are of the lengths of crest. It may be seen that the equations do not have such a wide range as in the previous case, and that the three equations agree more closely with each other as the size of the weir increases, and finally

become one parabola in the 3-ft. weir. The breaks occur at about the same relative positions as in the Cippoletti weirs.

Table 17 gives the discharges of each weir for every $\frac{5}{100}$ ft. of gauge height, as far as the experiments were carried. This table shows that these results bear a very marked proportionality to the various lengths of crest.

Table 18 gives the values of C in the formula, $Q = Clh^{\frac{3}{2}}$, for each of the rectangular weirs, for each $\frac{5}{100}$ ft. of gauge height to 0.3 ft. head, and for each $\frac{1}{10}$ ft. thereafter. These values are based on the discharge, Q, as given in Tables 11 to 14. It will be seen that these values are also variable, both as to gauge height and length of weir crest, thus again indicating the fallacy of the original formula, $Q = Clh^{\frac{3}{2}}$. Table 19 contains the values of C of Table 18 for weirs up to 3 ft. in length and values as given by the late Hamilton Smith, M. Am. Soc. C. E., for the larger weirs. The tables and plates given herewith indicate that the Francis formula is not applicable, within reasonable limits of accuracy, for gauge heights of more than one-fourth of the length of the crest, and also that the errors increase with the size of the weir. The varying values of C indicate, as in the case of the Cippoletti weirs, that the exponent, $\frac{3}{2}$, in the formula, $Q = Clh^{\frac{3}{2}}$, is incorrect, and that if this formula is used it will be necessary to obtain a new value of C for each computation of discharge. Owing to the proportionality existing among the various values of discharge for the same gauge heights, and the tendency toward one equation

in the logarithmic curves, it is recommended that, for weirs more than 3 ft. in length, the equation, $3.242\ lh^{1.46}$ be used; for the smaller weirs, the tables give the desired results.

As an alternative, Table 19 contains the values of C for various gauge heights and sizes of weirs. By means of these values, discharge tables may be prepared for any size of weir up to 19 ft. in length.

In the foregoing experiments, no attempt has been made to develop a formula that will apply to all weirs, but merely to obtain ratings, as far as possible, and a formula or table that may be used with a reasonable degree of accuracy for large weirs with heads higher than previously tested. In this manner sufficiently accurate tables can be made and applied to irrigation work.

DISCUSSION

Mr. Pierce. C. H. PIERCE, ASSOC. M. AM. SOC. C. E. (by letter).—Certain comparisons of current-meter measurements with weir discharge by standard formulas, made by the writer and other members of the United States Geological Survey in Hawaii during 1911, verify the conclusions reached by the authors in their experiments on weir discharge.

The weirs were on irrigation ditches which offered excellent opportunities for velocity-area measurements, either in flumes or prismatic sections, within short distances of the weirs. The methods of making the velocity-area determinations were those regularly used by the engineers of the Geological Survey, as follows: The total cross-section having been divided into a number of section units, the mean velocity and area of each were measured; the product of the mean velocity and area of each individual section gave the discharge for that section, the total discharge being the sum of those of the individual sections. In most cases the sections were ½ ft. wide, and they always extended vertically from the water surface to the bottom of the channel. The mean velocity of the section was taken as one-half the sum of the means for the verticals on each edge of the section, the mean velocity for the vertical being one-half the sum of the velocities at two-tenths and eight-tenths of the depth. In this way, four determinations enter into the computation of velocity for any individual section.

The velocity measurements were made with small Price electric current meters which had been rated by the United States Bureau of Standards at Chevy Chase Lake, Maryland.

Meter discharge comparisons were made with a large number of weirs, but the measurements in all cases did not cover a sufficient range in stage for a complete rating. The results of comparisons with four typical weirs will be given. These weirs were all much larger than those used by the authors, and may be considered as types of the better class, being well constructed, and designed to meet the requirements of standard weir formulas. Two of the weirs were rectangular; one had a 10-ft. crest and the other nine panels, each 29 in. wide. The other two weirs were of the Cippoletti type, having crest widths of 17 and 25 ft., respectively.

The comparisons covered a range in stage equal to that reached by the weirs under ordinary working conditions.

10-Foot Rectangular Weir.—This was an especially well-constructed weir, with a long approach channel and good end contractions. Its crest and sides were formed by a sharp-edged steel plate set in concrete. The width of the approach channel at the crest level was 23 ft.;

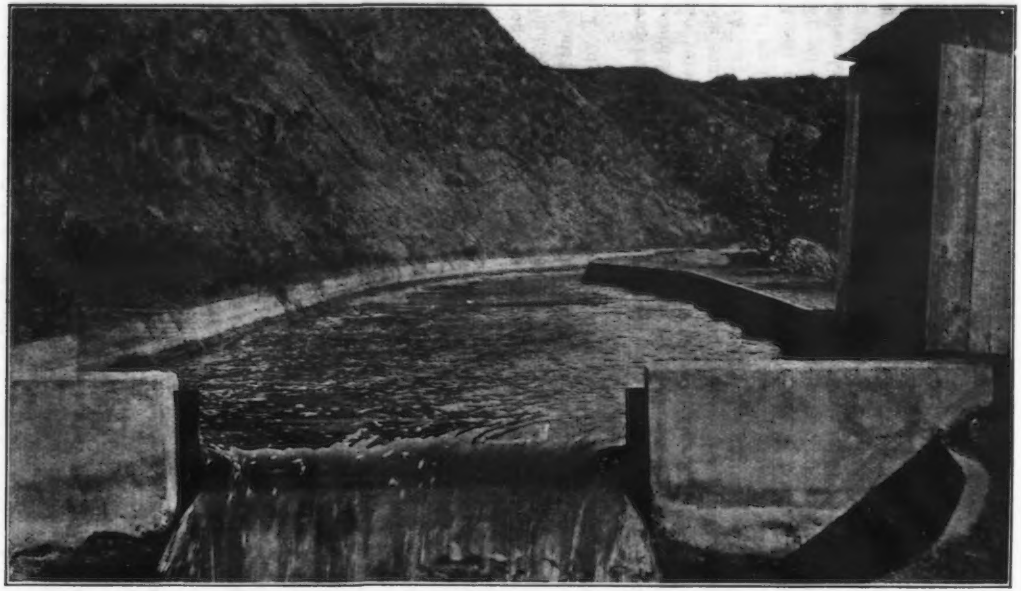

FIG. 4.—TEN-FOOT RECTANGULAR WEIR.

the depth below crest level was 5.3 ft., with side slopes of 1 to 4, giving an approach channel having an area of 115 sq. ft. below crest level. A continuous record of the head on the crest was obtained by an automatic clock register. Mr. Pierce.

Six discharge measurements, taken a short distance below the weir, give a rating curve which is very well defined between heads of 0.4 and 1.6 ft.

A comparison of the discharge curves obtained from the Francis formula,

$$Q = 3.33\ (b - 0.2h)\ h^{\frac{3}{2}}$$

and from current-meter measurements, is shown by Table 20 and by Fig. 5.

Nine-Panel Rectangular Weir.—Each of the nine panels in this weir had a crest width of 29 in. The crests and sides of the panels were formed by sharp-edged steel plates, but it is probable that, at the higher stages, the end contractions were not complete. The pool was approximately circular, and the weir panels were placed on a chord; water was delivered to the pool by a timber flume, 8 ft. wide and 6 ft. deep, the direction of flow of the water on entering the pool from the flume being nearly at right angles to the line of the weir. Here, also, a continuous record of the head on the crest was obtained with an automatic clock register.

Twelve discharge measurements in the flume above the pool give a rating curve which is very well defined between heads of 0.4 and 1.6 ft.

A comparison of the discharge curves obtained from the Francis formula and from current-meter measurements, is shown by Table 20 and by Fig. 5.

25-Foot Cippoletti Weir.—This weir had a sharp-edged crest and sides, formed by a steel plate set in concrete. The crest width was 25 ft. and the end inclinations were 1 to 4. Four current-meter measurements, taken in a lined section of the ditch a short distance above the weir, define a rating curve between heads of 0.4 and 0.9 ft. An automatic clock register gave a continuous record of the head on the weir.

A comparison of the discharge curves obtained from the Francis formula and from current-meter measurements is shown by Table 20 and by Fig. 6. The curves cross at about 0.55 ft. head, showing that, for the lower heads on this weir, the end inclinations should slightly exceed 1 to 4, in order to provide complete compensation for end contractions.* At the higher stages there was some velocity of approach at the center of the weir, diminishing to an inappreciable amount at the sides.

17-Foot Cippoletti Weir.—This was similar in construction to the 25-ft. weir, and likewise had a sharp-edged crest and sides, formed

1.12	0.02	67.1	68.5	+1.4	+2.1

by a steel plate set in concrete. The crest width was 17 ft. and the end inclinations were 1 to 4. Four current-meter measurements, taken in an unlined section of the ditch about ¼ mile above the weir, define a rating curve between heads of 0.3 and 1.2 ft. An automatic clock register provided a continuous record of the head on the weir.

A comparison of the discharge curves obtained from the Francis formula and from current-meter measurements is shown by Table 20 and by Fig. 6. The curves cross at about 0.8 ft., indicating that, for this weir, the end inclinations should somewhat exceed 1 to 4 for heads less than 0.8 ft., if the effect of end contraction is to be completely

Mr. Pierce.

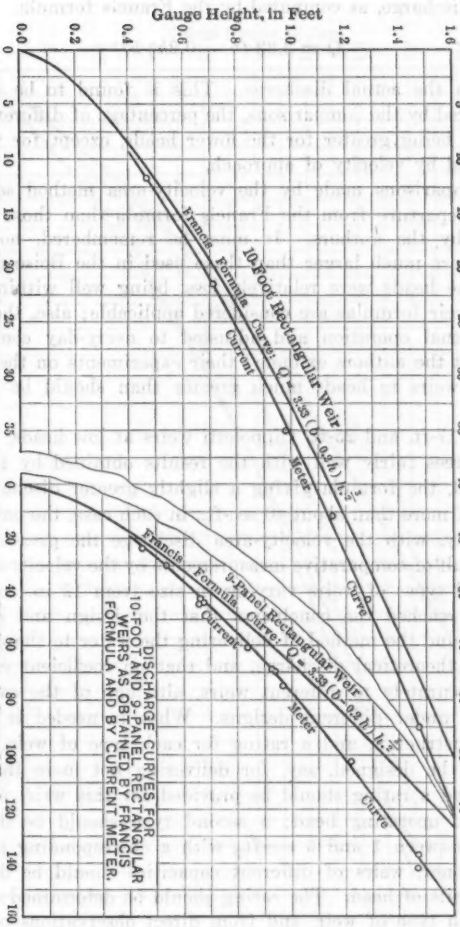

Fig. 5.

Mr. Pierce.

compensated. There was no appreciable velocity of approach at any stage.

General Conclusions.—The results of these comparisons agree with those obtained by the authors as far as showing that, for rectangular weirs, the discharge, as computed by the Francis formula,

$$Q = 3.33\ (b - 0.2h)\ h^{\frac{3}{2}},$$

is less than the actual discharge. This is found to be true for all stages covered by the comparisons, the percentage of difference varying, but usually being greater for the lower heads, except for weirs which were affected by velocity of approach.

The comparisons made by the velocity-area method seem to give a smaller departure from the Francis formula than those made volumetrically by the authors. It must be remembered, however, that the weirs were much larger than those used in the Boise experiments, and that the heads were relatively less, being well within the limits for which weir formulas are considered applicable; also, that the weirs were in actual operation and adjusted to every-day conditions. It appears that the authors extended their experiments on the small 6-in. and 12-in. weirs to heads much greater than should be allowed for those sizes.

For the 17-ft. and 25-ft. Cippoletti weirs at low heads, the Francis formula agrees fairly well with the results obtained by the velocity-area method, the formula giving a slightly greater discharge. For a discharge of more than about 40 sec-ft., in each case, the curves diverge quite rapidly, with the velocity-area discharge the greater.

As a result of comparative measurements by the velocity-area method with several types of weirs varying in size from 12 in. to 30 ft., the writer has reached the conclusion that the design and construction of the weir and the method of delivering the water to the crest greatly modify the theoretical discharge, and that no coefficient can be made to apply accurately to different weirs, although of the same type, if constructed under different designs. What is needed is a standard form of construction and a rating for each type of weir. A certain type should be designed, say, for delivering not more than 1 sec-ft. of water, and a rating should be provided for this weir, with definite limits as to operating head; a second type should be designed for quantities between 1 and 5 sec-ft., with a corresponding rating; and, in like manner, weirs of different capacities should be designed for specified limits of head. The rating should be determined experimentally for each type of weir, and from direct observations on that particular type. A set of standard plans and specifications for every rating would make it possible for different persons to construct weirs,

Mr. Pierce.

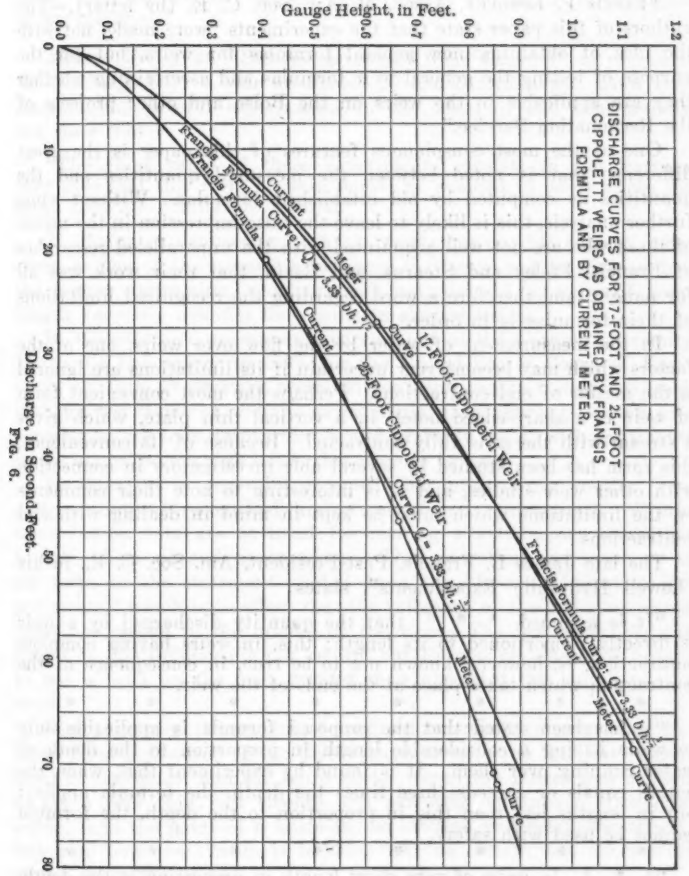

Fig. 6.

Mr. Pierce. and under different conditions, but according to the same design, and giving comparable results. The rating for any weir might be expressed algebraically, but probably not in the simple exponential equation of the Francis formula.

Mr. Longley. FRANCIS F. LONGLEY, ASSOC. M. AM. SOC. C. E. (by letter).—The authors of this paper state that the experiments "were made, not with the idea of obtaining new general formulas for weirs, but for the purpose of testing the general weir formulas and ascertaining whether they are applicable to the weirs on the Boise and other projects of the Reclamation Service."

One of the most conspicuous features of this paper is the great difference that is noted between the measured quantities and the quantities as computed by old established formulas. Without some further analysis, this is likely to leave the false impression in the minds of those who are not well acquainted with the unparalleled researches of Francis, Fteley and Stearns, and Bazin, that their work was all for naught, and therefore a word regarding the recognized limitations of their formulas is in order.

In the measurement of water by the flow over weirs, one of the factors which may become very uncertain if its limitations are ignored is the matter of end contractions. Perhaps the most convenient form of weir is a sharp-edged notch in a vertical thin plate, which gives a stream with the ends fully contracted. Because of its convenience, this form has been studied by several able investigators in connection with other weir studies, and it is interesting to note their comments on the limitations which must be kept in mind in dealing with end contractions.

The late James B. Francis, Past-President, Am. Soc. C. E., in his "Lowell Hydraulic Experiments", states:

"It is assumed * * * that the quantity discharged by a weir is directly proportioned to its length; this, in weirs having complete contraction, is, however, known not to be true, in consequence of the contraction which takes place at the ends of the weir.

* * * * * * *

"It has been stated that the proposed formula is applicable only to weirs having a considerable length in proportion to the depth of water running over them. It is found by experiment that, when the length equals or exceeds three times the depth, the formula applies; but in lengths less than this in proportion to the depth, the formula cannot be used with safety.

* * * * * * * *

"* * * In weirs of very short length in proportion to the depth, the effect of the end contraction * * * influences the discharge to a certain distance, A, from the end of a weir; if the whole length of the weir is greater than 2 A, the effect of the end contraction is independent of the length; but if the length is less than 2 A, the

whole breadth of the stream is affected in its flow by the end contractions, and, consequently, the proposed formula would not apply. Mr. Longley.

"In practical applications, this will seldom be an inconvenience, as it is nearly always practicable so to proportion the weir that the length may not be less than three times the depth upon it; if, however, there is no end contraction, the proportion of the length to the depth is not material."

Messrs. Fteley and Stearns developed their formula* to represent the discharge over a weir unaffected by end contractions. They conducted some careful experiments on the effect of end contractions, but state that:

"The chief value of these experiments consists in the warning they give that this form of weir should be avoided in cases where the most accurate results are desired."

M. Bazin, in connection with his researches on this subject, mentions, as one of the uncertain elements that must not be disregarded, the lateral contraction, which, though unimportant in weirs of great length, seriously modifies the results in shorter weirs.

In the extensive experiments carried out at the Cornell University Hydraulic Laboratory in 1899, for the United States Board of Engineers on Deep Waterways, weirs without end contractions were used, both for the standard and the experimental measurements, owing presumably to the uncertainty that would probably result with contracted weirs, at the rather high heads that were to be used.

In short, it is generally accepted that uncertainty results from disregarding the recognized limitations of end contractions. Within these limits, data are at hand for making a satisfactory correction for the effect of end contractions. The controlling condition is as set forth in the statement quoted from the "Lowell Hydraulic Experiments," which is in effect that the influence of the end contraction must not extend to the middle of the weir. The law governing the extent of this influence is not known, but Francis considered it unsafe to use a head on the weir greater than one-third the length of the crest.

Disturbance of stream lines sometimes extends to a surprising distance from the source of the disturbance, as note the familiar experiment of the faucet and the knife blade. Open the faucet just enough to get a very thin, but smooth and perfectly continuous stream of water; hold the point of a knife in the stream, well below the faucet, and note how the stream is broken, not only below, but for several inches above the knife.

The formula of Francis, and also that of Cippoletti, which is derived directly from it, are therefore admittedly unsuited for the com-

* *Transactions*, Am. Soc. C. E., Vol. XII, p. 111.

Mr. Longley.

putation of the discharge of weirs with end contractions when the head on the weir is greater than about one-third of the crest.

The authors, however, have recorded a comparison of their results with the results of computations by the Francis and Cippoletti formulas without regard for or comment on this limitation, although the maximum head of each separate series of their observations lies far above this limit.

TABLE 21.

	Length of weir, in feet.	Maximum head on weir, in feet.	Ratio of maximum head to length.
Cippoletti weir	0.5	0.95	1.89
	1.0	1.98	1.98
	2.0	1.99	0.99
	3.0	2.41	0.80

	1.0	1.34	1.34
	2.0	1.57	0.79
	3.0	2.06	0.69
Safe limiting ratio, as stated by Francis			0.33

An examination of the data of Francis, Fteley and Stearns, and Flinn and Dyer,* who experimented on the Cippoletti weir, shows that they all keep substantially within this approximate limit.

It is not surprising, therefore, that computations based on the Francis and Cippoletti formulas do not check the observed weir discharges. There are few or no precise data regarding the effect of end contractions on the discharge, when the weir is so short that the influences of the two end contractions overlap. A good idea of this effect may be obtained, however, from an analysis of the authors' data, on the assumption that their short weirs approximated the conditions of rectangular orifices.

Merriman gives the following formula for the rectangular orifice:

$$q = 8.02\, cbd\sqrt{h}$$

in which c is the coefficient of discharge,
b is the width,
d is the depth,
and h is the head on the center of the orifice.

Certain experiments by both Francis and Fteley and Stearns give the ratio of the depth of flow measured directly over the edge of a weir, to the depth measured above the origin of the surface curve, as approximately 0.86, and the depth of the orifice, therefore, may be taken as 0.86 of the observed head.

* *Transactions*, Am. Soc. C. E. Vol. XXXII, p. 9.

Mr. Longley.

From this, for example, compute a few of the quantities for the 12-in. rectangular weir. An examination of Fanning's tables shows that the coefficient of discharge for the conditions assumed does not vary much from 0.61.

TABLE 22.

Number of run.	Average gauge height, in feet = h^1.	Assumed depth of orifice, $D = 0.86\,h^1$.	C.	Head on center of orifice, $h = h^1 - \frac{d}{2}$.	Quantity, in Cubic Feet per Second.	
					By orifice formula.	By measurement.
1.....	1.338	1.150	0.61	0.763	4.91	4.780
20.....	1.233	1.060	0.61	0.703	4.34	4.292
3.....	1.205	1.037	0.61	0.687	4.20	4.177
4.....	1.130	0.972	0.61	0.644	3.81	3.757
2.....	1.126	0.968	0.61	0.642	3.79	3.743
5.....	1.044	0.898	0.61	0.595	3.39	3.332
6.....	0.982	0.845	0.61	0.559	3.09	3.025
7.....	0.909	0.782	0.61	0.518	2.75	2.695

Obviously, this computation comes a great deal closer to the measured discharge than does the Francis formula so far outside of its recognized limiting conditions.

The formulas the authors have deduced, and the rating curves they have prepared, are of value in computing the discharge of weirs identical with those used in the experiments; but the very diversity of coefficients and exponents which they have set forth in their twenty-one formulas, emphasizes the impossibility of their general application.

The points which are important to keep in mind are that the exhaustive work of Francis on weir measurement was corroborated in a substantial degree by the studies of Fteley and Stearns, and later by the even more extensive researches of Bazin; that the formulas deduced by them have certain recognized limitations, and that, having proper regard for these limitations, the reliability of the formulas cannot be questioned.

Messrs. Steward and Longwell.

W. G. Steward, Esq., and J. S. Longwell, Jun. Am. Soc. C. E. (by letter).—In his discussion Mr. Pierce brings out the point that the results of his experiments agree with those of the writers in that the actual discharge is greater than that given by the Francis formula, but that the velocity-area results show a smaller deviation than the volumetric tests. It should be remembered that Mr. Pierce's experiments were made on very large weirs, and that the departure of the actual discharge from the formula discharge occurs at gauge heights within the limits of accuracy, as generally taken, for the formulas, that is, for depths on the weir of less than one-third of the crest length. The results presented by the writers agree closely with the formulas

Messrs. Steward and Longwell.

for gauge heights above the limits of the formula in some cases, and practically to the limits in all cases. The percentages of difference between the writers' results and the formula at gauge heights equal to one-third of the length of the crest are shown in Table 23.

TABLE 23.

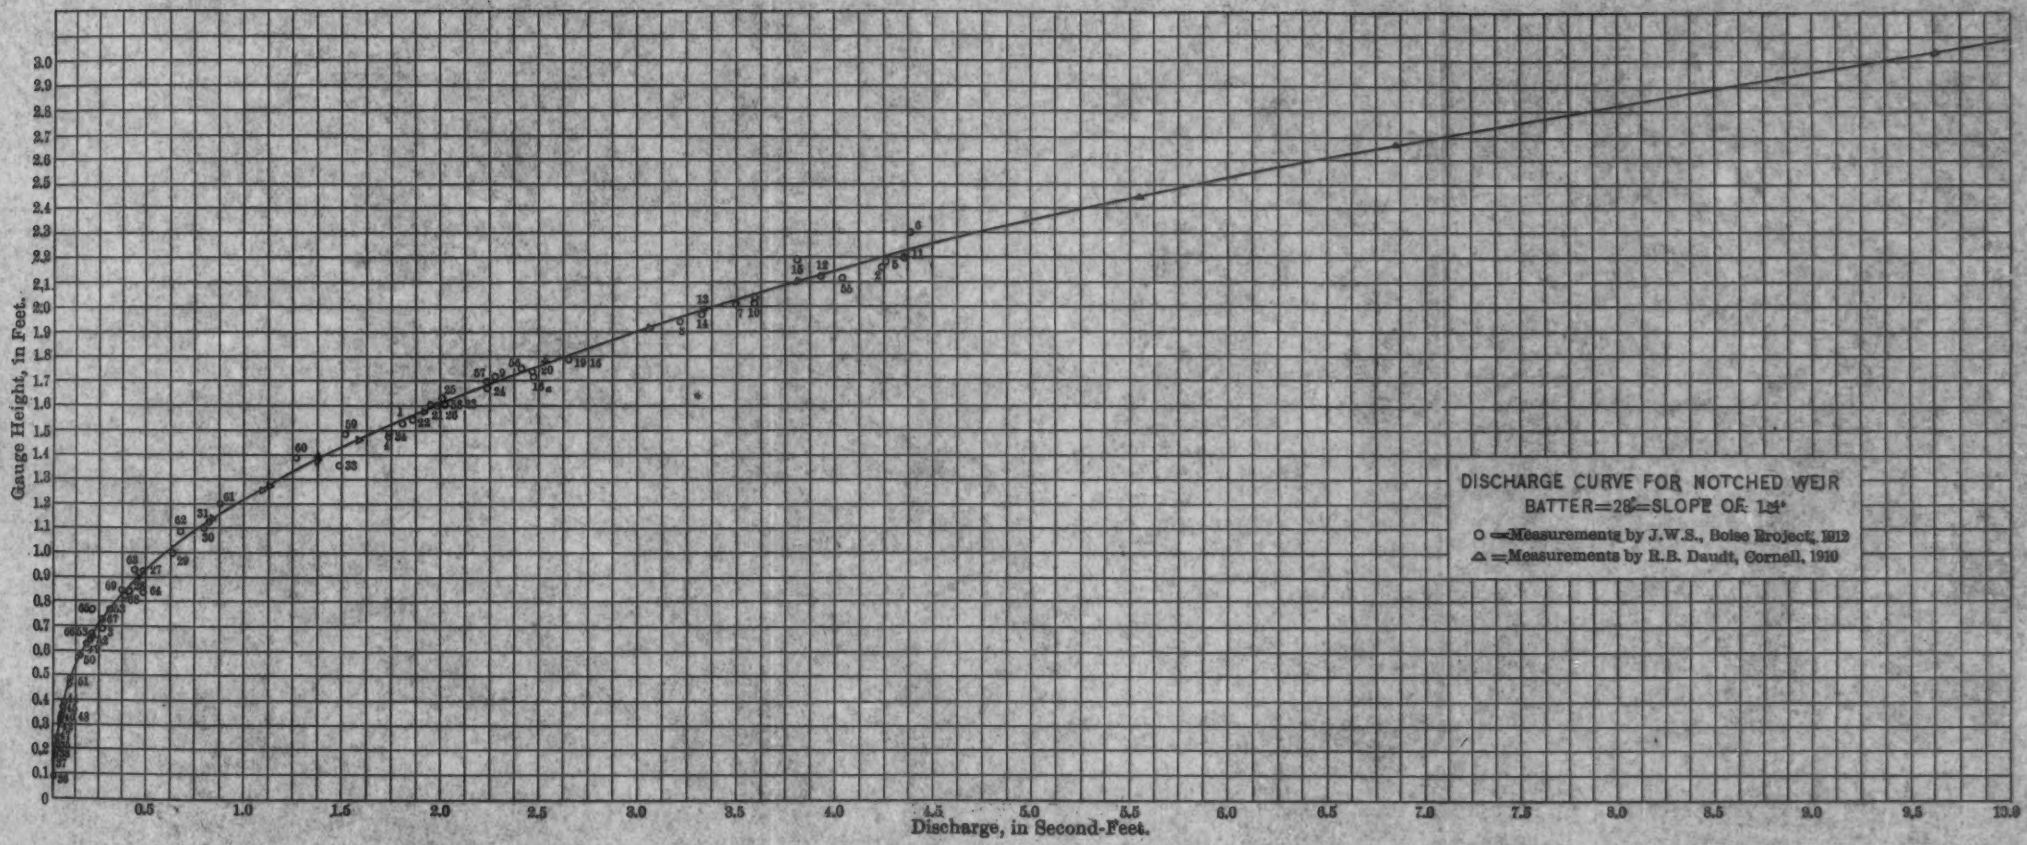
Size.	Percentage that the Actual Discharge is in Excess of the Formula at One-third of the Crest Length.	
	Cippoletti weirs.	Rectangular weirs.
6 in.	0	2.75
1 ft.	0	2.08
2 ft.	0.95	2.64
3 ft.	1.98	4.40

It will be noted that these differences are far below those given by Mr. Pierce for points of lower proportional gauge heights.

In the tabulation of the results of the writers' experiments, the discharge curves of the Francis formula and the Cippoletti formula have been used for a comparison of results. No attempt was made to show any discrepancy in these formulas; they were used for making a comparison, up to the limits of the formulas, and to show that, for gauge heights of more than one-third of the length of crest, the formula, as stated by Francis, does not apply. It is quite a common belief that the formulas are correct to almost any depth on the weir, in spite of the statement of Francis to the contrary.

The accuracy of the formulas within the stated limits was brought out quite clearly by the discharge curves, proving that, as long as the depth of water is less than one-third of the crest length, the formulas will give very accurate results.

No attempt was made to develop any formula to apply for all depths, but the results of the actual tests were given and the resulting equations of the discharge curves tabulated. It is to be hoped that some general law of flow for all depths may be worked out by some one.



The following conclusions and formulas are presented for consideration. They are based on:

(*a*) The series of weir experiments conducted by the writers on the Boise Project, Idaho, in 1911.

(*b*) The experiments on notched weirs conducted by Mr. J. W. Strohecker, on the Boise Project, in 1912. (See Plate XL and Table 24.)

(*c*) A series of experiments on notched weirs conducted by Ralph B. Daudt, Assoc. M. Am. Soc. C. E. (See *The Cornell Civil Engineer*, March, 1912; see also Plate XL and Table 24.

CONCLUSIONS.

1.—The discharge of a sharp-crested, contracted, rectangular weir, with any given base and gauge height, added to the discharge of a 28° notched weir, with the same gauge height, gives a discharge equal to that of a Cippoletti weir with the same base and gauge height. This is shown on Plate XLI where the combined discharge of a notched weir and rectangular weirs for various lengths of base are plotted, together with the discharges of Cippoletti weirs of equal bases.

2.—The relation of discharges of weirs of similar shapes, within the limits of experiments conducted, is the $\frac{5}{2}$ power of the proportion of bases at the same proportional gauge heights.

Messrs. Steward and Longwell.

FORMULAS.

Let Q_1 = Discharge of a calibrated weir at head, h_1;
Q_2 = Discharge of another weir at head, h_2;
b_1 = Length of crest of calibrated weir;
b_2 = Length of crest of another weir the discharge of which is required;
h_1 = Head on calibrated weir;
h_2 = Head on weir having a base = b_2.

This head is taken so that

$h_2 = \frac{b_2}{b_1} \times h_1$; that is, $b_1 : h_1 :: b_2 : h_2$, as shown by Fig. 7.

Then Q_1 (at h_1) $\times \left(\frac{b_2}{b_1}\right)^{\frac{5}{2}} = Q_2$ (at h_2) in which $\left(\frac{b_2}{b_1}\right)^{\frac{5}{2}}$ is a constant.

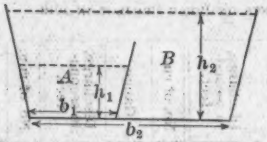

FIG. 7.

Which is derived as follows:

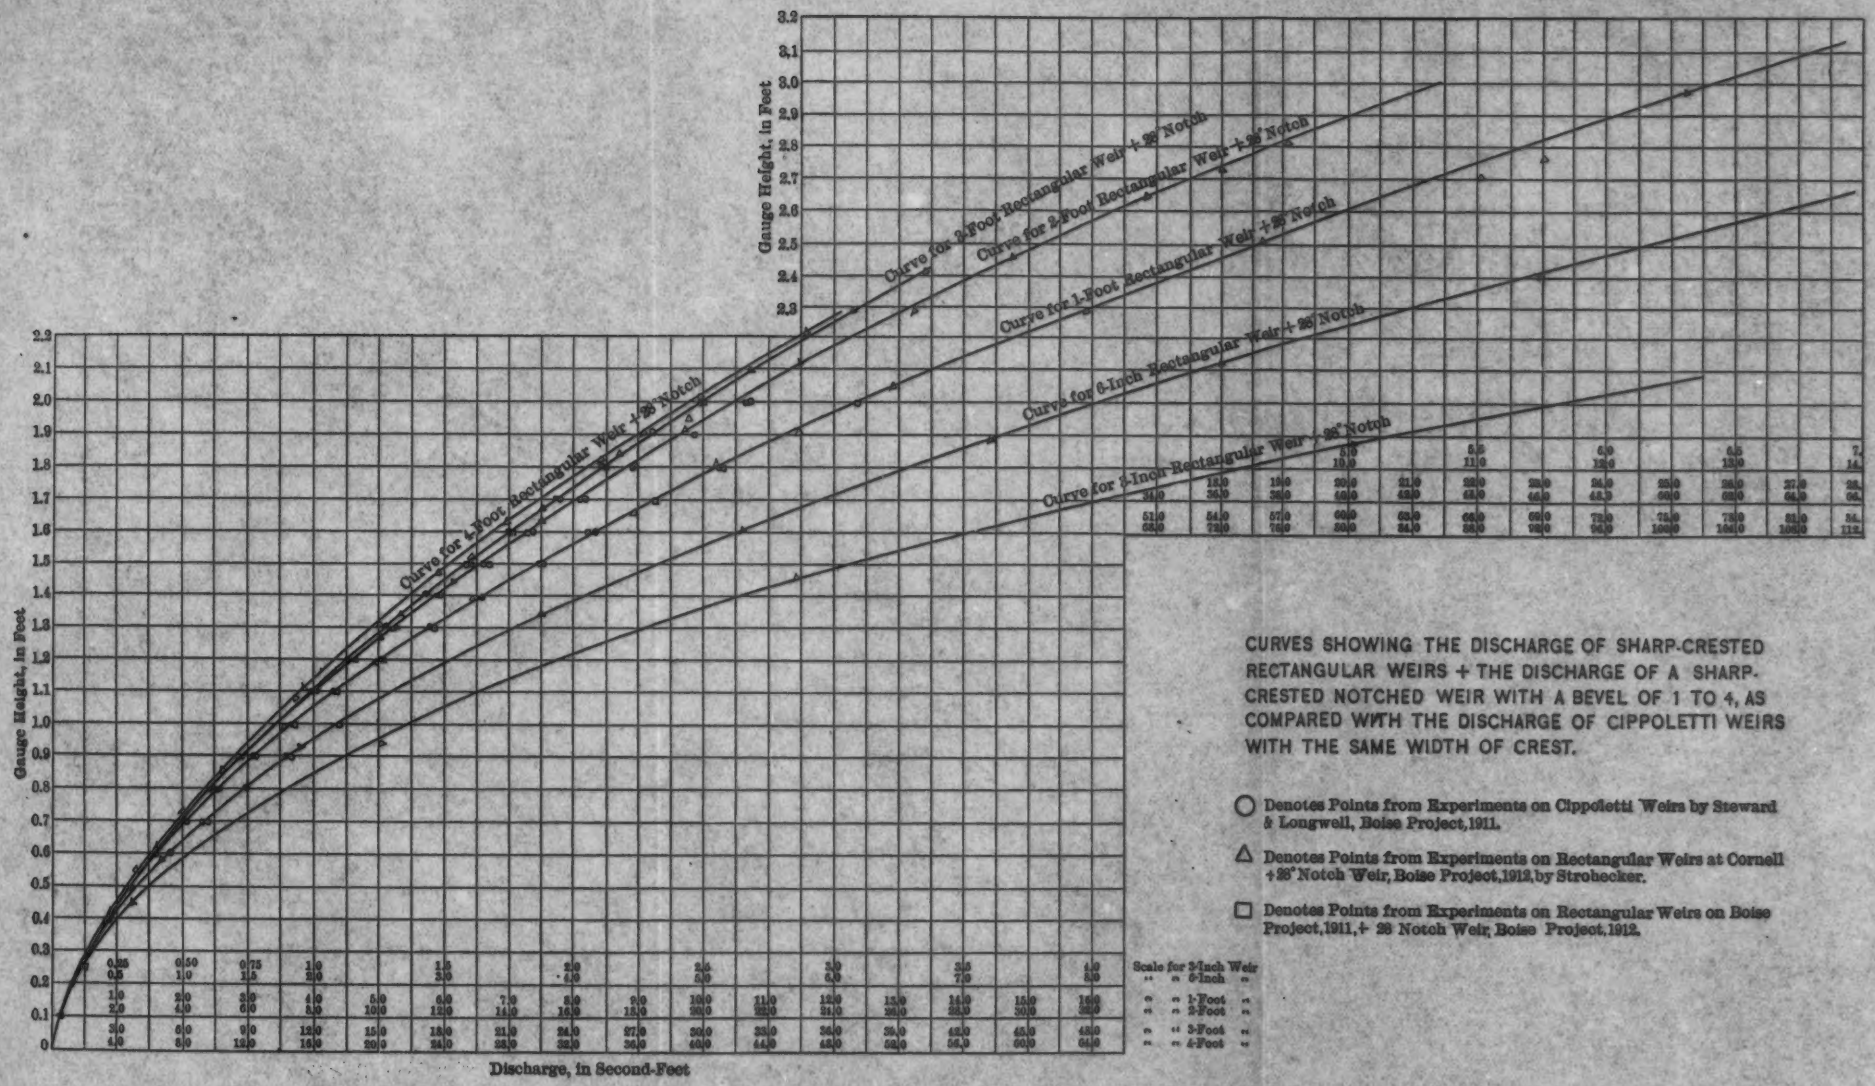
$Q = cbh^{\frac{3}{2}}$, the theoretical formula for discharge of weirs.....(1)

$Q_1 = ch_1 (h_1)^{\frac{3}{2}}$, the discharge of weir A at h_1 (at gauge height).(2)

$Q_2 = ch_2 (h_2)^{\frac{3}{2}}$, the discharge of weir B at h_2 (gauge height as specified above).....(3)

As assumed, $h_2 = \frac{b_2}{b_1} \times h_1$.....(4)

$Q_2 = cb_2 \frac{b_2}{b_1} h_1^{\frac{3}{2}}$. Substituting in Equation 3 the value for h_2 in Equation 4.....(5)



$Q_1 \times cb_2 \left(\frac{b_2}{b_1} h_1\right)^{\frac{3}{2}} = Q_2 \times cb_1 (h_1)^{\frac{3}{2}}$, multiplying Equations 2 and 5.....(6)

$Q_1 \times \frac{b_2 \times \left(\frac{b_2}{b_1}\right)^{\frac{3}{2}}}{b_1} = Q_2$. Dividing by $cb_1 (h_1)^{\frac{3}{2}}$ and eliminating c and h_1.....(7)

$Q_1 \times \left(\frac{b_2}{b_1}\right)^{\frac{5}{2}} = Q_2$.....(8)

(Conditions being specified above.)

Therefore, having the correct calibration of a weir with a given base and to any given height, the discharge of a weir of similar shape

CURVES SHOWING THE DISCHARGE OF SHARP-CRESTED RECTANGULAR WEIRS + THE DISCHARGE OF A SHARP-CRESTED NOTCHED WEIR WITH A BEVEL OF 1 TO 4, AS COMPARED WITH THE DISCHARGE OF CIPPOLETTI WEIRS WITH THE SAME WIDTH OF CREST.

AMERICAN SOCIETY OF CIVIL ENGINEERS

INSTITUTED 1852

TRANSACTIONS

Paper No. 1265

SOME EXPERIMENTS WITH MORTARS AND CONCRETES MIXED WITH ASPHALTIC OILS.*

By Messrs. Arthur Taylor and Thomas Sanborn.

With Discussion by Messrs. Logan Waller Page, William J. Boucher, A. T. Goldbeck, and Arthur Taylor.

Object of Tests.

Recently, the attention of engineers has been called to some tests of oil-mixed mortar and concretes,† by Logan Waller Page, M. Am. Soc. C. E., which are held to indicate that oil will mix uniformly with concrete or cement mortar, forming what may be termed an emulsion, and that concretes and mortars, thus mixed with certain percentages of oil, are "absolutely water-tight under pressures as high as 40 lb. per sq. in." and, "under low pressures, both are waterproof."

In order to determine whether these results would hold true for concretes mixed with western (asphaltic) oils, the writers began a series of tests in February, 1912, laying special emphasis on the question of permeability under pressure.

Conclusions.

1.—The following experiments, although incomplete and inconclusive, indicate that, with western (asphaltic) oils, the facts stated by Mr. Page in regard to strength and water-tightness of oil-mixed concretes

* Presented at the meeting of April 16th, 1913.

† "Some of the Properties of Oil-Mixed Portland Cement Mortar and Concrete." *Transactions*, Am. Soc. C. E., Vol. LXXIV, p. 255.

and mortars are open to serious question, and should not be accepted in practice until further experiments have demonstrated their truth more fully.

2.—Concrete and cement mortars with 5, 10, and 15% of oil, by weight of cement, were found by these tests to be more permeable than concrete and cement mortars without oil, when subjected to pressures of 20, 40, and 60 lb. per sq. in.

3.—The strength of mortars was found to be affected seriously by the addition of as low as 5% of oil.

4.—The absorption of water by mortars under low heads was found to be but little decreased by the addition of light oils, and increased with heavy oils.

Description of Tests.

Great care was taken to secure uniformity of qualities and quantities in all the experiments.

In the permeability tests, three specimens of each mixture were tested; and in the tensile and compressive tests, either three or six specimens of each kind were used.

The quantity of oil used in each case was determined as a percentage, by weight, of the quantity of cement. It was found, as stated by Mr. Page, that the western (asphaltic) oils will also readily emulsify with wet cement, cement mortar, or concrete, and can become mixed so thoroughly in the mass that on examination with a reading glass no unassimilated globules of oil are visible. The mixture has a rich glossy appearance, the oil, apparently, has spread itself out in a thin film enveloping each particle of sand and rock. Even a very thick oil—one which is so viscous that when cold it cannot be poured—will mix and disappear in concrete or mortar when it is heated and mixed with hot aggregates. The amount of mixing was found to be a principal factor in determining whether or not the oil is incorporated completely and uniformly with the other ingredients of a mortar or concrete.

The consistency of the concrete or mortar also governs the degree of emulsification; the wetter the mixture the better the oil emulsifies.

Materials.

The oils used were commercial products having trade names as indicated. Their mechanical analysis is shown in Table 1.

TABLE 1.—MECHANICAL ANALYSIS OF OILS.

Name.	Baumé gravity.	Flash point.	Burns.	Asphaltum.

Liquid Asphalt	0°.9	.....	.....	92%

Portland cement complying with standard specifications, clean river sand, and two kinds of river gravel were used for the concretes.

One gravel was graded from 1 in. to ¼ in., the other from ¼ in. down. The percentages of voids were: Sand, 33; fine gravel, 37½; coarse gravel, 49. Portland cement and standard sand were used in all mortars. The proportions used for concrete were for an aggregate of maximum density. The mechanical analysis of the aggregate is shown in Table 2.

METHODS OF MIXING.

Concretes.—The proportions of aggregate are by volumes, loose. The quantity of oil is given as a percentage of the weight of the cement. The quantity of water giving a quaky mixture was determined, and used thereafter.

All mixing was done in a box having an approximate volume of 2 cu. ft.

The sand, fine gravel, and cement were mixed in the usual way, and the oil was poured on the wet mass and thoroughly mixed in until it had completely disappeared, as shown by uniform color and absence of oil spots. To this mixture the previously soaked coarse gravel was

then added, and the whole was mixed again. In order to insure uniformity of mixing, the time of each separate operation was fixed and thereafter followed according to schedule.

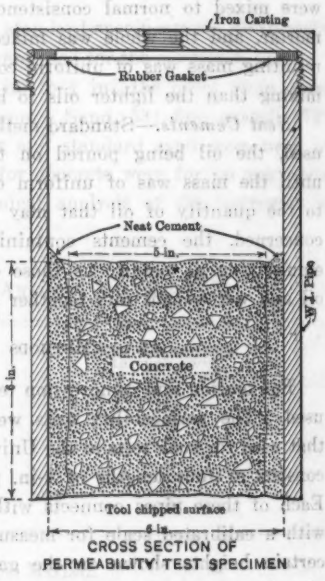
The most viscous oils, namely, liquid asphalt and road oils, required a larger percentage of water (for the same consistency) than the mixtures in which the lighter oils were used.

Mortars.—The proportioning of mortars was done by weight. Three parts by weight of standard (Ottawa) sand and one part of cement were mixed to normal consistency; the oil was then poured on the mortar, and the whole was mixed until the oil disappeared and the resulting mass was of uniform color. The viscous oils required more mixing than the lighter oils to bring about this condition.

Neat Cements.—Standard methods of mixing the cement paste were used, the oil being poured on the wet paste and mixed as before until the mass was of uniform color. Apparently there is no limit to the quantity of oil that may be used, as far as emulsification is concerned, the cements containing the largest percentages of oil emulsifying as readily as those containing smaller quantities. The oil and wet cement mix together as perfectly as two grades of oil.

Methods of Testing.

For tension and compression tests, the usual standard methods were used. The permeability tests were made with apparatus similar to that used for such tests at the University of Wisconsin. The apparatus consists of four lengths of ¾-in. pipe tapped into a horizontal main. Each of these pipes connects with an 18-in., glass water-gauge fitted with a calibrated scale for measuring the quantity of water between certain heights shown on the gauge. On the end of each vertical pipe there is a union for connecting the specimen holder. These holders are of 6-in., threaded, wrought-iron pipe, 11 in. long, fitted with cast-iron caps which screw down on a rubber gasket, thus making a water-tight joint. A ¾-in. pipe from this cap connects with the union previously mentioned.



After the specimens are connected up, water is let in from the top, through a valve on the horizontal pipe, until it stands at a certain height on the gauge glass. The pressure is applied by compressed air, which is kept constant by two supply tanks and is gauged at its entrance to the apparatus.

A valve is placed between each specimen and the horizontal main, so that a leaky or broken specimen can be shut off without disturbing the test of the other specimens.

The permeability specimens were made in the holders previously mentioned, Fig. 1. The concrete specimens were 6 in., and the mortar specimens 3 in., thick. Before the concrete or mortars were put in place, a ½-in. lining of neat cement was plastered on the inside of the pipe, which insured a perfectly tight bond.

All specimens stood dry for 24 hours after mixing; water was then put on top of the specimen until the test was made.

The top and bottom surfaces of each specimen, before being attached to the testing machine, were chipped uniformly by hand tools, in order to provide for each specimen a surface as nearly uniform as possible.

CROSS SECTION OF PERMEABILITY TEST SPECIMEN

FIG. 1.

RESULTS OF TESTS.

Time of Set.—It was found that, with oil-mixed specimens, the time of setting was retarded, in both the initial and final set. These tests were made with the Vicat needle according to the Standard Specifications. The oil used was an average middle-grade oil. Table 3 gives the time of initial and final set for various percentages of oil.

TABLE 3.—TIME OF INITIAL AND FINAL SET.

Percentages of oil.	Initial set, in hours.	Final set, in hours.
0	4.	5.20
5	5.20	6.
10	5.80	7.30
15	6.80	9.50
25	12.20	36.

These results confirm the observations of Mr. Page.* A theory may be advanced that the time of setting is retarded and the strength is decreased, due to the fact that the oil film separates particles of cement from each other, so that there is not the complete intimate association of every particle of cement, as there is in a mixture without oil.

Tensile Strength.—Either three or six specimens of each kind were broken. All tests were made on specimens set 24 hours in moist air, the remainder of the time under water. Table 4 gives the strength and relative values of specimens having various percentages of oil.

Road No. 6, 10.....	146	45.0	184	42.8
Liquid Asphalt, 10..	141	43.5	220	51.2

Crushing Strength.—All compressive specimens were made of 1:3 mortar in 3-in. cubes. Specimens stood 24 hours in moist air; the remainder of the time before testing they were under water. All tests were made on an electrically-driven machine, the load being applied slowly. In every test the specimens failed regularly, the sides sloughing off uniformly. In Table 5, are given the compressive strengths and relative values of oil-mixed specimens compared with plain or no-oil mortar.

Absorption.—Mortars containing percentages of middle-grade oil up to 25 were slightly less absorptive than plain mortars, the absorption decreasing with the increase in the percentage of oil. The specimens containing heavier oils showed an increase in absorption.

* *Loc. cit.*, p. 258.

It was found that at the end of 24 hours the mortars had reached just about complete absorption. At the end of 72 hours the weight had only increased a negligible fraction over that at the end of 24 hours.

Permeability Tests.—The permeability tests were made with the specimens heretofore described; at the end of 20 days with concrete, and 10 days with mortar. Three of each were tested, and the average value was taken, except in some cases when the specimens proved to be faulty. Water pressure was applied on concrete for periods of 4 hours each under pressures of 20, 40, and 60 lb. per sq. in., and finally a 4-day test under 15 lb. per sq. in. was run. With mortar specimens, 10- and 20-lb. pressures were applied for 4 hours under each pressure. Tables 7, 8, and 9 give the number of cubic centimeters of water passed through the specimens under the various pressures.

SUMMARY OF CONCLUSIONS.

The following conclusions are drawn from the results of these investigations with asphaltic oils:

1.—Oil-mixed concrete containing 5, 10, or 15% of oil, by weight of cement, is more permeable under pressures from 20 to 60 lb. per sq. in. than concrete without the incorporated oil, and oil-mixed mortar containing 10% of oil is more permeable than plain mortar under pressures of 10 and 20 lb. per sq. in.

2.—Oil-mixed mortars containing percentages of oil up to 25 show slightly less absorption of water than plain mortar, except that with the most viscous oils the mortar becomes more absorptive, and absorption is not an index of the permeability. The absorption decreases with the increase in the quantity of oil.

3.—The tensile strength of oil-mixed mortar is decreased considerably below that of plain mortar. The strength decreases with the increase in the quantity of oil.

4.—The compressive strength of oil-mixed mortars follows lines similar to those of the tensile strength, but with a greater decrease in strength with the quantity of oil.

5.—The strength decreases with the viscosity of the oils, and with the most viscous oils it requires considerably more water to keep a mixture at normal consistency than is required in the fluid oil mixtures.

6.—The relative decrease in strength with the increase in the quantity of oil in mortars is less in 50 than in 28 days.

The writers wish to acknowledge their indebtedness to Professor C. B. Wing, M. Am. Soc. C. E., for his aid and advice in the work, and to the Standard Oil Company of San Francisco for its courtesy in furnishing the oil samples.

DISCUSSION

Mr. Page.

LOGAN WALLER PAGE, M. AM. SOC. C. E. (by letter).—Since reporting the results of his oil-concrete investigations* in September, 1911, additional data have been obtained by the writer which will be of interest at the present time in showing the effect of different types of oils on the strength of oil-mixed concrete and mortar at the age of 2 years. These results, some of which have already been reported at an early age, are given in Tables 10, 11, and 12.

Referring first to Table 10, Tensile Strengths, it will be noted that Oils Nos. 4923, 4981, and 5053 have no deteriorating effect on the tensile strength, at the end of 1 year in the case of No. 5053, or at the end of 2 years in the cases of Nos. 4923 and 4981. Oil No. 5856 more nearly resembles those used by Messrs. Taylor and Sanborn than any of the others, and the effect on the strength is not greatly different from that reported by them. The few tests made with Oil No. 6536, at the end of 28 days, show an increase in the tensile strength with the addition of this oil. It would seem from these results, combined with those of Messrs. Taylor and Sanborn, that some types of oils might be seriously detrimental to the strength of mortars, and, therefore, that their selection should be made from the results of tests of mortar mixed with the oil under consideration.

* *Transactions*, Am. Soc. C. E., Vol. LXXIV, p. 255.

Mr. Page. The results on crushing strength given in Table 11, and extending up to a period of 2 years, show, in general, that oil-mixed concrete gains strength with age, a pretty strong indication that, with the small quantity of oil incorporated, the concrete is not likely to suffer future deterioration. The ratio of the strengths, however, is not the same with different kinds of oils. When 10% of Oil No. 4981 is mixed with concrete, the strength is cut down to about one-half of that of the plain mixture at all periods up to 2 years. Oil No. 4923, however, does not have this severe effect in decreasing the strength; and, in general, with a very dusty crushed gneiss aggregate, the crushing strength with 10% of oil is about 75% of that of the plain concrete, and with 5% of oil is about 85% of the plain concrete strength. With a well-graded, clean, gravel aggregate, excellent results were obtained with 2½, 5, and 10% of Oil No. 4923, the 5% mixture having 93% and the 10% mixture 90% of the strength of plain concrete. The results obtained at the end of 1 year, on the compressive strength of mortar mixed with five different kinds of oils, and reported in 1911, do not show the serious decrease in strength obtained by Messrs. Taylor and Sanborn with the California asphaltic oils.

Regarding the question of absorption, it is to be regretted that the authors have not explained thoroughly their absorption tests, particularly with regard to the preliminary treatment of their specimens in securing complete dryness. It has been the writer's experience, and likewise that of other investigators, that a 1:3 mortar which will absorb only 2½% of its weight during an immersion of 24 hours, is a rare curiosity. With all the oils that the writer has tried for absorption, he has obtained results the opposite of those reported by Messrs. Taylor and Sanborn. It has been his experience that the heavy oils are more effective as damp-proofers than the lighter oils, when properly mixed. The difficulty of mixing an oil with concrete increases with its specific viscosity, and it is unwise to use an oil with a higher specific viscosity than 45.

The authors' permeability results are not a surprise to the writer, considering the early age at which the tests were made. As time goes on, the oil-mixed specimens, under high pressures, as well as the plain specimens, become impermeable, but, at early periods, oil-mixed concrete, under high pressure, is no more impermeable than plain concrete, although the writer has succeeded, even at early periods, in making the oil mixture of concrete more impermeable than the plain mixture, by using a very carefully graded gravel aggregate. Oil-mixed mortars seem to be, in general, impermeable. The writer would like to make it clear that he considers the addition of oil to the concrete mixture of benefit as a damp-proofer rather than as a means for preventing the percolation of water under great pressure; and not only his laboratory tests, but the results from numerous con-

Type	Asphaltic petroleum	Asphaltic petroleum.
Character	Sticky, viscous fluid, with gasoline odor.	Slightly sticky fluid, with naphtha odor.
Specific gravity at 25°/25° cent.	0.945	0.945
Loss at 163° cent., 5 hours, 20 grammes	30.84	21.76
Character of residue	Soft, sticky, ductile, with slight flow.	Soft, sticky, semi-solid, crystalline appearance on surface.
Soluble in CS_2, air temperature	99.93	99.97
Organic matter insoluble	0.07	0.03
Percentage of total bitumen insoluble in 86° paraffin naphtha	7.71	14.42
Fixed carbon	4.22	7.57
Specific viscosity, Engler at 25° cent.	50.0	15.0

The writer has had very successful results with oil-mortar parging applied to the exterior, and in some cases to the interior, of basement walls, with oil-concrete roofs and walls, in the United States Treasury vaults, and in basement floors. He has also had reports regarding oil-mixed concrete structures that were perfectly waterproofed when subjected to heads of 10 ft. Oil-mixed concrete has likewise been used for the construction of pumping pits in very wet soil. Similar constructions of plain concrete in the vicinity were always wet, whereas the oil-concrete constructions remained perfectly dry. The ease with which the oil can be incorporated with the concrete, and the comparative cheapness of the process, make it a desirable one for use in structures subjected to low heads. The following specification for oil is given as one which, it is believed, will give effective results as a damp-proofing agent when used in a concrete or mortar mixture:

SPECIFICATION FOR OIL TO BE USED IN OIL-CEMENT CONCRETE.

(1) The oil shall be a fluid residual from the distillation of petroleum, and shall contain no admixture of fatty or vegetable oils.

(2) It shall have a specific gravity of not less than 0.920 at a temperature of 25° cent.

(3) It shall show a flash point of not less than 150° cent. by the closed-cup method.

(4) When 240 cc. of the oil are heated in an Engler viscosimeter to 50° cent., and maintained at that temperature for at least 3 min., the first 100 cc. which flows out shall show a specific viscosity of not less than 15 nor more than 30.

In conclusion, it would seem to the writer that, should a duplication of the tests by Messrs. Taylor and Sanborn give the same results

with the California oils as those already obtained, they would be dangerous and valueless oils to use. The writer cannot help being a little doubtful of the reported absorption tests, as they are at variance with those of a number of investigators. He regrets that his own experiments have not included the California oils, but rather the semi-asphaltic product. He hopes, however, to be able to duplicate the authors' tests with the asphaltic oils, in order to throw additional light on their application to oil-concrete mixtures. Mr. Page.

Regarding the effect of drippings of oil on concrete, it must be acknowledged that in a great many instances the concrete mixtures have suffered great deterioration. This, however, is an entirely different proposition from that of mixing oil in very small percentages with wet concrete. A great many lubricating oils have vegetable and animal oil admixtures, and such oils, it is known, cause the destruction of concrete, the lime in the cement causing a saponification of the oil. Moreover, in such cases, as the oil is concentrated on a small surface of concrete, its effect is very serious. In the case of the oil admixture, only a very small percentage of oil is used, and this is distributed throughout the mass.

WILLIAM J. BOUCHER, ASSOC. M. AM. SOC. C. E.—The following brief remarks do not relate to the asphaltic or other heavy oils, but to the lighter varieties, such as kerosene. Mr. Boucher.

In the period just preceding the opening of the present Rapid Transit Railroad, in New York City, barrels of kerosene were kept at convenient locations, from which the lanterns of the watchmen were filled. One night a barrel leaked, and in the morning an oily spot on the concrete roadbed showed where the kerosene had disappeared. Considerable discussion followed as to whether damage would result, and on account of the layers of asphalt and felt water-proofing about 10 in. below the surface of the concrete, which it was believed would surely be damaged by the kerosene, the concrete was dug up, the water-proofing relaid, and new concrete placed. It has always been a matter of interest to the speaker as to what would have happened to the kerosene-soaked concrete if it had been left in place. Probably on a smooth troweled surface, such as a sidewalk or station platform, it would run off and evaporate, but would it cause deterioration if allowed to remain in ordinary concrete?

On looking up some references on oil mixed with concrete, the speaker found a very interesting article,* giving the experiments and part of the conclusions of James C. Hain, Assoc. M. Am. Soc. C. E., who conducted quite an elaborate series of tests on cement briquettes, treated with or immersed in lard oil, whale oil, castor oil, boiled lin-

* *Engineering News*, March 16th, 1905.

Mr. Boucher.

seed oil, crude petroleum, and signal oil (the latter a mixture of animal fat and mineral oil). Mr. Hain's account of the tests covers more than three pages, and he summarizes as follows:

"At the outset we failed to find [in railroad or industrial works] a specimen of concrete that we felt was positively disintegrated by oil, though we not infrequently heard of it. * * * On the other hand, plenty of concrete was found that oil had penetrated but not disintegrated. Further, our tests on comparatively new briquettes, which were weakened by exposure to air, showed that, with one exception, they were disintegrated by all classes of oils and fats. These oils and fats when arranged according to their effect (as far as our experiments indicate), are as follows: 1, animal fat; 2, animal oil; 3, vegetable oil; and 4, mineral oil. * * * On the following points we are reasonably certain: (1) Most oils penetrate concrete mortar, which makes them dangerous. (2) Concrete is more liable to be disintegrated when saturated with oils and fats if not thoroughly set. (3) A good quality of concrete is less susceptible to the effect of oil than a poor quality, such as a porous, frosted, lean, poorly mixed, or improperly seasoned concrete."

In the issue of April 20th, 1905, of the same periodical, Maximilian Toch, Assoc. Am. Soc. C. E., comments on Mr. Hain's experiments, and says:

"We found that the disintegration [of the briquette immersed in signal oil] was due to the formation of oleate and stearate of calcium. To reduce this to its simplest expression, the animal oils contain acids which combine with the lime, and crystals of stearate and oleate of lime are formed. It is very likely that these crystals in the process of formation have increased the bulk in the briquette and the bond which has been formed by the lime in the set cement has been totally disintegrated and ruptured.

* * * * * *

"Machinery oil which contains no animal fat is evidently harmless to cement concrete for the reason that no combination can occur. Machinery oils are almost exclusively paraffine oils."

Mr. Goldbeck.

A. T. GOLDBECK,* ESQ.—It is a peculiar thing that, with all the oils used in Mr. Page's experiments, the tensile strength of 1:3 mortar has been but very slightly affected by the oil admixture. In a great many instances the tensile strength even exceeds the strength of plain 1:3 mortar, although, at the same time, the crushing strength of concrete mixed with the same kinds of oils is invariably somewhat less than that of plain mixtures. Only one oil, thus far, has been found to affect the tensile strength seriously, and this oil perhaps more nearly resembles the asphaltic California products than any of the others used.

* Testing Engineer, Office of Public Roads, U. S. Dept. of Agriculture.

Mr. Goldbeck.

As has been stated, the influence of lubricating oils on plain concrete foundations is, in a great many instances, very severe. Animal and vegetable oils disintegrate concrete, and many of the lubricating oils contain animal and vegetable oil admixtures. This disintegrating action is particularly severe on lean, absorbent mixtures which may take up a very large quantity of oil. The mineral oil concrete mixture must be regarded in a different light from that of a plain concrete subjected to the penetrating action of lubricating oils. It is true that a very large percentage of oil, when mixed with the wet concrete, will cause it to lose all strength, but such excessive admixtures are unnecessary as well as dangerous. A small percentage, however, of the right kind of oil seems to be of benefit as a dampproofing agent, and does not seem to be dangerously detrimental to the strength of the mixture.

Mr. Taylor.

ARTHUR TAYLOR, ESQ. (by letter).—It is very pleasing to note that Mr. Page has been able to supply some additional data on his oil-mixed concrete investigation; primarily, because it undoubtedly furnishes the incentive for the Profession to enter further into this comparatively new field of concrete experimentation.

It has been the desire of the writers, since their inextensive tests were undertaken, that they be instrumental in creating an interest in the investigation of this possibly economical means of water-proofing mortars and concrete, and they now believe that, due to Mr. Page's discussion, their hopes will be realized to some extent.

At the outset, the writers were quite confident that Mr. Page had demonstrated an economical and practical means of water-proofing mortars and concrete by the admixture of a mineral oil with wet mortars and concrete. In this belief, it was expected that they would be able to verify some of his conclusions and enlarge on the scope by the use of Western (asphaltic base) oils.

Somewhat negative results were first observed when the strength of the 7-day tensile specimens fell off with the "oil-mixes" to a greater relative degree than in Mr. Page's tests. In no case did the strength of the oil-mixed briquettes approach that of the plain mortar; nor did the strength of the oil-mixed specimens reach 80% of that of the no-oil specimens in the 28-day tests. Again, with the permeability test, the first specimens were watched to see the effect of the oil, and it was observed with regret that the oil-mixed specimens were more permeable than the plain ones, for it was hoped that results similar to Mr. Page's would be obtained.

Regarding the absorption tests, the noticeably slight absorption may be accounted for by the fact that the specimens were the broken halves of briquettes, undoubtedly poor examples from which to show normal absorption, but reasonable indicators of relative absorption of the various oil-mixed mortars. It was the practice of the writers

Mr. Taylor.

to mix the mortars with exceptional thoroughness, and to pack the moulds quite vigorously, so that, without doubt, the latent voids were greatly reduced. This naturally brought about low absorption.

All specimens were taken out of the water at the same time, wiped, "baked" in an open gas oven at 160° Fahr., weighed, and again placed in water. At the end of the 24 and 72-hour periods the water was wiped off and the specimens were again weighed.

In the permeability test, though the age of the specimens was not great, the results of the plain concretes and the various oil-mixed ones, with relation to each other, should be quite correct. It is likely that the oil ingredient retards the time required for the concrete to reach its normal state, or permanent set; however, the writers cannot help but believe that the results of long-time tests would follow lines similar to those at 28 and 35 days, but probably with less divergence between the no-oil and oil-mixed specimens. By an oversight, the age of the 4-day test was omitted. These tests were begun on the thirty-fifth day.

The writers wish to make clear that the reporting of their tests was no flaunting declaration that oil as an incorporated ingredient in concrete is not an aid to its water-proofing qualities. It would be lamentable, indeed, if experimenters lacked the courage to make public their findings, merely because they did not agree with those of others. Believing in this principle, they offered their conclusions.

Though Mr. Page does not claim that oil adds to the strength, nor does the extra manipulation required to incorporate the oil (for it is not so shown in his compressive tests), yet the writers fail to comprehend why so many of Mr. Page's oil specimens have shown greater strength than the plain mortars. They have been inclined to believe that the "personal equation" is a factor in the results of new-field experimental work of this nature, regardless of how conscientiously it is carried on, and they dare say that it is likely that a repetition of many of these tests, where equative handling is paramount, would show appreciable reversals.

To some extent, the applicability of the colloidal theory does not seem futile. Considering oil the colloid, "that amorphous part of 'clays' which envelops the crystalline constituent, * * * when it is in excess, the clay is most plastic, and when it is dry, it is the less permeable and less absorptive." This, however, is not in perfect analogy to cement, where a mechanical-chemical change takes place; therefore, can we impose the colloidal theory here?

Again, it is plausible to believe that the oils of different character account to some extent for the variation in the results obtained from the experiments by Mr. Page and those by the writers.

J. B. Lippincott, M. Am. Soc. C. E., reported* that the tensile

*Transactions, Am. Soc. C. E., Vol. LXXIV, p. 283.

Mr. Taylor.

tests in the laboratory of the Los Angeles Aqueduct showed lack of uniformity, and were not considered to be encouraging for the use of California oils with concrete. These tests, however, were for tensile strength only, and no comment on any others was made.

When we consider the extent to which oil-mixed mortars and concretes has been investigated, it is only infinitesimal compared with what has been done with plain mortars and concretes. How many dozens of men have brought to light new and diverse results in their studies, but every result showing the investigators new light, and enticing them to experiment further. Therefore, this should encourage men to undertake more detailed study. Whether or not the writers' work led to the correct conclusion, they rest satisfied that they have created a stimulus for further investigation.

AMERICAN SOCIETY OF CIVIL ENGINEERS
INSTITUTED 1852

TRANSACTIONS

Paper No. 1266

ADDRESS
AT THE ANNUAL CONVENTION, IN OTTAWA, ONTARIO, JUNE 18TH, 1913.

SOME TENDENCIES AND PROBLEMS OF THE PRESENT DAY AND THE RELATION OF THE ENGINEER THERETO.

By George Fillmore Swain, President, Am. Soc. C. E.

In asking your attention this morning to the remarks which I shall offer for your consideration, I cannot forbear expressing to you, once again, my appreciation of the honor which you have done me in electing me to the position in which I find myself. It is a distinction which I shall always value above any other, and it involves a responsibility to the profession of which I am deeply sensible. This feeling, together with my conviction of the importance of our profession as a part of the social organism, has guided my choice of a subject for this address.

As we gather here, interested in widely divergent branches of engineering science, it has seemed to me that I could most profitably occupy the time by asking your attention to some matters in which we all should be equally interested. I have, therefore, chosen for my subject a consideration of "Some Tendencies and Problems of the Present Day," and the part which the engineer should play in their solution.

We are living in a most remarkable age, an age different from any that has preceded it in the history of the world, and one in which changes are taking place with marvelous rapidity. As a profession, we are largely responsible for the present conditions, and therefore we should

do our part in solving such problems as exist, and in helping to direct aright the tendencies of the day. We have a duty to ourselves, to our profession, to society, and to our successors, and we must perform it.

We have been often reminded of the fact that in one sense engineering is the oldest of the professions, since engineering constructions of some form are necessary even in the rudest communities; but in another, and perhaps a truer sense, it is the youngest of the professions. The priesthood is doubtless the oldest distinct profession recognized as such, for the most uncivilized tribes had priests to mediate between themselves and their crude deities. The priests were also lawgivers, practiced the healing art (such as it was), and, as civilization progressed, were also the builders. Bridges and temples were built by them, and the most stately buildings were those devoted to ecclesiastical uses. In course of time, the lawgiver, the physician, the architect, became distinct, and then for a time the engineer was either an architect or a priest. It is fair to say that engineering is the last profession to be differentiated into a class by itself, and that its beginning dates from about the Seventeenth Century, later receiving its great impetus from the series of inventions which were made toward the end of the Eighteenth Century—the spinning jenny, the loom, the puddling process, the steam engine, and the steam locomotive. Since that time, the profession has grown by leaps and bounds, has become separated into a dozen branches, and has probably become, directly or indirectly, the chief occupation of mankind. If this age may be designated as predominantly that of any profession, it is certainly the age of the engineer or applied scientist. He furnishes us with thousands of comforts, necessities, and luxuries, of which previous generations never dreamed, and which they would have laughed at as impossible. By supplying the fundamental material elements of modern civilization—transportation, the transmission and dissemination of intelligence (by telegraph, telephone, and printing press), machinery, prime movers, and the working of metals—the applied scientist becomes the minister to the other and older professions, furnishing tools for the surgeon and dentist, and chemical products for the physician; while engineering projects and problems probably supply as large a field as any for the employment of lawyers. The priest—originally lawgiver, physician, and builder—now stands alone, concerned only with the moral law and its application, and with our relation to the Infinite.

Civilization, as we know it to-day, then, seems to me to be due mainly to the engineer, or applied scientist, using the term in its widest sense. Of course, a great ethical advance has also been made, of which any student of history must be fully conscious; but, when we consider that moral principles were known and recognized by the ancients, in as perfect a form as that in which they can be stated to-day, without producing much, if any, wide-spread ethical progress, or any advance in civilization, for many centuries, we must, I think, conclude that it is the dissemination of intelligence, the facilities for transportation, the development of machinery, which have made the whole world kin, and thus have been the chief elements in promoting the universal brotherhood of man and the practical recognition of human rights, and so have been the main agents in the progress of civilization. This, somewhat differently expressed, is, as I understand it, the position taken by Buckle, often misunderstood by those who assume him to assert that no ethical progress has been made. However this may be, few will deny that the work of the engineer, if not the cause, has been a necessary condition, of progress.

This progress, both material and ethical, has been wide-spread, and astonishing in degree. In material things, not only necessities, but comforts and luxuries of which our forefathers would never have dreamed, are now within the reach of every man who is sober and industrious. Wages have risen, not only in absolute amount, but in purchasing power. The poor can now receive medical advice, medicines, and many other things free, where our predecessors could not have obtained the same things at all. Simple foods in great variety, and clothing of good quality, can be obtained at reasonable prices; and in every respect the poor man to-day is better provided for than his predecessors were. Ethically, too, he is far better off. The best books are available, if he wants them, at ridiculously low prices, free public schools are provided for his children, and all sorts of free industrial and vocational instruction is available for him in his leisure hours if he desires to use them. His hours of labor have been shortened, his civil rights have been generally recognized, he is treated as the equal of any man before the law, and his right to a fair chance in life—to opportunities commensurate with his ability to make use of them—is generally admitted in theory, if not yet entirely in fact. With free public and trade schools, with conditions which allow a common laborer

in a steel mill at 15 to become the head of the greatest industrial organization in the world at 50, certainly it cannot be said that men do not have opportunity in the United States.

Continued progress, however, and the interest of the social organism as a whole, require that individual initiative and ability shall be encouraged to the utmost and allowed to enjoy the reasonable fruits of its exercise; that property shall be protected; that taxation shall be equitable and uniform; that leaders shall be chosen from those most enlightened, capable, honest, and judicious; that those who are only fitted for manual labor shall not acquire a distaste for it or look down upon it as inferior in dignity to other occupations*; and that waste and extravagance shall be reduced to a minimum. There should be a recognition of the facts that wealth must be unequally divided, since men are unequal in ability and in character; that the prosperity of one depends on the prosperity of all;† that each man must feel secure in the enjoyment of all that he can legitimately win; that wealth, position, and luxury, do not in themselves bring happiness; and that the selfish desires of the individual must be subordinated to the interests of society as a whole if progress and not retrogression is to ensue. A state of equality of condition, as has been well remarked, would mean equality, not of wealth, but of wretchedness.

The political and social evolution in the past, up to a comparatively recent period, has not involved any diminution of the incentive to individual effort, nor to any great extent the attempt to deprive the individual of the fruits of his industry and ability. Of late years, however, with growing political power in the hands of the less intelligent classes, symptoms of a change have shown themselves. The spectacle of isolated instances of great wealth acquired unfairly or too rapidly, and of rewards out of proportion to service, instead of being looked upon as necessary phenomena, seeing that men are human, and that no human affairs can ever be perfect, has led to a wide-spread spirit of envy and discontent, and sometimes to a desire to deprive men of the results of their honest toil.

---

*"But we exhort you brethren * * * that ye study to be quiet, and to do your own business, and to work with your hands," wrote the Apostle Paul.

†"This, then, above all, ought to be regarded by every one as an established principle, that the interest of each individual and that of the entire body of citizens are identical, which interest, if any one appropriate to himself alone, he does it to the sundering of all human intercourse." Cicero, "De Officiis."

It is to some unfavorable phenomena incident to this movement that I wish to call your attention to-day, believing that, if they continue, disaster may result, in which case, as always, the suffering will mainly come upon those least able to bear it.

1.—In the first place, let me refer to the tendency to consider men equal, or to what I may term a false democratic ideal.

What I conceive to be the true democratic ideal is this: that all men are equal before the law—so that neither differences in wealth, race, social position, nor talent, shall confer any advantage or impose any disadvantage in the impartial administration of justice; that while ability should be admired, every man who is honest, industrious, sober, and faithful, and who does his work in the world as well as he can and with due regard to the rights of others, is deserving of equal respect and regard, whether he occupy the humblest or the most exalted position; that success depends on the spirit with which one's natural endowments are utilized and the degree to which they are developed, and not on those endowments themselves, so that the humblest laborer on the street may be making as great a success of his life as the most gifted; that there should be kindliness and a spirit of brotherhood between all men, and neither envy of those more capable, who receive greater rewards, nor contempt of those less gifted, who do the menial work of the world; and that neither race, poverty, nor inferior social position, should prevent the possibility that a man, by hard work, integrity, and conscientiousness, should be able to reach, by some available ladder, a position commensurate with his abilities. A man should be judged by what he is, not by what he has, whether he is black or white, or who his grandmother was. He should have the opportunity to get such education as best fits his natural qualifications. Rich and poor should be judged by the same standard—inherent worth. But, though respect should be equal, rewards should not be. They should be in proportion to the value of the service, and governed by the law of supply and demand; nor are great rewards necessary for happiness.

Unfortunately, a democratic government, especially with universal suffrage, instead of tending to the realization of this ideal, tends in some respects directly away from it, and leads not seldom to the grossest perversions of it. The equality of man, which the framers of the Declaration of Independence held to be self-evident, instead of being

interpreted as above, is held to mean that men are inherently equal in all respects.

It is self-evident that, instead of being equal, men are very unequal. There is perhaps more difference between the most intelligent and the least intelligent voter than there is between the latter and an intelligent animal. It is held that all, being equal, should have equal opportunity; but why should there be equality of opportunity for unequal individuals? As Harris remarks, "Inequality of opportunity for unequal men is a nearer approach to true equality than equal opportunity for unequal men." Why, for instance, should all men have opportunity for a college education, when only a few can profit by it, and the great majority should work with their hands, not with their heads? Not every man who is able to pass successfully through a college course is able to use it when he has finished, and by its means many a good mechanic has been spoiled to make a poor and discontented clerk or lawyer.

One of the conditions of individual progress is the willingness to recognize and admire superiority, and without envy to rejoice in its success. The idea of the equality of man limits this recognition, and thus hampers individual progress, and therefore collective progress. In college, there is little in class associations to stimulate a man to excel. If he does, he is termed a "grind" and is looked down upon. If all men are equal, he has no right to exhibit any superiority to his fellows. The same is true among the so-called laboring classes. No man must do any more work, or do it any better, than another. Individual excellence and initiative are discouraged. Indeed, individual freedom is not seldom infringed upon, and a man is not allowed, at times, to work at wages satisfactory to himself, when he desires to do so—a strange result of freedom, and in reality as great an outrage as any that can be quoted from the mediæval annals of despotism. With growing discontent, many minds turn to socialism, that impracticable Utopia which, as President Butler has well said, "would wreck the world's efficiency for the purpose of redistributing the world's discontent."

The idea of the equality of man, instead of allowing the best men to govern and fitting the man to the proper vocation, leads to the placing of unfit men in power, the control of large masses of men by demagogues, the judging of men by the number of votes they can

control; and thus it leads to the withdrawal of many of the best men from active participation in public affairs, because they see how little influence they can exert without the use of money or the arts of the demagogue, and that the only reward of one who unselfishly serves the public is likely to be criticism and contumely. It also discourages loyal and faithful service, and makes difficult the maintenance of proper relations between employer and employee. Where every one is his own master, it follows that every one is his own servant.

What the ultimate result will be, cannot be foretold. The political doctrine of the equality of man is still on trial. Yet, as regards the United States, where that doctrine has its fullest expression, Lincoln long ago observed that if it fails, it will not be on account of interference from without, but it will be by suicide. It behooves us, therefore, if we can, to see to it that our institutions shall not fail by suicide.

Nevertheless, it is a somewhat striking fact that several of the most philosophical and learned historians have distrusted the ultimate success of our institutions. Froude, Macaulay, and Lecky, all express the gravest doubt of the permanence of our form of government.*

*Froude, for example, writes, "I am no believer in democracy as a form of government which can be of long continuance. It proceeds on the hypothesis that every citizen is entitled to an equal voice in the management of his country, and individuals being infinitely unequal—bad and good, wise and unwise—and having rights dependent upon fitness to make use of them, the assumption is untrue, and no institution can endure which rests upon illusions."

Macaulay, too, had great doubt of the permanence of our form of government. One of his letters to a friend in America has been often quoted, but, for convenience in this connection, it may be well to reproduce it here.

"Holly Lodge,
Kensington,
LONDON, May 23, 1857.

"DEAR SIR:

"You are surprised to learn that I have not a high opinion of Mr. Jefferson, and I am surprised at your surprise. I am certain that I never wrote a line, and that I never in Parliament, in conversation, or even in the hustings—a place where it is the fashion to court the populace—uttered a word, indicating an opinion that the supreme authority in a State ought to be intrusted to the majority of citizens told by the head; in other words, to the poorest and most ignorant part of society. I have long been convinced that institutions purely democratic must, sooner or later, destroy liberty or civilization, or both. In Europe, where the population is dense, the effect of such institutions would be almost instantaneous. What happened lately in France is an example. In 1848 a pure democracy was established there. During a short time there was reason to expect a general spoliation, a national bankruptcy, a new partition of the soil, a maximum of prices, a ruinous load of taxation laid on the rich for the purpose of supporting the poor in idleness. Such a system would, in twenty years, have made France as poor and barbarous as the France of the Carlovingians. Happily, the danger was averted; and now there is a despotism, a silent tribune, an enslaved press. Liberty is gone, but civilization has been saved. I have not the smallest doubt that, if we had a purely democratic government here, the effect would be the same. Either the poor would plunder the rich, and civilization would perish, or order and prosperity would be saved by a strong military government, and liberty would perish.

"You may think that your country enjoys an exemption from these evils; I will frankly own to you that I am of a very different opinion. Your fate I believe to be certain, though it is deferred by a physical cause. As long as you have a boundless extent of fertile and unoccupied land, your laboring population will be far more at ease than the laboring population of the old world; and while that is the case the Jeffersonian polity may continue to exist without causing any fatal

Their predictions, we hope, will prove erroneous; we must make them so, if we can. Nevertheless, the more we reflect, the more I think we shall realize that out of the false theory of the equality of man have sprung many real dangers. A spirit of unhealthy discontent has been aroused, and the people, who are sovereign, endeavor, by various kinds of legislation, to realize in fact the untruth of equality. They make the common mistake of assuming that legislation is a sovereign remedy for all ills. Not knowing how to proceed, they become the prey of every selfish demagogue who, while stirring them up to exaggerate their troubles, and professing his ability to remedy them, is simply seeking his own ends. These men know that a large part of the voters to whom they must appeal are ignorant, easily swayed by claptrap, and deceived by hypocrisy, "incapable of disentangling a difficult question, judging distant and obscure consequences, realizing conditions of thought and life widely different from their own, estimating political measures according to their true proportionate value, and weighing nicely balanced arguments in a judicial spirit." The

---

calamity. But the time will come when New England will be as thickly settled as Old England. Wages will be as low, and will fluctuate as much with you as with us. You will have your Manchesters and Birminghams; and in those Manchesters and Birminghams hundreds of thousands of artisans will assuredly sometimes be out of work. Then your institutions will be fairly brought to the test. Distress everywhere makes the laborer mutinous and discontented, and inclines him to listen with eagerness to agitators who tell him that it is a monstrous iniquity that one man should have a million while another cannot get a full meal.

"In bad years there is plenty of grumbling here, and sometimes a little rioting; but it matters little, for here the sufferers are not the rulers. The supreme power is in the hands of a class, numerous indeed, but select—of an educated class—of a class which is, and knows itself to be, deeply interested in the security of property and the maintenance of order. Accordingly the malcontents are gently but firmly restrained. The bad time is got over without robbing the wealthy to relieve the indigent. The springs of national prosperity soon begin to flow again; work is plentiful, wages rise, and all is tranquility and cheerfulness. I have seen England pass, three or four times, through such critical seasons as I have described. Through such seasons the United States will have to pass in the course of the next century, if not of this. How will you pass through them? I heartily wish you good deliverance. But my reason and my wishes are at war, and I cannot help foreboding the worst. It is quite plain that your Government will never be able to restrain a distressed and discontented majority. For, with you, the majority is the government, and has the rich, who are always the minority, absolutely at its mercy. The day will come when, in the State of New York, a multitude of people, none of whom has had more than half a breakfast, or expects to have more than half a dinner, will choose a Legislature. Is it possible to doubt what sort of a Legislature will be chosen? On one side is a statesman preaching patience, respect for vested rights, strict observance of public faith; on the other is a demagogue, ranting about the tyranny of the capitalists and usurers, and asking why anybody should be permitted to drink champagne and to ride in a carriage while thousands of honest folk are in want of necessaries. Which of the two candidates is likely to be preferred by a workman who hears his children cry for bread?

"I seriously apprehend that you will, in some such season of adversity as I have described, do things that will prevent prosperity from returning; that you will act like people who should, in a season of scarcity, devour all the seed corn, and thus make the next year not one of scarcity, but of absolute famine. There will be, I fear, spoliation. The spoliation will increase the distress. The distress will produce fresh spoliation. There is nothing to stop you. Your Constitution is all sail and no anchor. As I said before, when a society has entered on its downward progress, either civilization or liberty must perish. Either some Cæsar or Napoleon will seize the reins of government with a strong hand; or your republic

demagogue, therefore, appeals to class interests and class animosities, and does his utmost to foment a spirit of discontent, even though every condition justifies the opposite, gaining his reward by newspaper headlines, notoriety, public office, or not seldom, wealth secured at the expense of the public that he deceives. The spirit of servility and sycophancy which in former times led men to grovel in the dust at the feet of kings and princes, is still with us, unchanged in form, only its object is different, and its adulation is now directed to the sovereign voter—the more ignorant, the more easy to flatter and deceive. Knowing human nature, may we not doubt the man who claims to act for the good of the people; and trust him rather who frankly admits that his actions are governed by his selfish interests, but who has learned that these can only be served by promoting the best interests of all.*

---

will be as fearfully plundered and laid waste by barbarians in the twentieth century as the Roman Empire was in the fifth—with this difference, that the Huns and Vandals who ravaged the Roman Empire came from without, while your Huns and Vandals will have been engendered within your own country by your own institutions.

"Thinking thus, of course I cannot reckon Jefferson among the benefactors of mankind.

"Yours respectfully,
"THOMAS BABINGTON MACAULAY."

Lecky, one of the most thoughtful of English historians, expresses in a number of places his doubts regarding the success of democracy. For instance, he says:

"Strong arguments may be adduced both from history and from the nature of things to show that democracy may often prove the direct opposite of liberty. * * * Democracy destroys the balance of opinions, interests, and classes, on which constitutional liberty mainly depends, and its constant tendency is to impair the efficiency and authority of parliaments, which have hitherto proved the chief organs of political liberty. * * *

"A despotism which secures order, property and industry, which leaves the liberty of religion and of private life unimpaired, and which enables quiet and industrious men to pass through life untroubled and unmolested, will always appear to many very preferable to a democratic republic which is constantly menacing, disturbing or plundering them." (Lecky, "Democracy and Liberty," pp. 256-260.)

Again, he says, in another place:

"In every field of human enterprise, in all the competitions of life, by the inexorable law of Nature, superiority lies with the few and not with the many, and success can only be attained by placing the guiding and controlling power mainly in their hands. * * * Yet, surely, nothing in ancient alchemy was more irrational than the notion that increased ignorance in the elective body will be converted into increased capacity for good government in the representative body; that the best way to improve the world and secure rational progress is to place government more and more under the control of the least enlightened classes. The day will come when it will appear one of the strangest facts in the history of human folly that such a theory was regarded as liberal and progressive." (*Ibid*, p. 26. Speaking about parliamentary government, he says: "In all the instances in which this form of government has been conspicuously successful, the representative body was returned on a restricted suffrage." The great German historian, Sybel, said: "The realization of universal suffrage and its consequences has always been the beginning of the end of all parliamentarism." Professor Freeman said: "The real special weakness of pure democracy is that it almost seems to require slavery as a necessary condition of its existence." Aristotle, Goethe, and Voltaire, all disbelieved in a purely democratic form of government.)

*"The men who, in former ages, would have sought by Byzantine flattery to win power through the favor of an emperor or a prince, will now be found declaiming on platforms about the iniquity of privilege, extolling the matchless wisdom and nobility of the masses, systematically trying to excite their passions or their jealousies, and to win them by bribes and flatteries to their side." Lecky, "Democracy and Liberty," p. 30.

Some of the remedies for these dangers, it seems to me, are obvious. In the first place, we should realize that the statement that all men are created equal, properly interpreted, simply means that they are equal before the law, that all men should be treated with justice, should have fair opportunities, and that each should be secured in his right to the products of his own labor, and to his own liberty, so far as his acts do not injure others. Aside from this, instead of considering men equal, we should recognize and encourage inequality, for it is easily to be seen that the progress of society depends on it. Equality of condition means pauperism or savagery; the inequality of man means the division of labor, progress, civilization.

In the second place, we should encourage the recognition and admiration of superiority.

In the third place, we should preach the gospel of content, instead of discontent. "Do violence to no man, neither exact anything wrongfully; and be content with your wages" said John the Baptist. There are two kinds of discontent: one praiseworthy; one ignoble. The former springs from a laudable ambition and a desire to perfect oneself, so far as natural endowment will permit. The other springs from envy and the desire to reap the rewards of the industry of others. The former kind of discontent is to be encouraged; every man should be given an opportunity to develop himself and to be confirmed in the possession of the prizes which he may gain; but the discontent which springs from envy, which leads men to depend on government help, instead of self-help, which sanctions forms of unjust taxation which may be nothing less than legalized robbery, should in every possible way be repressed. The attention of men, instead of being concentrated on what they want, should be directed to a realization of what they have. In contrast with the conditions which existed one or two centuries ago, even the conditions of the poorest classes at the present time are immensely improved. Yet with all the reduction of working hours that has taken place in the last 50 years, and the other improvements in condition, I doubt if there is any more real happiness and content among the poorer classes. Nor have I any doubt that the excessive talk about bettering the condition of the working classes blinds them to the opportunities for their own thrift and industry.

Unfortunately, it is a vain hope that there will ever be an absence.

or even a dearth, of demagogues to stir up this spirit of unworthy discontent, but we should do all in our power to counteract it. Much of it is due to the unwise use of wealth by those who possess it, who think that money can buy everything, and is the end and aim of existence, and who, instead of being governed by a feeling of the brotherhood of man, and the spirit of respect for true worth, even in the humblest occupations, assume an attitude of superiority, or even of insolence, toward those less fortunate than themselves.

It is also vain to hope that we can ever reach a point where there will be no poverty.* This would realize what Dr. Johnson termed the triumph of hope over experience. It would mean a radical change in human nature. As long as there are masses of men who are shiftless, lazy, incompetent, and vicious, whom nobody would willingly employ, poverty will exist. Still, every effort should be made to relieve it where it is undeserved. It will be well, however, to bear in mind that suffering is a remedy, and that unwise philanthropy may do harm instead of good. If men will learn in no other way the lessons of life, they must learn them by suffering, which is Nature's cure. Of course, it is often hard to distinguish deserved from undeserved suffering. The latter may be wisely relieved; the former generally not. Surely an all-wise Creator would not have filled the world so full of it except for some good purpose, and that purpose cannot be to afford to others the opportunity for relieving it, for much of it cannot be relieved.

2.—The Tendency to Disregard Authority.—Out of the tendency to look upon all men as equal, spring some other tendencies to which I will refer. One of them is to disregard authority, and to consider that one man's opinion is as good as that of any other. We see this tendency about us every day; it leads to intellectual arrogance, dogmatism, and lawlessness.

Every man has presented to him, almost daily, questions which he is not competent to decide for himself, either because he has not had the necessary time, training, or experience, or because he is incapable of judging.

*"Its causes lie chiefly in incompetence, lack of energy, bad heredity, and unhealthy surroundings, rather than in a vicious economic system, or in lack of opportunity. The relief of poverty has become so judicious that few poor persons are left to suffer from want. The prevention of poverty is to be found in good sanitation enforced by the municipality, in suitable education of individuals according to capacity, and in self-help, rather than in economic revolution or in indiscriminate equality of opportunity." Harris, "Inequality and Progress."

In these days, when literature is so superabundant, it is most important to choose our advisers wisely, to know whom to trust, to discern wisdom, to select the proper books to read, to choose the best authorities to whom we shall listen, and, when we have so chosen, to consider attentively the message they bring, and to distinguish advice that springs from self-interest from that which is disinterested. There is a great temptation to form hasty or immature judgments on slight authority; and the habit, once formed, may be difficult to eradicate.

The disregard of authority is peculiarly observable in the younger generation. It is not confined to the uneducated, but is even more observable in many whose self-esteem has been increased by a course in college. Finding that men disagree on almost every subject, and that even those in positions of authority do not hold the same opinion, it is easy to conclude that one man's opinion is as good as another's. Let us examine this matter further.

The subjects of study may be broadly divided into three classes: First, the relations of abstract ideas, that is, mathematics and logic; second, natural science; third, the so-called humanities.

With regard to subjects in the first class, no observation or experience is necessary, and there will be no differences of opinion. They are not, properly speaking, matters of opinion at all. There can be no discussion as to whether two and two make four, or as to whether the three angles of a triangle amount together to two right angles.

With regard to natural science, conclusions depend to some extent on observation, experiment, and experience. Hypotheses may be formulated, experiments made, conclusions deduced therefrom; and differing conclusions may be arrived at by different persons. In this class then, there may reasonably be divergencies of opinion. These subjects, therefore, are less definite, more hypothetical, more uncertain, than those in the first class.

Under the third class are comprised what are called mental and moral philosophy, politics, government, history, language, etc. This class of subjects is even more uncertain and less definite than the second. Experiments are less conclusive, and cannot be made under determinate conditions, as in natural science, the data are more shifting and variable, experience is of great value, and extreme differences of opinion will often occur.

The thoughtful man will recognize these differences between the

various subjects of investigation. He will form his conclusions on subjects in the first class with definiteness and certainty, and will be justified in feeling confident of their correctness. He will recognize the greater indefiniteness of subjects in the second class, and if he forms definite opinions, he will hold them in a sort of tentative manner, realizing that the next experiment or discovery, or greater experience, may show them to be incorrect. He will realize the still greater indefiniteness of subjects in the third class, and though he may well form definite opinions regarding these also, he will hold them with still greater modesty, realizing that in almost every question of this character there is much to be said on the other side, and that he may be entirely wrong. Only the man who has studied the subjects in all three of these classes will realize fully the different degrees of certainty attaching to each. Such a man will be much more modest and safe in his conclusions than one who has studied only one class of subjects. It may further be remarked that a man who has studied only the third class of subjects, will be likely to be more dogmatic and less safe than one who has studied the first or the second, or both; because, not being familiar with subjects in which a great degree of certainty, or even absolute certainty, is attainable, he may assume that such degree of certainty is attainable in the subjects of the third class; whereas, a man who has studied mathematics or science, and is accustomed to definiteness, will, when he is confronted with problems of politics, economics, government, or ethics, be at once struck with the great difference in reliability of the data, the impossibility in many cases of making crucial experiments, and the fluctuating conditions involved. For this reason, it is not uncommon that scientists, mathematicians, or engineers hold and express opinions regarding politics, economics, or ethics, with much less dogmatism than less well-informed men who have devoted their attention more strictly to these last-named subjects.*

*Sir George Cornewall Lewis, one of the deepest political thinkers of England, or of all time, lays down the following rules regarding the qualities which render a person a competent authority in matters of opinion:

"The first qualification is, that a person should have devoted much study and thought to the subject-matter if it be merely speculative; and that if it be practical, he should also have had adequate experience respecting it.

"Secondly, his mental powers must be equal to the task of comprehending the subject, and they must be of the sort fitted to it.

"Thirdly, he ought to be exempt, as far as possible, from personal interest in the matter; or, if he be not exempt, his honesty and integrity ought to be such as to afford a reasonable security against the perversion of his opinions by views of his individual advantage." "On the Influence of Authority in Matters of Opinion." London, 1849, p. 27.

Lord Brougham, in his "Political Philosophy" (Vol. 1, p. 3), says: "Mathematicians who run hardly any risk of error—naturalists who run but little more—have never been so bigoted and so uncharitable as those whose speculations are fated to be always involved in more or less of doubt; and when we come to political reasoners, we find, besides the intolerance of metaphysicians, a new source of error and of fault in the excitement which men's interests, real or supposed, lend to their passions."

Excellent books on economics have been written by mathematicians or astronomers, and it is remarkable to observe how many works on these subjects have come from men who have been senior wranglers at Cambridge.

As Lewis says:

"The qualities which render a man a trustworthy authority in matters of opinion, are much rarer than those which render a man a credible witness in matters of fact. Accordingly, the honesty which induces a man to speak the truth is more common than that which induces him to form sound opinions. There are many men who, under ordinary circumstances, would never be seduced by interest to report a fact falsely or to express an insincere opinion, whose judgment might, nevertheless, be perverted by interest."*

Lecky also expresses the same thought when he says:

"There is such a thing as an honest man with a dishonest mind. There are men who are wholly incapable of willful, deliberate untruthfulness, but who have the habit of quibbling with their convictions and by skillful casuistry, persuading themselves that what they wish is right."

Indeed, one of the first principles which we must thoroughly grasp, if we wish to judge correctly as to the authority of a writer, is that personal honesty and good intentions do not in themselves constitute any sufficient guaranty of authority. History, as well as the experience of almost every man, abounds in instances of the truth that the most honest and well-intentioned men may be the worst advisers. The French have a witty saying that "virtue is more dangerous than vice, because it is not subject to the restraints of conscience." Similar is the old saying, quoted by Cicero, that "The extreme of right is the extreme of wrong."

Two of the most important requisites for authority in matters of opinion, seem to be a spirit of conservatism, and the possession of

*Loc. cit., p. 35.

good judgment. The man who is slow to advocate a change, who adheres instinctively to old ideas and practices until there is reasonable ground for the belief that a change will be beneficial, is clearly a safer guide than he who rushes into all sorts of new schemes and is ever ready to throw aside the results of years, because perfection has not been attained. Conservatism is the brake which prevents our rushing to destruction. The possession of grasp and of good judgment is also essential. By these are meant the ability to see all the elements entering into a problem and to see them in their proper proportion. The narrow-minded man does not see all the elements in a problem; such a man lacks grasp. The unbalanced man, though he may see all the elements, exaggerates some and minimizes others; such a man has poor judgment. The advice of either is unreliable.

It is worthy of fuller inquiry what the reasons are, reduced to their elements, which cause men to differ in their opinions. Take almost any subject, except one dealing with abstract relations, and opinions may be cited which are diametrically opposite. Consider such a matter, for instance, as the relation of forests to stream flow. Here we have a scientific subject, regarding which it might be supposed that experiments or observations might be made, scientific principles applied, and opinions reached which would be agreed upon by all intelligent men conversant with the subject; and yet, on this subject, and still more so on even more speculative matters, men of equal authority or experience will be found holding diametrically opposite views. Why is it?

It seems to me that, if intelligent men differ on any subject, it must be due to one or more of the following causes:

a.—One or the other is not in possession of all the facts or principles involved;

b.—One or the other may use facts or principles which are incorrect;

c.—One or the other may reason incorrectly;

d.—One or the other may see the facts out of proportion, attributing too great importance to some and too little to others;

e.—One or the other may illustrate the natural stubbornness or imperviousness of the human mind.

It is not always clearly recognized that often facts cannot be compared directly, because they cannot be expressed except in incom-

mensurable terms. For instance, if we ask which is the greater, six feet or two meters, there will be no disagreement in the answer; but, if we ask which is the more important, 10 feet or $5, or which is more important, truthfulness or beefsteak, the reply is not entirely obvious. These are not fanciful illustrations. We are continually obliged to make comparisons between things which have to do with our physical well-being and those which have to do with our moral or spiritual well-being. They are incommensurable, yet they must be compared and an opinion formed from the comparison. In planning a railroad station, for instance, one design may require the passengers to walk a certain number of feet, while another design costs more but requires less walking. Here is a comparison which must be made between feet and dollars. In such a case, some will endeavor to express the comparison in commensurable terms. They will compute, perhaps, the value of the shoe leather that would be saved in a year if all the passengers using the station have to walk the given distance less, and compare it with the interest on the additional expenditure. Similarly, the expenditure of millions of dollars is asked for electrification, the advantage urged being the saving of a certain number of minutes each day for each passenger, and because the aggregate saving of time in a year, valued at the average annual wage of an individual, amounts to a sum greater than the interest on the cost. Such comparisons are generally made by those who find their judgment unable to deal with the subject in any other way—who cannot compare except by measuring or weighing, as they have been trained or accustomed to do. Yet such persons do not realize that the comparisons they make may be entirely deceptive. Although more rapid transit may render a journey quicker, it does not follow that the time is saved. It may be usefully employed in reading, or in conversation, or in sleep, or in meditation. An additional fifteen minutes spent in going from one's house to one's office, is not necessarily lost; it may be utilized like any other fifteen minutes in the day. Even if spent solely in meditation, it would be most beneficial, for, as Arnold Bennett says, the great defect of the age is the absence of meditation. In such arguments as that for electrification the mistake is also made of not considering whether the individuals who would make the saving claimed are the same individuals who would bear the increased cost.

Referring to the classification above, it is evident that an ability

to observe correctly, the faculty of getting at all the facts, and of knowing when all the pertinent facts have been collected, the ability to reason from those facts, the possession of conservatism, the absence of stubborn persistence in holding a previously formed opinion in the face of proof of its error, and, above all, the faculty of seeing things in proper proportion, or good judgment, are essential in forming an authoritative opinion.

How can the absence of these qualities be detected? To discuss this would lead us too far, but there are one or two points to which I wish to refer. For one thing, dogmatism, or intellectual arrogance in speculative or uncertain matters, is an almost certain indication of disqualification. The man who in such matters shows intolerance of opinion, may generally be disregarded. He who in matters of opinion is cock-sure, who terms all men who disagree with him knaves or fools, who resorts to epithets and extreme statements, who asserts that all honest men should believe as he does, or who makes similar assertions, is either willfully trying to mislead, or is unworthy of credence. This is a fault which is observable particularly in the immature, whether young or old in years.*

*Let me quote once more from Sir George Cornewall Lewis on this subject:

"Whenever a person, having formed an opinion upon grounds which appear satisfactory to himself, asserts it confidently, and adheres to it resolutely, without showing due deference to the authority of others, he is justly exposed to the charge of *arrogance or presumption* in judging. The opinion of experienced men, having a special acquaintance with the subject, is always entitled to weight, even if it be unsupported by argument. Hence, all young persons, who attempt to judge for themselves, either are, or appear to be, arrogant; as they can scarcely fail to set at nought the opinions of persons more experienced and of greater authority than themselves. It is difficult for a young man, on account of the narrow circle of his experience, to discriminate between the cases in which he ought to judge for himself, and those in which he ought to defer to the opinions of others. He ought not to form, in youth, a habit of blind submission to authority, such as the Jesuits inculcated upon their disciples; but a spirit of docility, and respect for the opinions of their elders, undoubtedly becomes the young; and it is certain that their opinions, especially on practical questions, however formed, will in general be of very little value to others, however important it may be to themselves to cultivate a habit of independent and conscientious judgment.

"Persons who have formed habits of independent thought and examination likewise generally subject themselves to the same reproach—inasmuch as they often attach an undue weight to a chain of reasoning which they have gone through in their own minds, as compared with the opinions of persons who appear to be entitled, by their experience, to pronounce authoritatively on the subject. It is no easy matter to define the point where firmness, resolution, and proper self-reliance begin. It is difficult, again, to discriminate between teachableness, humility, and reverence for high authorities, and a tame and passive submission of the understanding.

"Universally, indeed, it may be said, that no person ought to express a confident opinion upon speculative grounds, until he has ascertained, by careful investigation, the unsoundness of the reasons for a different opinion, held by practical and experienced men. If, however, after a due examination, he differs from their conclusions, he cannot, even if he be wrong, justly be taxed with arrogance. To persist in error after proper inquiry and reflection, is not presumptuous, although it may imply *other* moral or intellectual defects. * * *

"'That man' (says Hesiod, in some celebrated verses, which acquired in antiquity almost an oracular authority,)—'that man is the most excellent, who can always think for himself. He, too, is a good man who will take sound advice from others. But he who can neither think for himself, nor will listen to the sound advice of others, is a worthless man.'" *Loc cit.*, pp. 113-117.

If, therefore, we find an author proposing changes in political or social conditions who refers to eminent men at least as honest and intelligent as himself, and more learned and experienced than he is, in terms of disrespect, we may be pardoned if we surmise that his own temper and judgment are not such as to entitle his words to be received with authority. So also, if we detect what we believe to be frequent gross errors in reasoning, or a temperamental lack of the power to see things in what is clearly their proper perspective, we may save ourselves the trouble of pursuing such an author farther, even though his sentences are adorned with flowers of rhetoric or by Biblical quotations.

3.—The Disregard for Experience.—One of the most serious tendencies of the present day, particularly in the United States, a tendency which, like the disregard of authority, seems to result from that to regard men as equal, is the disregard for experience. It is a tendency fraught with great possibilities for evil, which must be recognized by every serious thinker.

In any occupation, except those which have to do with the study of purely abstract relations, which, as above explained, may be arrived at correctly in the seclusion of the study, it is almost self-evident that experience is of great value. In any occupation having to do with pure or applied science, and particularly in those having to do with man and his relations to society—that is to say, in politics, economics and government, as well as in engineering—experience is a necessary qualification for arriving at correct judgments. A person having a power of perception of mathematical relations may become a profound mathematician at an early age; indeed, the perception of mathematical truths is essentially a subjective faculty, and may be most correct and powerful when the mind is removed from the objective state. Some mathematical prodigies have reached their greatest power when mere boys, and have lost it with increasing age and contact with the objective world. In business affairs, however, no amount of reading of books or of closet meditation can take the place of actual experience; but, if all men are equal, then the boy's opinion is as good as the man's, and experience is a mere useless drag.

It seems to be an inherent tendency of our form of government to disregard the value of experience; any man is considered good for any job; all he has to do is to get the votes, by one means or another. Men

who have made little or no study of government, and who have had no experience in it, are considered capable of judging of and administering laws, and of occupying any elective or appointive position. The butcher, the baker, the candlestick-maker, are all eligible for the state legislature, for congress, for the senate, for the mayoralty, for the presidency. This condition necessarily results in gross inefficiency and waste, not always through evil intent, but perhaps more often through stubbornness, ignorance, conceit, or the unwillingness or inability to select and take good advice. We talk much of graft, and rightly condemn it; but, as Lecky has pointed out, corrupt governments are not necessarily extravagant. Graft is injurious mainly to those who practice it. Inefficiency and inexperience are much worse for society in general; and laws which hamper industry, which harass property, or which—through unwise taxation, or extravagant state expenditures for the benefit of particular classes—plunder large portions of the community, are much more injurious to the general good than the pilfering of a few thousands of dollars a year. Sir Henry Maine remarks that the form of bribery which is most to be feared in a democracy is that of "legislating away the property of one class, and transferring it to another."*

Only in one department do we recognize experience, knowledge, and specialized training as necessary, and that department is the administration of justice. No one but a trained lawyer is considered eligible for the position of judge, and in most instances, judges are appointed and not elected, and are, therefore, not driven to seek the votes of the mob, or subject to popular whim, or the arts of the demagogue. For this reason, our Courts have been rightly deemed the safeguard of our liberties. Not until our legislators and our administrators of public affairs are chosen from men trained and experienced, and who have ascended from the bottom step by step, will efficiency, economy, and wisdom be attained in our government. Whether this time will ever be reached may well be doubted. We are much less advanced in this respect than some of the countries in Europe, where the expert is more recognized and has a higher standing, and where knowledge, and particularly experience, are valued more highly than here. If financial measures are under consideration, men experienced in finance should be sought and their advice followed. In our country, experience in finance

*"Popular Government," p. 106.

seems to be to-day looked upon as a disqualification for giving sound financial advice; and it is the same with railway and other affairs. Under such conditions, satisfactory results cannot be attained. Either, as a people, we are more dishonest, or more unwise, than the people of Europe.

In these days, when higher education is a fad, there is an increasing tendency, in my opinion very pernicious, to regard book knowledge as the equivalent of experience. We are more and more inclined to regard those as able to speak with authority, whose knowledge is derived simply from books, who perhaps have spent their lives in a professorial chair, with no actual experience in the subjects they teach or write about. We shall in time learn the fallacy and danger of this; but, in my opinion, at the present time great harm is being done by taking too seriously, in questions of politics, government, economics, finance, and business, and sometimes in engineering, the opinions of theoretical men and closet reformers, whose advice we would not think of following in the conduct of our own private affairs. Some of these men will come within the class of those who, to use the phrase of Mr. E. P. Ripley, President of the Atchison, Topeka and Santa Fé Railroad, have "zeal without knowledge, and enthusiasm without sanity."

Of course, it must not be supposed that experience is everything. In some cases, experience only confirms a man in rule-of-thumb practice, works him deeper and deeper into a rut, and destroys his power of vision. Probably all of us have seen instances of men, whose long experience in doing a particular thing in a particular way has only destroyed their power to see that there is another and a better way, and whose only reason for doing that thing in that way is that they have always done it in that way. Such men, however, would never, under any circumstances, be leaders. They are the soldiers in the ranks, whose only function should be to obey orders. It not infrequently happens, in the administration of some business affair, that a new man with a fresh mind, without experience in that line, but with a power of selecting good advisers, of grasping a new situation quickly, of seeing all the elements involved and of judging them correctly, will arrive at a truer decision than another man of less grasp and judgment, though experienced in the matter in question. This, however, is no argument against experience, but simply illustrates that experience must be combined with grasp and judgment; for the new

man, before he becomes really proficient, must either gain his experience, or must be able to select his advisers well and to rely on them. If we are obliged to choose between judgment and experience, we may well prefer judgment; but experience added to judgment is unquestionably better than judgment alone.

Not only is experience discredited to-day, but we actually find inexperience put forward as a virtue by men who should know better. One candidate for an important elective office, in an address to the electors just previous to the election, urged his qualification for the post on the ground that he had had no business experience which would prejudice his judgment in the matters which would come before him. Is not this a serious disqualification—an admission that his temperament is such that experience would prejudice him, and not teach him? Do we not want men in office experienced in the affairs they are to deal with, but fair-minded and of good judgment, whose experience, instead of warping their judgment, aids and matures it? Woe be to us as a nation when we place inexperienced men in office because experience would warp their judgment.

It is, nevertheless, true that men differ greatly in the amount of experience which they need in order to perfect their powers. This will depend on the rapidity with which they can assimilate it, and the philosophical character of their minds. It has been said that the wisest man is he who can do with the least experience; that is to say, the one who does not need to have an experience repeated again and again before he learns the lesson which it teaches, but who only needs one experience to learn its lesson, and who can extend that lesson to cover other possible experiences, thus rendering the latter unnecessary.

When we are asked, therefore, to believe and advocate any proposed policies, let us train ourselves to apply certain touchstones before we commit ourselves. If the subject is one within our experience, knowledge, and reasoning powers, let us endeavor earnestly to think the matter out for ourselves and arrive at our own conclusions. In the many cases in which we cannot do this let us carefully scrutinize the policies and their proposers, to determine how much credence we can give. Let us observe whether the author asserts them dogmatically or modestly; let us note whether he makes assertions without proof, and by incessant repetition endeavors to make us believe that assertion constitutes demonstration; let us ask whether he speaks from

experience or simply from book knowledge; let us remember that he is not free from the frailties of human nature, and let us, therefore, inquire whether he has any personal interest at stake; let us assume an attitude of doubt and distrust toward all human opinions until that doubt and distrust are effectually removed. It is said that it is better to be deceived than to distrust; but, after we have been deceived, we shall be more inclined to reverse this saying, and to consider that, in the reversed form, it will be, upon the whole, safer and more conducive to our happiness. Let us be on our guard against assuming that good intentions are a guarantee of authority, and when we find ourselves in danger of being influenced by flowers of rhetoric, let us remember that "no man is more dangerous in a state than he who possesses in an eminent degree the power of moving, dazzling, and fascinating his contemporaries, while in soundness of judgment he ranks considerably below the average of educated men"; and let us further bear in mind that "an excessive love and admiration of rhetoric is one of the diseases to which democratic communities are most liable."

4.—*The Tendency to Relax Discipline.*—Another of the demoralizing tendencies of the equality of man is that which has led in recent years, it seems to me, to the gradual but steady relaxation of discipline. It will probably be denied by few that for the proper training and full development of the human being, discipline is necessary. Life itself is little more than discipline; it is not for pleasure; it is for work, accomplishment, development; without discipline there will be no proper development. He who is born with a golden spoon in his mouth and whose life is a continual round of pleasure, is likely to go out of the world less developed than when he entered it. "The beginning of wisdom," says Solomon, "is the desire of discipline." Work, which is itself an end, and rather to be sought than what it brings, consists largely in doing things which in themselves are uninteresting and perhaps distasteful, and we must accustom and train ourselves to be able to do this kind of work cheerfully and well. This ability will be attained only through discipline. Moreover, the man who attains a position of responsibility must be able to direct and command the work of others, and no one can command wisely until he has first learned how to obey. For this, too, discipline is necessary. Yet the tendency of recent years seems to me to have been toward a steady

relaxation of the discipline imposed by law and custom upon the growing individual.

A tendency to relax discipline is strikingly shown where its necessity is obvious, namely, in our educational system. Formerly, the boy was put through a rigid course of prescribed study, some of it interesting and some uninteresting to him; but all of it, presumably, if the course was properly prepared by a capable faculty, necessary for the end in view. The modern tendency has been to substitute what he chooses to do or likes to do. The result has been, and is, that many young men come out of our colleges with minds and faculties practically wild and undisciplined, without willingness to do as they are told; and without the faculty of concentrating their attention on unpleasant but necessary tasks; but, if all men are equal, why should the teacher have the power to impose unpleasant tasks upon the pupil?

That the tendency in education has been to relax discipline, will not, I think, be questioned by many educators who themselves appreciate what discipline is. I understand, for instance, that the National Educational Association has recently said that high schools should be allowed to omit the study of algebra and geometry, and that the colleges should be compelled to accept for admission an equivalent amount of "science." As if we could study science intelligently without a knowledge of elementary mathematics! President Hadley, in a recent address,* comments upon this and emphasizes the fact that real training in science depends upon the method, not the subject; and he adds that "fifty years ago the one course in the academic department of Yale College where modern science was really taught, was the course in freshman Greek," because it was taught by the scientific method. Would that we had more teachers like the Hadleys, father and son. Our teachers are generally, I think, chosen upon an incorrect principle; they are appointed by reason of what they know; it seems to me they should be selected for what they are—for their ability to teach, and their power of enforcing scientific discipline. We may well ponder to-day the words of that fine old English schoolmaster, Richard Mulcaster, who died 302 years ago, and who wrote:

"I would rather hazard the reproach of being a severe master in making a boy learn what may afterwards be of service to him, even though he be negligent and unwilling at the time, than that he should

Science, May, 1913.

lack any advantage when he is older, because I failed to make him learn, owing to my vain desire to be considered a courteous teacher."

The tendency toward a relaxation of discipline shows itself also in our laws. We congratulate ourselves on our humanity, because the long list of severe penalties, which formerly existed, has been replaced by a code much less severe; but have we not gone to the other extreme, encouraging a spirit of lawlessness and an unwillingness to submit to proper restraint? If one person shoots another with intent to kill, is the crime any less when the wound is slight than when it is fatal? Why is an attempt to wreck a railroad train, or to dynamite or set fire to a building which may involve the sacrifice of many lives, any less serious than to kill a man in a quarrel? Why should not the depraved individuals who commit acts like these be at once put out of the way for the good of society? Our nerveless laws and the misdirected efforts of inflamed philanthropy condone offenses all along the line. We coddle and sympathize and send flowers, where we should be stern and insist that the good of society is the first thing to be considered. Even in our daily dealings with individuals in matters not within the province of the law, we fail to realize that a prescription often needed, instead of coddling, kind words, sympathy, and self-sacrifice, is the prompt and energetic application of the toe of the boot to the lower end of the spinal column, repeated if necessary, until relief is obtained. We are victims to-day, it seems to me, of an exaggerated humanity, as well as of a decay of discipline. Large numbers of men and women with warm hearts and good intentions are exalting sentiment above sanity, sympathy above truth, and ease above discipline.

5.—Another of the tendencies very marked at the present time, is the spirit of innovation, which seems to pervade all things; whatever is, is wrong; the social custom must be changed in order to keep up with the time. This spirit is particularly observable among the young and the immature, especially if it has been preceded or accompanied by a lack of discipline in early training. It is an instance of what Ferrero terms "that youthful spirit of innovation which is in all ages the main source both of perversion and of progress." Many of our young men, "all aflame with an enthusiasm unquenched as yet by any continuous contact with affairs," set out to reform the world, not so much because it needs reform, as because they wish to justify their

existence. This spirit of innovation is at all times one to be expected and reckoned with. Every generation, as it comes along, will endeavor to change the condition in which it finds itself, and will designate that change with the name of progress, even though it be perversion. Oh! Progress! what crimes are committed in thy name! Even if a social condition were perfect and ideal, a new generation would endeavor to change it. Youth desires change; often because it knows no better. Age becomes conservative because it knows by experience the dangers of hasty or unwise change. The spirit of equality accelerates this tendency.

The United States is often spoken of as the country of the young man; the old are laid on the shelf just as soon as they become conservative, because wisdom, experience, and the authority of age are not respected. The adage, "old age for counsel, youth for action," is modified by the omission of the first half. Old age is not regarded at all, as soon as it desires stability and permanence rather than change. This tendency is certainly much more observable in this country than in Europe, where the wisdom which comes from age and experience is recognized and utilized. Gladstone and Voltaire did their best work after they were 60; Bismarck did his after he was 50. Gray hairs are common in the highest councils abroad. Here they are considered rather a symptom of decay.

This spirit of innovation which pervades all things seems to be largely a result of scientific progress; the rapid advances made in inventions of all kinds, the improvements in the arts and manufactures, have resulted in a complete revolution of the methods in many branches of industry within a comparatively few years. Men now living were born before there were any railroads, and almost all of us can remember the time when the applications of electricity were just beginning. An industrial plant but a few years old may be out of date and unable to compete with newer and more economical installations. In engineering matters we are accustomed to see things completely remodeled within a short time.

This familiarity with industrial change and the recognition of its benefits have naturally led to the idea that everything must be reconstructed, or it is old-fashioned and out of date, even though it be a thing in which there have been no new discoveries, warranting any change whatever: music, painting, dancing, education—everything, in

fact—must be completely reorganized. This willingness and desire for change afford the opportunity for unsuccessful mediocrity and for ambitious and unscrupulous failure to foist upon the public, which eagerly accepts it, forms of change which discerning men must characterize as gross, ridiculous, and demoralizing. The result, in many cases, is a deterioration pitiable to behold. Let any one compare, for instance, the modern painting, dancing, and music, with that in vogue fifty or one hundred years ago, and he will find abundant proof of this. In politics and government, too, the same tendency, the same recklessness, the same demoralization, are equally observable.

Now, of course, an existing condition is not necessarily the best because it is old; neither is a proposed change advisable because it is new. In many cases, however, suggested changes, ignorantly proposed by those unacquainted with history, have been tried and have been found wanting centuries ago. History repeats itself. Nations, like individuals, will only learn by costly experience. Away with the old, make way for the new! We will not profit by the lessons of our forefathers, we must experiment and learn for ourselves. Is it not much better that we should try to cultivate the breadth of view, the tolerance of opinion, which will lead us neither to adhere to that which is old, from extreme conservatism, nor to indulge in rash experiments; but to study history, cultivate a sound and deliberate judgment, and endeavor to guide the inevitable spirit of innovation into proper channels; and to remember, as Lecky well says, that "an appetite for organic change is one of the worst diseases that can affect a nation?"

6.—Advancing civilization and increase of wealth inevitably lead to increased luxury and extravagance; and, with our advancing civilization, this tendency is not wanting. If the experience of the past is of any value, however, it is a serious symptom of degeneration. The sudden accession of great wealth, particularly to those who are incompetent to use it wisely, engenders luxury and ostentation, and a contempt for those less fortunate; thus stimulating, to a certain extent, an attempt of the latter, particularly if endowed with the ballot. to recoup themselves and gain what they conceive to be their rights at the expense of wealth, by various forms of unjust taxation and other well-known expedients. If it is our duty to preach the gospel of content and the inequality of man, it is equally our duty to preach the proper use of wealth, and the proper attitude of the wealthy toward

those less fortunate; and while believing that individual initiative should be stimulated to the utmost, and allowed to enjoy the fruits of its success, it may, nevertheless, fairly be questioned whether some of the rewards under present conditions are not too large, and whether men would not exert themselves as well for the prospect of a more reasonable recompense as for the prospect of unreasonable and excessive riches. But, again history repeats itself, and things move in cycles. Peace causes prosperity, prosperity gives rise to wealth, wealth gives rise to luxury and extravagance, luxury and extravagance are the source of contention, contention results in war or social revolution, these result in poverty, poverty results in peace, and so the cycle is completed.*

Ferrero, writing of the condition of Rome in the Second Century, B. C., wrote:

"The destruction of Carthage and Corinth had already worked serious havoc in Roman life, spreading luxury and ostentation among the upper classes, a distaste for work among the lower, and wastefulness and intemperance in all ranks of society."

Do we not see before us to-day in America the same phenomena? It is not the destruction of Carthage and Corinth which have worked and are working serious havoc in our life, but it is the conquest of the virgin resources of a great continent. Wealth, luxury, and ostentation are the result, and nothing is more plain than the fact that a distaste for work exists and is spreading broadly among the lower classes, and wastefulness and intemperance everywhere.

7.—The last tendency to which I will call attention is what seems to me the distinct tendency, under present conditions, and, in fact, under conditions which have existed in increasing degree as civilization has advanced, toward the deterioration of the race. The law of evo-

*The following verse is taken from a collection of old French proverbs:

"Paix engendre prospérité,
De prospérité vient richesse,
De richesse orgueil et volupté,
D'orgueil contention sans cesse,
Contention la guerre addresse
La guerre engendre pauvreté,
Pauvreté humilité,
D'humilité revient la paix,
Aussi retournent les humans."

"The following passage from Ramsay's 'Voyages de Cyrus' contains a similar view with respect to the succession of causes and effects in the affairs of nations:—'Pendant l'espace de trois cens ans la valeur des rois de Médie avoit augmenté leure conquêtes. Les conquêtes avoient engendre de luxe, et le luxe est toujours l'avant-coureur de la chûte des empires. Valeur, conquêtes, luxe, anarchie, voilà le cercle fatal, et les différens périodes de la vie politique de presque tous les états.'"

lution in all species of animals and plants, the law which we ourselves recognize and follow in breeding and cultivating them, is for the survival of the fittest, the gradual elimination of the weak and unfit. This is distinctly the law of progress. In the case of man, however, there is added an element which does not exist with the lower animals or with plants, namely, the element of human reason. Under the domination of this element, has not the tendency steadily been, with the growth of altruistic ideas and the prevalence of philanthropic institutions, toward the survival of the unfit? Are we not encouraging in many ways the survival of the weak, the inefficient, the incompetent, the depraved? If all men are equal, he who is born with an inheritance which makes him depraved or incompetent is not responsible for that inheritance, and is as much deserving of preservation as the strongest and the best.

Galton, in his researches on heredity, comes to the conclusion that the average Greek of the Athenian Age was as much superior intellectually to the average European of to-day, as the latter is superior to the average African savage. At the present time, in all probability, the uncivilized races are governed by the law of evolution, the survival of the fittest; while, in the case of the so-called civilized races, the reverse seems true. The two tendencies must meet and cross at some point in the future, if they continue.

This problem is one of the most serious that confronts us to-day. I have no time, even had I the knowledge, to discuss it in detail; I will content myself with merely mentioning it. It may seem wrong to believe that all have not equal right to survive, yet it seems to me that the interests of society as a whole must lead us to the conclusion that serious evil, and perhaps ultimate ruin, await us unless some means can be devised for solving this problem and in some manner regulating the perpetuation of our species. If present-day humanitarianism leads to race degeneration, it cannot be the way of progress intended by an all-wise Creator, and we should try to see in what way we are misapplying it. The subject is manifestly beset with great difficulties. In the first place, we must define the "fit." Clearly, the term is not synonymous with the physically strong, or the wealthy; many of these are most unfit. Equally clear is it that the fit do not include those afflicted with serious hereditary disease, the dishonest, the vicious, the intemperate, the indolent, the good-for-nothing. "If any will not work,

neither let him eat," says the Apostle. Those that will not work should starve, in other words. He adds: "For we hear of some that walk among you disorderly, that work not at all, but are busybodies." May it not be that the true main-spring of progress and prosperity is an enlightened selfishness—a selfishness which leads the individual to seek as his paramount object his own good, subject only to one limitation, that no injury should be done to any one else—that not self-sacrifice, but only a scrupulous regard for the rights of others, is the condition of race progress?

And now you may very likely have asked, what has all this to do with engineering, or with the engineering profession; what is the appropriateness of a discussion of social conditions before a society of engineers? My answer is that the engineer is primarily a member of the social body; that its problems are his problems; and that he cannot avoid the responsibility of taking a share in their solution. The problem of the Twentieth Century, it seems to me, will be pre-eminently a social problem, and upon its solution will depend the happiness of mankind for years to come. Moreover, this social problem is largely, as I have shown, the outcome of the work of the engineer who, as the advance agent of civilization, has been the main factor in creating the conditions which give birth to this problem. It will be evident, therefore, that I differ from one of my predecessors who, in his annual address, intimated that social problems were out of the province of the engineer and that he should not meddle with them. On the other hand, I maintain that it is his duty to exert himself in their solution. Moreover, I consider this duty the more necessary because I believe the engineer to be well fitted—possibly better fitted than any one else—to solve these problems wisely. Let me briefly give you my reasons for this opinion.

The engineer is by training a scientific man. If his education is what I conceive it should be, and what it will be more and more in the future, it will consist of a training in mathematics, logic, science, and in the technical branches of his profession, together with a sufficient amount of study of the humanities—history, economics, language, literature—to give him a clear view of the relations of things. He will be pre-eminently by training a scientific man, but with a power of understanding and grasping social questions. Now, a scientific training has this great virtue, that its end and aim is constantly

the discovery of the truth. The truth for its own sake, independent of everything else, is the object of the scientific man and therefore of the engineer. In this respect, it is, in my opinion, the noblest as well as the most widely useful of the professions. The lawyer is not always concerned in arriving at the truth; he is too frequently tempted to make the worse appear the better reason. As one of that profession has expressed it, his object is not to get at the truth but to win cases. He is constantly under the temptation to pervert the truth, or to suppress it, if the exigencies of his case demand.

Furthermore, the engineer is exposed to a very direct personal responsibility which cannot but steady his character and increase his self-reliance and self-control. Though he does not always receive the credit of his successes, he cannot succeed in throwing the responsibility for his failures upon others. If a lawyer loses his case, as Mr. Choate once remarked, it is never his fault; he can always charge it to the prejudice of the judge, or the ignorance of the jury, or the untruthfulness of witnesses. He goes on and obtains new clients and new fame. If the doctor loses his patient, it is never his fault; he can always charge it to the disobedience or delay of the patient, or maintain that a cure was impossible. But if an engineer builds a structure which fails or a machine which will not work, the responsibility is his and he is held accountable.

Again, the engineer is a business man, for engineering is business and business is engineering; he deals with men, he has to do with financial affairs, he learns the characteristics of human nature, and his training, therefore, tends to teach him tact, moderation, conservatism, and the value of experience.

Of course, any sweeping eulogy or disparagement of any class of men cannot be truthfully made. Engineers will differ on questions of opinion, as other men will. There are dishonest, untruthful, unreliable engineers, as there are men of this type in every class. No doubt the ranks of our Society include men who will widely disagree on the questions which I have discussed; men who will hold extreme views in one direction or in the other; men who will be dogmatic, intemperate in language and in thought, inaccurate in reasoning, insincere in opinion. No class of men has a monopoly of virtue or of error. Neither are these excesses confined to men of weak minds or deficient training. As Lecky says:

"Strange veins of insanity and capacities for enthusiastic folly sometimes flaw the strongest brains, and the impetuous ebullitions of youth which impel some men into extravagances of vice, develop in other natures into not less wild extravagances of thought."

Nevertheless, on the whole, if there is anything in training and experience, may we not believe that engineers, as a class, have the training, temper, and experience which will best enable men to judge sanely and solve wisely the social problems which confront us?

What, then, may the engineer do to aid in the solution of the social problems of the Twentieth Century?

In the first place, he should consider it his duty not to retire into the technical recesses of his professional work and content himself with being the servant of other men, but should actively exert himself and take the initiative in the great problems of the day. He will find that many of these problems in their details are largely of an engineering character.

What, for instance, is involved in the problem of administering the affairs of a great city? Do they not involve, in the main, the preservation of the health, safety, property, and order of the community? and are they not, therefore, predominantly of an engineering character? Financial and legal questions of great importance, of course, are included, but why should the engineering problems be considered secondary to these? Engineers can employ financiers and lawyers, as well as be employed by the latter. I see no reason why the position of mayor of a city could not be filled at least as satisfactorily by an engineer with proper breadth of view, training, and experience, as by a man of any other profession. Yet I doubt if the mayor of any large city in the United States is or has been an engineer.

The same holds true of other administrative positions. The management of our great corporations involves problems largely of an engineering nature, and high administrative positions in these concerns are being more and more given to engineers. Even such a position as that of president of a republic is not one which the engineer should necessarily consider himself excluded from. Why is he not as well qualified to fill it as a soldier, a lawyer, or a college professor, provided his training and experience, judgment and breadth of view warrant? Two of our greatest presidents, Washington and Lincoln, though not engineers, did have some little practice in what was then

termed engineering, and one president of the French Republic has been a professional government engineer.

There is perhaps a tendency to-day toward better recognizing the qualifications of the engineer in the administration of municipalities and larger political units. The position of commissioner of public works in a city is perhaps the most important municipal position next to that of mayor. Formerly, this position was monopolized in most cities by men who were mere politicians. Nowadays, it is quite common to appoint engineers to such posts. In Boston, Philadelphia, Cincinnati, and very likely other cities, these positions are now held by trained and educated engineers, and this recognition I consider significant and deserved. Engineers, however, will not and should not be recognized in this way unless they are as individuals equal to the responsibilities involved, unless they show their interest in public questions, unless they inform themselves about them, unless they study the economic and social, as well as the engineering problems involved, and unless they assert themselves before the public. This I trust they will do more and more as years go by.

"The fault, dear Brutus, is not in our stars,
But in ourselves, that we are underlings."

A question which is much before us at the present day is that of conservation. Conservation, as I understand it, consists in a wise economy and proper use of the materials and resources that are afforded us by Nature. It is essentially the avoidance of waste; it does not mean that natural resources shall be withdrawn from use, but that they shall be used wisely and economically. It does not mean that the present generation shall *suffer* for the benefit of future generations, but that the present generation shall not *rob* future generations. Now, the technical problem of the avoidance of waste and the proper use of natural resources is a problem already solved. Applied scientists can tell just what to do and how to do it. They know how to utilize the power of falling water and how to transmit it; they know how to utilize coal most economically, they know how to utilize forest products without waste, how to prevent the erosion of the soil, how to conserve health. The unsolved problem of conservation—the problem which now concerns us most—is not an engineering problem, but a social one. It is to alter the public state of mind, to make people thrifty and economical instead of extravagant and wasteful. It is

thus an attitute of mind that we have to deal with. If the attitude of mind of the public toward this problem could be made the correct one, if the individual man could be made thrifty, frugal, careful, thoughtful of the future, the problem of conservation would be solved. Why should not applied scientists, who know how to solve the problem technically, lead in educating the people to perceive the necessity for its solution? Should not mere self-interest, not to speak of public spirit, prompt us to do this?

In education, too, where, as I view it, the tendencies I have referred to are plainly evident, we may as a profession exert a good influence. I have often expressed the opinion that an engineering education is the best possible education for any vocation, because it combines, or should combine, in the best proportions, the study of abstract relations with that of natural science and of the humanities. These, combined with training and experience in the profession itself, should make the engineer as well educated as any class of men. He should be sane and sensible, not likely to be carried away by fallacious economic theories; conservative, and yet safely progressive. Engineers, I think, should exert more influence than they do in education, by actively interesting themselves in it, serving on school committees, and insisting on the maintenance of rigorous discipline and the scientific method. Above all, they should aid in maintaining the standard of engineering education, and prevent it from succumbing to the prevailing tendency to relaxation of discipline. The best students do not really seek such relaxation; and schools which make students work hard and which insist on a high standard of accomplishment, will attract strong men. The tendency of the times shows this, and proves that one movement to-day is toward utilitarian and vocational training. Some of the tendencies I have referred to may be in large measure only surface currents, and a strong undercurrent may perhaps be generated in another direction if the proper means are used. This is indicated by the growth of the engineering departments of our State universities within the last thirty years, and by the surprising development of such a school as the Massachusetts Institute of Technology from its first small beginnings to its position of recognized leadership in less than one-third of a century. Let us make the engineering schools the place of refuge for those who are opposed to the relaxation of discipline which prevails so largely elsewhere.

Finally, let us inquire what this Society, representing the Engineering Profession, may do in the directions which have been suggested. We have been criticized in the past as being inactive, as taking no part as a Society in large public questions. I must frankly confess that the criticism has seemed to me in some measure deserved. Our Society is large, rich, influential, but we have been too content to sit down in dignified ease, taking little or no initiative, and allowing other and younger societies to outstrip us in actual work performed and in real influence exercised. We have had some committees which have done good work in unifying practice in relation to technical matters. In these respects, however, we have been far surpassed by two or three of the newer societies, whose committees, after long and conscientious labor, have exercised far greater influence that we have in the solution of even professional problems. It is true that this is largely due to the fact that those societies are more specialized than ours, that they are composed of men all engaged in one line of work, who could co-operate and lay down the results of experiment, experience, and opinion more easily than we could. This Society, however, is the American Society of Civil Engineers, and includes engineers in all branches and from all sections of the country. There is no reason why the engineers in the different branches should not associate themselves together in sections, or why we could not do more committee work along the various engineering lines than we have done in the past.

I believe, therefore, that we should favor the establishment of branches of the Society in various parts of the country, and of student branches in the several technical schools; and that we should urge our committees to activity, supply them with funds, and perhaps pay the mileage of members who attend meetings. The Society is rich, and it is not a philanthropic institution. If members give their time to committee work, I see no reason why they should be expected to give money, and the expense of attending many meetings may not seldom be considerable.

Moreover, we have been very loath to take any steps in formulating answers to questions which are largely matters of opinion; and we have done, thus far, little or nothing to influence public opinion in regard to questions of the day. I believe that we could and should go much farther in these directions; that we should step forward, take

the initiative, and become a moving force in the community. Let me make some more definite suggestions.

In the first place, I believe we should have a standing Committee on Public Relations, its province being to keep track of all public affairs involving engineering questions directly or indirectly, in all the States in the Union, and to take such action as may be deemed desirable to insure a wise treatment of such questions. This committee might perhaps consist of the President and Secretary of the Society *ex officio*, of a certain number of members of the Board of Direction to be appointed each year by the President, and of a certain number of members of the Society not members of the Board of Direction, to be nominated by the Board of Direction. These outside members might be in considerable number, perhaps one or more from each State, or group of States, so that the committee could keep in touch with public affairs affecting the profession in all parts of the Union.

Further, our Committee on Engineering Education should, in my opinion, be enlarged, supplied with funds, and encouraged to active and exhaustive work. If we could lay down the principles which we believe should govern in engineering education, the general curriculum which should be adopted, the proportion of the humanities which should be included, and similar matters, we might, I believe, do much good, and, while still leaving ample room for individual initiative and divergencies in practice in different institutions, render effective aid to those teachers who are striving to resist some prevailing tendencies.

In the next place, I believe it will be wise to have more committees of the Society, dealing with specific problems, than we have had in the past. You have before you at this meeting, I am glad to state, a report from the Board of Direction stating that, as provided in the Constitution, it has voted to appoint two Special Committees, to deal respectively with the Regulation of Streams and with Uniform Water Legislation. I believe that still other committees could be appointed to advantage. We have no reason to be afraid of having too many committees. We should, rather, be sure that we lose no opportunity to exercise legitimate influence on public opinion or to aid in the solution of large problems. We might well, I believe, have a standing committee on conservation, perhaps another on corporation legislation, another on the history of American engineering. Let us give our earnest attention to this matter, and let us not hesitate to

suggest any and every means that may occur to us to promote the welfare of the Society, of the profession, and of the public. The Board of Direction will be always ready, I am sure, to act promptly with any members of the Society who can show a proper field for legitimate action.

Reviewing then, the points which I have brought to your attention, I have endeavored to show that the problem of the times is pre-eminently a social problem. I have outlined some of the tendencies of the day, as they appear to me. I have given the reasons for my belief that it is the duty of engineers to aid in the solution of these problems, and that by training and experience they are well qualified to do so. If my tone has appeared to indicate a pessimistic attitude toward the tendencies of the day, I fear I must plead guilty in some degree to the imputation; whether wisely or not, as the years have gone by, I have grown more conservative, and I find myself having little sympathy with many of the tendencies which I seem to see about me. I believe that this age will be looked upon by future generations, not as an age of progress, except in some material things, but more distinctively as an age of deterioration, an age of fads, frivolities, fancies, and follies; of much reading and little thought; an age of impulse rather than an age of reason. I am not alone, however, in a feeling of dissatisfaction. M. P. Leroy-Beaulieu, writing in 1890, and referring to conditions in France, expressed himself as follows:

"Every age is characterized by its particular craze. The present craze is for education, unlimited and injudicious, and for philanthropy equally unlimited and injudicious, both absolutely superficial. By their aid we have succeeded in producing a mental condition and in creating certain social circumstances which are most unfavourable to the growth of the population."

However, after all, it is only an epoch in the history of man. It will pass away, and others will solve the problems that we leave to them. Progress is not always continuous; there are waves, reactions, times of apparent retrogression. May we only do our part, as members of one of the greatest professions, to help direct the tendencies of our day in such manner that our successors may look back upon us with approval and not with blame, and that we may aid to the utmost in forwarding the true progress of mankind.

Paper No. 1267

A MECHANISM FOR METERING AND RECORDING THE FLOW OF FLUIDS THROUGH VENTURI TUBES, ORIFICES, OR CONDUITS, BY INTEGRATING THE VELOCITY HEAD.

By J. W. Ledoux, M. Am. Soc. C. E.

During the last century, and even prior thereto, investigations, both theoretical and practical, and many experiments were made in order to solve the problem of the flow of water through pipes, orifices, short tubes, etc. Venturi, an Italian investigator, made very interesting experiments about 1790, and devised what has since been called Venturi's tube, which, due to its peculiar shape, possessed the property of discharging water with a very small amount of friction. He, as well as later investigators, deduced formulas for the velocity and velocity head which do not differ much from those at present in use.

In 1887 and 1888 Clemens Herschel, M. Am. Soc. C. E., first suggested the practical use of Venturi's tube as a water meter.* His suggestion was far-reaching, because any device that could be used to record or integrate the velocity head of the Venturi tube would also perform that function for any orifice or contraction in a pipe or conduit wherein the flow is a function of the velocity head. Since that time many efforts have been made, with varying degrees of success, to design a registering mechanism which would indicate reliably the

* *Transactions*, Am. Soc. C. E., Vol. XVII, p. 228, and Vol. XVIII, p. 133.

total discharge through such a tube or orifice. Mr. Herschel has made several inventions of this character.

One of the most attractive devices for this purpose consists of a small meter in a by-pass connecting the full and contracted sections of a Venturi tube. Several engineers, including the writer, have independently conceived this idea, but afterward abandoned it as impracticable. At high velocities such a contrivance will give approximate results, but when the velocity is low, the velocity head, or moving force—which varies as the square of the velocity—is too minute to operate a moving mechanism.

Some of the early devices for indicating and recording the velocity head were based on Bourdon tubes, and in some cases diaphragms balanced by springs were used. One of Mr. Herschel's earliest devices was an ingenious apparatus based on the former principle; but, eventually, all these were abandoned in favor of mercury, which was found to be much more constant, reliable, and satisfactory as a transmitting medium.

The fundamental principles of the subject will be considered briefly. The flow of water and other liquids as well as gases follows the eternal and unchangeable law of gravity. For steady flow this may be represented by the expression: "Velocity is proportional to the square root of the head producing velocity," or, algebraically,

$$V = C\sqrt{H},$$

in which V = the velocity, in any convenient unit,

H = the head producing such velocity,

and C = a constant depending on the unit of measurement and the character of space through which the fluid flows.

V may be expressed in feet per second, miles per hour, etc., and H, the effective head, may be expressed in feet, or in pounds per square inch, etc.

The space may be a pipe of any length, a submerged orifice, an open inclined channel, a Venturi tube, or a nozzle. It is seen that this is the form of the simplest equation of a parabola:

$$y^2 = cx.$$

For practical purposes, the ideal form of meter would be a device, connected by small tubes with adjacent parts of a pipe through which fluid is flowing, which would measure automatically the square root

of the head or pressure producing the velocity. Such a device would offer no resistance or obstruction to the flow through the pipe. It has been impossible, heretofore, to achieve this ideal, because the forces due to velocity head are so minute as to be difficult, if not impossible, to measure or integrate when the velocity is low.

Theoretically, the Venturi tube is a contraction in the pipe, formed so as to cause small frictional resistance to flow; and it is remarkable how slight this contraction may be in order to produce the same difference in velocity head as that caused by Pitot tubes without contraction in the pipe. In fact, the diameter of the contracted portion need not differ from that of the full section by more than 17.7% in order to produce the full effect of two Pitot tubes, one pointing up and one pointing down stream, with their openings in the center of the pipe, or at the points of maximum velocity. In practice, however, the Venturi tube is composed of a short pipe continuously connected with the main pipe by a conical section pointing up stream and a longer conical section pointing down stream, the convergence of these two sections being dependent on experimental determinations, the object being to obtain the highest flow with the least frictional or unrecoverable loss of head through the entire Venturi tube. These angles of convergence and divergence have been determined by Venturi and, in more modern times, by Weisbach, Eytelwein, Francis, Smith, Herschel, and possibly others, but, at any rate, it is pretty well settled that they should be somewhere between fairly wide limits, beyond which the results are certainly not as good. However, they may be relatively the same for all Venturi tubes, whether the contraction is nearly as large as the pipe or very much smaller, the difference being that in the former case the entire Venturi tube would be short and in the latter case long. Of course, the purpose of a Venturi tube, the contracted section of which is small as compared to the full bore of the pipe, is to exaggerate the velocity head indications so that they can be observed and measured, especially for low flows. To illustrate, consider the simple formula of a standard Venturi tube, having a coefficient of velocity = 0.977:

$$V = 7.84 \left(\frac{H}{\left(\frac{D}{d}\right)^4 - 1} \right)^{\frac{1}{2}}$$

in which the only two variables are V and H.

V = the velocity through the full section, in feet per second;
H = the difference in piezometric heads between the up-stream section and the contracted section, in feet;
D = the diameter (or radius) of the full section;
d = the diameter (or radius) of the contracted section.

This formula may be written:

$$H = 0.0163\ V^2\left(\left(\frac{D}{d}\right)^4 - 1\right).$$

Now, assume a velocity in the main as low as 0.25 ft. per sec. Then the formula may be written

$$\left(\frac{D}{d}\right)^4 = 1 + 982\,H;$$

and assume 0.01 ft. to be as low as it is possible to indicate H; then

$$\frac{D}{d} = \sqrt[4]{10.82} = 1.86,$$

which means that when the velocity through the main is as low as 0.25 ft. per sec., if it is desired to get an indication of the velocity head as great as 0.01 ft., the contracted section of the Venturi tube must be less than 54% as large in diameter as the main. However, with a tube having ratios of diameters equal to 3 to 1,

$$H = 0.0815 \text{ ft. for } V = 0.25 \text{ ft. per sec.}$$

Even this result cannot be obtained with the best apparatus formerly in use, unless one of the essential features of the Venturi meter is seriously sacrificed, namely, the measurement of high velocities.

The best types of Venturi meter registers have formerly depended for their registration on some form of cam having a parabolic curve, fashioned around a drum or revolving about a center. Near zero, or the origin, the curve changes in direction rapidly, and at zero crosses one of the axes of reference at right angles and becomes parallel to the other. It is probably this feature, more than any other, which has limited the minimum velocity measurable by a Venturi meter; and though the measurement of low velocities is attainable by a high ratio of tube diameters, there is thus encountered the other difficulty of excessive frictional loss through the Venturi tube for comparatively high velocities. If it is even intended to measure velocities as high

as 10 ft. per sec., which is occasionally desirable, the frictional head through a Venturi tube having a ratio of 3 to 1 in diameters, or 9 to 1 in areas, would be 17 ft., obtainable from the formula:

$$H_f = 0.0021\ V^2_2,$$

in which H_f = the frictional head, in feet,

and V_2 = the velocity through throat, in feet per second.

Besides that, in any form of register depending on mercury as the medium of indicating the velocity head, in order to cover ranges of velocity from 10 ft. per sec. down to zero, the apparatus would have to be more than 11 ft. high. In a tube having a ratio of 2 to 1 in diameters, or 4 to 1 in areas, with a velocity of 10 ft. per sec. through the main, the frictional head would be only 3.36 ft. This is still a material loss, but a velocity of 10 ft. per sec. is unusually high.

It must be remembered that, as far as metering a fluid is concerned, any form of orifice or contraction in a pipe would be just as good as a Venturi tube. It is also highly probable that the coefficient of flow would remain as nearly constant through just as wide a range of velocities; but the great advantage of a Venturi tube is in its small frictional resistance to flowing fluid, and in this respect it is the best shape yet devised.

The writer will now describe a form of meter register particularly adaptable to the registration of flows through any form of orifice, such as by the use of Pitot tubes and Venturi tubes of small ratios and consequently minimum frictional heads. The fundamental principles were discovered by the writer in 1904 and were finally developed into the best practical working form in 1909. The basic idea is a float, shaped so that, when acted on by the head due to the velocity of flowing liquid, its movement will be directly proportional to that velocity.

The device is novel in form, and covers a principle in hydraulics, which, although rational and perfectly obvious on analysis, the writer believes has not heretofore been recognized. This may be stated as follows: If a hollow body of any shape, with open bottom, floats freely in a liquid having the same specific gravity and touches another liquid of greater specific gravity, and if the relative pressures without and within this hollow body are changed so as to make the internal pressure less than the external pressure, then the body will sink into the heavy liquid, and the amount of displacement will be exactly

equal to the quantity of the heavier liquid which will pass up into the interior of the body and above the level of the heavier liquid outside of the body.

Let the hollow body, or float, be represented by *n n a a*, Fig. 1; assume it to be a figure of revolution, and call the total volume of heavy liquid, *a a m m*, within the float *M*.

The principle may be understood by a consideration of the laws of equilibrium—the algebraic sum of the vertical forces must be equal to zero; the sum of the horizontal forces, and the sum of the moments must all be equal to zero. We need consider only the first condition as affecting the problem. At the plane, *b c c b*, the heavier liquid is subject to the same unit pressure within and without the hollow body, but the resultant of external forces acting downward on the hollow body is measured by the weight of the heavier liquid, *m m c c*, and the total upward force acting on the body is the displacement of the annular portion of the body, *bcabca*. For equilibrium, the algebraic sum of these two forces must be equal to zero, and, as one is positive and the other negative, they must be equal in amount; but, if that is the case, the entire quantity of liquid equivalent to the displacement of the hollow body, and no more, must be found in the interior of the hollow body, and hence the outer level of the surface of the heavy liquid does not change with variations of pressure outside and

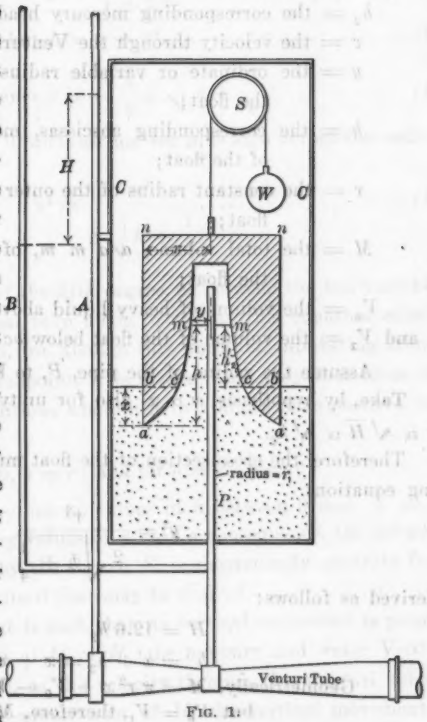

FIG. 1.

inside the float.* If there is a difference of pressure, H, then the float will sink into the heavier liquid an amount represented by the annular volume, *acb*, which will be called V; and the net volume of liquid *m m c c*, will also be equal to V, and h_2 will be proportional to H. As before stated, the level *bb*, will always be the same, no matter what the values of H, h_2, and V may be.

Let x = the vertical movement of the float from a given datum;
H = the Venturi head;
h_2 = the corresponding mercury head;
v = the velocity through the Venturi tube;
y = the ordinate or variable radius of the inner portion of the float;
h = the corresponding abscissas, measured from the bottom of the float;
r = the constant radius of the outer cylindrical portion of the float;
M = the total volume, *a a m m*, of the heavy liquid within the float;
V_0 = the volume of heavy liquid above *cc*;
and V_1 = the volume of the float below *bc cb*.

Assume the radius of the pipe, P, to be small and negligible.

Take, by hypothesis, $v \propto x$, also for unity coefficient, $x^2 = h_2$, for $v \propto \sqrt{H} \propto \sqrt{h_2}$.

Therefore, the cross-section of the float must conform to the following equation:

$$y^2 = \frac{r^2}{2\sqrt{h + \frac{1}{4}}}$$

derived as follows:

$$H = 12.6\, h_2$$

$$h = x + h_2 = x + x^2.$$

Geometrically, $M = \pi r^2 x + V_0 - V_1$

but $V_0 = V_1$, therefore, $M = \pi r^2 x$ .....(6)

Differentiating, we have $\frac{dM}{dx} = \pi r^2$ .....(7)

* If the float were not free to move vertically—that is, if it were restricted in any way, as with a variable lever arm, counterweight, or spring—then the movements of the liquids would not follow the law stated; but, as the difference of pressure became greater, the surface level of the heavy liquid would fall below a fixed level on the outside and rise above a fixed level on the inside.

Also, by the differential equation of cubature,

$$M = \pi \int_{h=0}^{h=x+x^2} y^2\, dh \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (8)$$

Differentiating, we have $\dfrac{dM}{dx} = \pi y^2 (1 + 2x)$ $\ldots\ldots\ldots\ldots\ldots\ldots\ldots (9)$

Combining Equations (7) and (9) and reducing, we have

$$y^2 = \frac{r^2}{1 + 2x} \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (10)$$

$$\text{but } h = x + x^2 \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (11)$$

$$\text{hence } x = -\frac{1}{2} \pm \sqrt{h + \frac{1}{4}} \qquad \ldots\ldots\ldots\ldots\ldots\ldots (12)$$

and as $h = 0$ when $x = 0$, we must use the plus sign before the radical, therefore,

$$y^2 = \frac{r^2}{2\sqrt{h + \frac{1}{4}}} \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (13)$$

This is an equation of the fifth degree, as between the two variables, h and y. No attempt has been made to discuss this equation exhaustively or plot all the loci, for, though this would be interesting from a purely mathematical standpoint, it is evident that only that locus will satisfy the physical conditions wherein both h and y have positive, real values.

For $h = 0$, $y = r$; and for $h = \infty$, $y = 0$,

thus it is seen that there are no values of h between 0 and ∞ which give infinite or imaginary values of y. As a consequence, the integrating apparatus operated by the sheave, S, is theoretically accurate from zero up to any practical limit that may be desired.

The shape of the float is such that its vertical movement is proportional to the square root of h_2 or H (the mercury and water Venturi heads, respectively); and, as the velocity through the Venturi tube is also proportional to the square root of H, the vertical movement is directly proportional to the velocity or quantity of water passing through the Venturi tube. The same principle will hold true if the Venturi tube is replaced by any form of orifice, or if the pipes, A and B, be connected with Pitot tubes in a main; for, in any of these cases, the H values represent velocity heads, the same as they do for Venturi

tubes, and the velocity heads are always proportional to the square of the velocity producing the head.

It is perfectly practical to have x^2 less or greater than h_2, for, if we assume $cx^2 = h_2$, Equation (13) becomes:

$$y^2 = \frac{r^2}{2\sqrt{c}\sqrt{\frac{c}{4} + h}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (14)$$

which is the more general form, in which we can give to c any value, consistent with practical limitations. For general use, however, Equation (13) is satisfactory, particularly as there is no value of c which increases or diminishes the accuracy of the apparatus.

In these calculations, the radius of the pipe, P, within the float, is assumed to be so small that it does not affect the results. Even if no correction is made for this volume, the error at low velocities would be negligible, and, at maximum velocities, it would be less than half of 1%, provided the pipe is made as small as possible. Its effect is to raise slightly the level of the heavy liquid, both inside and outside the float, by the same amount and aggregating the volume of displacement of the pipe, P; and, where it is desired to make this inside pipe, P, of an appreciably large outside diameter, allowance must be made for its disturbing influence. The final rationally derived formulas for that purpose are as follows:

$$x^2 = h_2$$

$$h = x + x^2 + \frac{r_1^2 x^2}{y^2 + R^2 - r_1^2 - r^2}$$

$$x = \frac{(r^2 - y^2)(y^2 + R^2 - r_1^2 - r^2)}{2y^2(y^2 + R^2 - r_1^2 - r^2) - 2r_1^2(r^2 - y^2)}$$

in which the only variables are x and y,

h_2 = the mercury rise as before;

x = the vertical movement of the float;

and y = the variable radius of the interior.

The constants are:

R = radius of cylinder containing float;

r = radius of outer surface of float;

and r_1 = radius of pipe P.

To use these formulas practically, it is necessary to tabulate x and y, h_2, and finally h; h representing the abscissas, as before, and y the

ordinates. The necessity of this complication can be avoided by enlarging the outer cylinder at the location of the surface of the mercury.

Although the writer has devised many other forms and modifications, the form of float illustrated in Fig. 1, and covered by Equations (13) and (14), is believed to be by far the most practical, because it provides for maximum increments of volume and consequent accuracy at minimum velocities; and, with a float of a given radius, the minimum clearances are possible with the smallest cylindrical casing; also, there are several other practical advantages of importance. When this paper was first prepared it contained a discussion of every practical modification of form, with the derivation of the equation of each float. These, however, would take up too much space and be of mathematical rather than of mechanical interest.

At first thought, it might seem that a more practical shape would consist in a cylindrical interior and a curved exterior, because that would be formed more readily and accurately. Its cross-section would be a curve of the second degree, and the volume would be a paraboloid of revolution, convex outwardly. However, it cannot be made with greater accuracy, or probably with greater facility, and, for an apparatus of the same size, the form shown in Fig. 1 is almost seven times as accurate at minimum velocity.

The essential requirements of a water meter are:

1st. Accuracy within the range of the apparatus.

2d. Range, or ability to measure accurately flows in which the percentage of the maximum is a minimum.

3d. Minimum frictional resistance to flow.

4th. Reliability, or ability to perform with the greatest continuity, the minimum of attention, and the least danger of accident or damage.

5th. Long life and small repairs.

6th. Low cost.

7th. Simplicity.

8th. Accessibility—easy to examine and adjust.

9th. Minimum dimensions and weight, so as to occupy the least space.

10th. Good appearance.

The apparatus having the principles shown in Fig. 1, and described more in detail herein approximately fulfills these ten requirements.

One of the first difficulties to overcome was to prevent air from accumulating at the upper interior of the float in Fig. 1. Such an accumulation, of course, would lighten the float and therefore vitiate the results. Two check-valves opening upward are placed in the cap of the float. These are opened automatically when the velocity head reaches the maximum, and they can be opened at will, by a hand device, from the outside of the bottom of the pressure chamber, without otherwise dismantling the meter. This same device also automatically prevents the loss of mercury when the flow reaches an amount beyond the maximum capacity of the meter register, as it equalizes the pressure within and without the float.

An additional device for this purpose has been designed to prevent loss of mercury due to a sudden break of either of the pipes leading from the meter register to the Venturi tube, but these are safety devices of not unusual novelty, and, therefore, a detailed description of them is unnecessary.

Figs. 2 and 3 show front and side views of this meter register.

The float is made of hard rubber to conform to a metal template; but, to make sure that it is correct and will perform according to the theory on which it is designed, each float is tested in a regular working machine by applying, under pressure, piezometric heads corresponding to the velocity heads of the Venturi tube or Pitot tube with which it is to be used, and noting upon a standard rate-of-flow dial the corresponding velocities, which are compared with the theoretical velocities.

For heads, H, greater than $\frac{1}{2}$ ft. the coefficient of velocity through a standard Venturi tube is so nearly constant as to secure results within 2% of the actual. However, with the apparatus above described, Venturi heads, H, of less than 0.01 ft. are readily integrated. The velocity coefficient through the Venturi tube, however, is materially different, amounting to as much as 7% at low velocities, and the instrument is modified accordingly so as to produce accurate results down to less than 0.01 ft.

The data for this modification, as well as the method of making the correction, are intended to be the subject of a later paper.

Leading up to the final development of the apparatus illustrated in Fig. 1, it will be interesting to consider two of the earlier forms. Fig. 4 shows an extremely simple apparatus, which, at first sight, would appear to be superior to the device shown in Fig. 1.

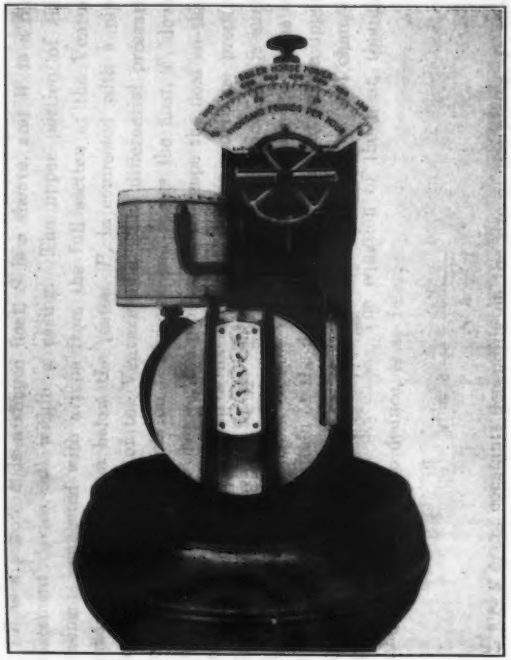

Fig. 2.

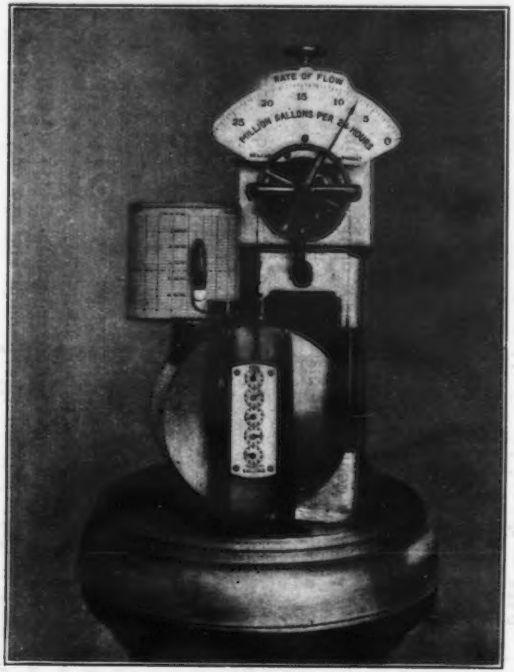

Fig. 3.

P is a piston, F is a shaped float, S is a sheave, and W is a displacement device, all within a casing. The upper portion of this casing is connected with a pipe from the full section of the Venturi tube, and the portion below the piston, P, is connected with a pipe leading to the throat of the Venturi tube. The differential pressure, or Venturi head, H, acts on the piston and forces the float, F, down into the mercury. As before, the problem is to shape the float so that its vertical movement from a fixed line of reference will be proportional to the square root of H. The displacement device, W, is such that when there is no flow in the Venturi tube and the apparatus is in equilibrium, the bottom of the float, a, will be tangent to the upper surface of the mercury. The level of the mercury, m m, will change, of course, as the float descends. The equation of the float, though rather more difficult to deduce, is as follows:

$$y^2 = e - \frac{f}{\sqrt{h+g}}$$

e, f, and g being constants depending on the size of the piston, P, the assumed movement of the float, F, with the given Venturi head, H, and the relative weights of mercury and water. The only radical difference in form between this formula and the one corresponding to Fig. 1 is in the constant, e, before the fraction. The curve, however, is still one of the fifth degree, and in this case when h becomes zero, y becomes zero, for the actual formula is:

$$y^2 = \frac{a_1}{\pi} - \frac{1}{2 \times 0.454\ \pi} \sqrt{h + \frac{\frac{(0.454\ a_1)^3}{0.434\ c\ a}}{4 \times 0.434\ c\ a}}$$

in which a_1 = the area, in square inches, of the cylinder containing the mercury;

a = the area of the piston, P;

h = the depth of submergence of the float in mercury, in inches;

c = the ratio of the square root of the Venturi head to the velocity;

0.434 = the ratio of the pressure, in pounds per square inch, to the Venturi head, in feet;

0.454 = the weight per cubic inch of mercury in water.

The objection to this apparatus is the friction of the piston, P. This was recognized immediately, and, to overcome it, a diaphragm of an accordion or some very flexible type was substituted for the piston; this, however, introduced difficulties caused by the elasticity of the diaphragm and the necessity of modifying the shape of the float to provide for these variations, as the diaphragm could never be depended on to remain in a permanent condition.

Another form is shown in Fig. 5. This is on an entirely different principle, but the treatment of the problem is analogous to that of Fig. 1.

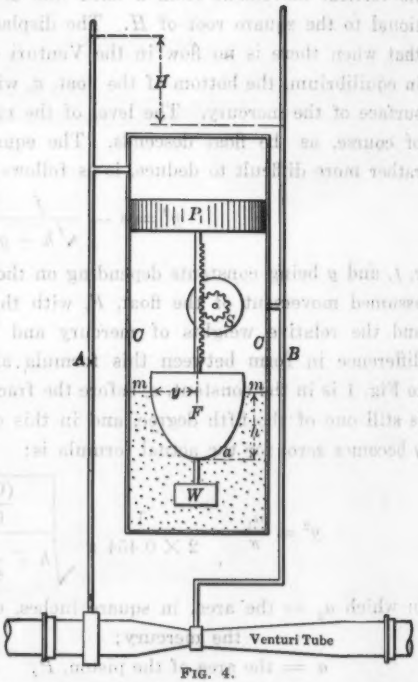

FIG. 4.

C represents a casing within which is contained a fixed displacing device, F, and a movable cylindrical vessel, P, containing, say, mercury buoyed up by the displacing volume, W. The pipe leading from the full section of the Venturi tube connects as shown above the vessel, and the pipe leading from the throat of the Venturi tube connects within the displacing device, F. The differential pressure, or Venturi head, H, forces mercury from the outside of the displacing device, F, to the inside; but, for equilibrium, the depth of the mercury in the vessel, P, must always be the same; that is, d must always be a constant. With these data it is found that the equation representing the inner curve of the displacing device is exactly the same as that of the float in Fig. 1, namely:

$$y^2 = \frac{r^2}{2\sqrt{h + \frac{1}{4}}}.$$

This device, in some respects, is superior to any of the others considered, and, in fact, it was the one of which a complete working model was first made and tested, and the results were good. The only objection is the large quantity of mercury required for the displacing device, *W*. It is obvious that the vertical movement of the cylindrical vessel, *P*, may be guided by rollers, as shown, or in some other practical manner. The cross-section of the rod, *l*, need not be sufficiently large to make its variable displacement affect the results appreciably.

However, the form in Fig. 1 is that which has been adopted as the most practical; and of all the twelve other devices, each of which has been developed by the writer to a working design, that shown in Fig. 5, next to that in Fig. 1, is the most meritorious. In all cases the registering mechanism outside of the casing may be exactly the same as shown. It comprises a rate-of-flow dial, a chart device to record the rate of flow, and a total-flow dial. The first requires only a graduated dial and a hand actuated by the shaft of the sheave, *S*. The second requires a pen reciprocating along the surface of a revolving figure having straight-line elements, such as a cylinder. The third requires a dial having hands which always revolve at a speed proportional to the angular position of the sheave, *S*. This is readily accomplished by hanging from the sheave, *S*, the dial which is connected with and operated by a traction wheel, the latter

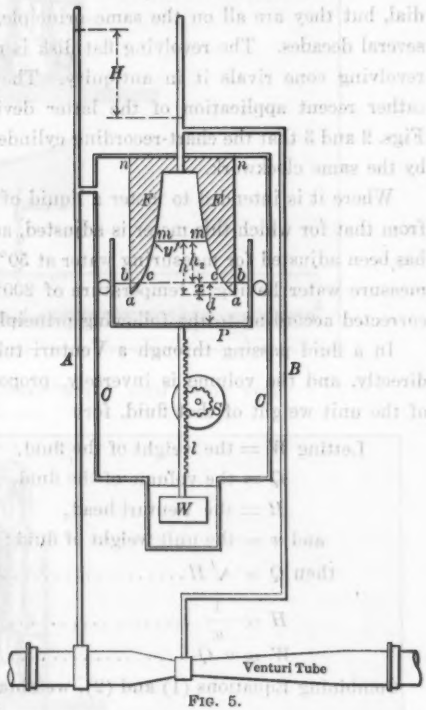

FIG. 5.

being rotated by a constantly revolving disk. When the sheave, S, sets at zero, the traction wheel stands at the center of the disk, and therefore has no rotating motion. As the flow increases from zero and the sheave, S, revolves, the traction wheel moves away from the center of the disk and therefore revolves at a speed proportional to its distance from the center of the disk and to the rate of flow through the Venturi tube.

There are other equally simple means of actuating the total-flow dial, but they are all on the same principle, and have been in use for several decades. The revolving flat disk is probably the oldest, but the revolving cone rivals it in antiquity. The Nicholson ship's log is a rather recent application of the latter device. It will be seen from Figs. 2 and 3 that the chart-recording cylinder and the disk are operated by the same clockwork.

Where it is intended to meter a liquid of a specific gravity different from that for which this meter is adjusted, as for instance, if the meter has been adjusted for measuring water at 50° Fahr., and it is desired to measure water having a temperature of 200° Fahr., the results can be corrected according to the following principle:

In a fluid passing through a Venturi tube or orifice, the weight is directly, and the volume is inversely, proportional to the square root of the unit weight of that fluid, for:

Letting W = the weight of the fluid,
Q = the volume of the fluid,
H = the Venturi head,
and w = the unit weight of fluid;
then $Q \propto \sqrt{H}$ .....(1)

$$H \propto \frac{1}{w} \quad \text{.....(2)}$$

$W \propto w\,Q$ .....(3)

Combining Equations (1) and (2), we obtain

$$Q \propto \sqrt{\frac{1}{w}} \quad \text{.....(4)}$$

Combining Equations (1), (2), and (3), we obtain

$W \propto \sqrt{w}$ .....(5)

Equations (4) and (5) being the stated relations.

Tables 1 and 2 contain data relating to typical tests of meter registers constructed on the principle described herein, in which

C = the Venturi head as measured, in feet;

V = the theoretical velocity through the full section of the Venturi tube, in feet per second;

V_1 = the velocity as indicated by the meter register;

D = the differences;

and P = the percentage of error.

This meter register is in use in several important cases for recording and integrating the flow measured by Pitot tubes, and has also recently been adapted in portable form utilizing Pitot tubes for city main leakage survey purposes. This form is shown in Fig. 8. Quite a number of these instruments are already in service. A typical test of one of these recorders is shown in Table 3.

The first column shows the direction of movement, U being where the column is increasing and D where the column is decreasing.

C represents the Pitot tube velocity heads, in feet;

V represents the theoretical velocity as calculated for the Pitot heads;

V_1 represents the velocity as measured by the Pitot recorder;
D represents the differences;
and P represents the percentage of error.

Paper No. 1268

RECENT IMPROVEMENTS IN LEVELING INSTRUMENTS.*

By Dunbar D. Scott, M. Am. Soc. C. E.

While the geodesist and the precise mechanic have been striving by independent or collateral effort to raise the art of leveling to the dignity of an exact science, it is quite evident that such investigations have induced too great a complexity in instrumental construction.

In any leveling operation the tangential axis of the bubble should be regarded as the datum plane, and the line of sight as the base line on which the survey is constructed. If the telescope is properly collimated, the line of sight, or rather the plane of vision indicated by the central horizontal wire, will occupy the equator of the field of view, and, for any ordinary distance, will describe a true horizon when regulated by a properly adjusted spirit-level of sufficient sensibility.

The fundamental requirements in any leveling instrument are simple in the essentials, but they have been made intricate by the intrusion of mechanical details between the elements on which depend the accuracy and rapidity of the operation.

The primary object is to preserve parallelism between the bubble-axis and the line of sight; and to provide an easy method of making a telescopic observation simultaneously with an ordinary observation, necessary to adjust the bubble accurately to the center of its run.

In the Wye-level† we are required to test this most vital adjustment through the Y-supports and the collars, which, at various times,

* Presented at the meeting of May 21st, 1913.

† Invented by Jonathan Sissons, of London, in 1740. See article by Daniel Eckstrom in the *Journal*, Royal Swedish Acad. of Sci., Vol. V, 1743, p. 144.

have been made of red metal, bell metal, steel, or invar, and supported on ivory or agate pivots, depending on the degree of precision sought in the work. The collars are, in reality, at the basis of adjustments, and the idea of supporting them on agate pivots, or anything else that would tend to wear them out, is only one of the fallacies experienced in the attempt to eliminate the instrumental inequalities which affect the final result.

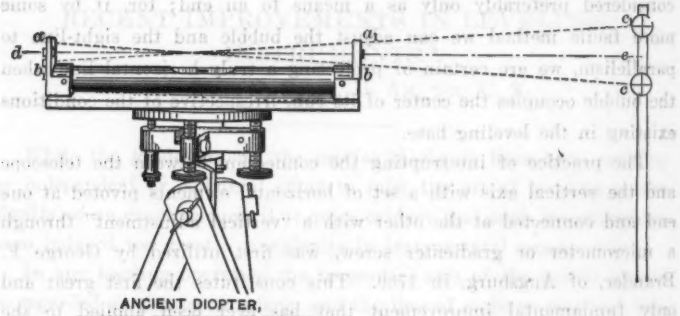
In the Wye-level, we are also dependent, for a successful performance, on the perfect verticality of the vertical axis, which should be considered preferably only as a means to an end; for, if by some more facile method we can adjust the bubble and the sight-line to parallelism, we are certain of projecting a truly horizontal line when the bubble occupies the center of its run, irrespective of the conditions existing in the leveling base.

The practice of interrupting the connection between the telescope and the vertical axis with a set of horizontal elements pivoted at one end and connected at the other with a "vertical adjustment" through a micrometer or gradienter screw, was first utilized by George F. Brander, of Augsburg, in 1769. This constitutes the first great and only fundamental improvement that has ever been applied to the mechanical construction of the Wye-level. It was adopted by Professor Stampfer, of Vienna, then by Kern and other European manufacturers, until to-day, it is practically the only type of Wye-level used on the Continent.

The pivots were not moved to the center of the base-bars until Ertel, of Munich, did so in 1842;* and, as we learn from Englebreit's "Instrumente der Geodasie" (Nurnberg, 1852), they were soon after elevated in the cradle-wye to the center line of the telescope where no amount of correction would have any effect upon the height of instrument.†

The Stampfer, or the Kern model, which does not differ in essential details of construction, was first adopted in the United States Lake Survey in 1876, and was used to the exclusion of other types in the U. S. Coast and Geodetic Survey until 1900.

Professor Stampfer, who applied the gradienter screw of this con-



* See article by Cotta in *Dingler's Polytechnisches Journal*, Vol. 84, 1842.

struction to the portable transit instrument in the early Seventies of the last century, began experiments, in the early stages of his career, by applying to all leveling operations the principle of reversion in the widest sense, not only to the instrument itself, but to the operations performed with the instrument.

In principle, the primitive diopter of ancient origin was well adapted to the theory, as will appear from inspection of Fig. 1.

It is difficult to say where instruments of this character had their origin, but we need not look back farther than 1660 when Thevenot

ANCIENT DIOPTER,
SHOWING REVERSION PRINCIPLE
OF ADJUSTMENT

FIG. 1.

invented the bubble-vial. They were supplied only with peep-holes and crossed horse-hair sights, but their construction reduced the process of adjustments to the simplest possible terms.

In this case we are relieved of any necessity for perfect verticality in the vertical axis. If the first sight, which may be assumed as having been taken through *ab*, intersected the rod at *c*, on reversing the instrument, and re-centering the bubble, if necessary, we should have the second observation, as through b_1 a_1, intersecting the rod at c_1, under precisely the same conditions which controlled the first observation. Having established by this artificial means a true horizon for the height of instrument at *e*, it is not difficult to arrange the sights, *a* and *b*, into the alignment, *de*, which must be parallel with the axis of the bubble. This simple operation constitutes a most accurate and effective means of adjustment, and one which is free from the influence of any mechanical defects in the instrument itself.

In a telescopic sight, however, with a carefully collimated and unalterable sight line, we are confronted with a slightly different problem, in which the telescope must first be brought into coincidence with the mean of two such observations and the bubble finally readjusted to fit this condition.

Professor Stampfer's attempt to substitute an optical system which could be utilized for this peculiar purpose resulted in the model illustrated in Fig. 2.

The optical sight consisted of two plano-convex lenses of about 5 mm. aperture and about 32 mm. focal length, placed at opposite ends

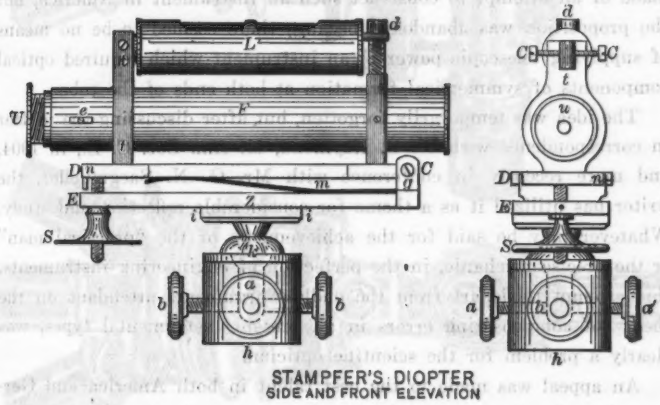

FIG. 2.

of the tube, at twice their focal length apart. Cross-wires in the common focal plane were located midway between them.

The aperture was purposely reduced to that of the pupil of the eye, for, in such a combination of lenses, the focus must be practically universal, with an emergent beam consisting of nearly parallel rays. Nothing would be gained, therefore, by producing a larger image than could enter the eye.

Each lens in turn could be used either as an eye-piece or an objective, and focusing was unimportant or rarely necessary. The focal length of the "objective" and the "ocular" being equal, the instrument possessed no telescopic power and did not elevate the problem beyond the most commonplace consideration, except that it was possible to

secure a simultaneous view of the cross-hairs and a distant target, without straining the accommodative function of the eye.

Fig. 2 is reproduced from Bauernfeind,* who says, as one would translate:

"The method utilized the most rational means of instrumental adjustment and of balancing observations, and was really capable of very accurate work. The lengths of sights were strictly limited to the range of human vision, but experience has demonstrated that its error fell within 1:20 000."

In the first edition of Gillespie's "Surveying" (1855), mention is made of an attempt to construct such an instrument in America, but the proposition was abandoned because there seemed to be no means of supplying telescopic power to an instrument which required optical components of symmetrical formation at both ends of the tube.

The idea was temporarily forgotten, but after discussing the matter in correspondence with W. G. Raymond, M. Am. Soc. C. E., in 1904, and more recently in conference with Mr. G. N. Saegmueller, the writer has utilized it as a theme for considerable reflection and study. Whatever may be said for the achievements of the "practical man" or the precise mechanic, in the perfection of engineering instruments, this attempt to depart from the endless arguments attendant on the theory of compensating errors in all present instrumental types, was clearly a problem for the scientific optician.

An appeal was made to the best talent in both America and Germany,† and, after nearly three years of investigation in both the laboratory and field, telescopic optics of any desired power have been applied at last to the principle of reciprocal vision in the palindromic telescope herein described, which might be otherwise known as an optical Janus.

The new "Compensation Level" is shown in both elevations in Figs. 3 and 4, and in transition in Fig. 5. The writer is responsible for the details in its mechanical construction, which is, as it should be, only a means to an end—a vehicle of manipulation which does not in any appreciable manner enter into the character of the result.

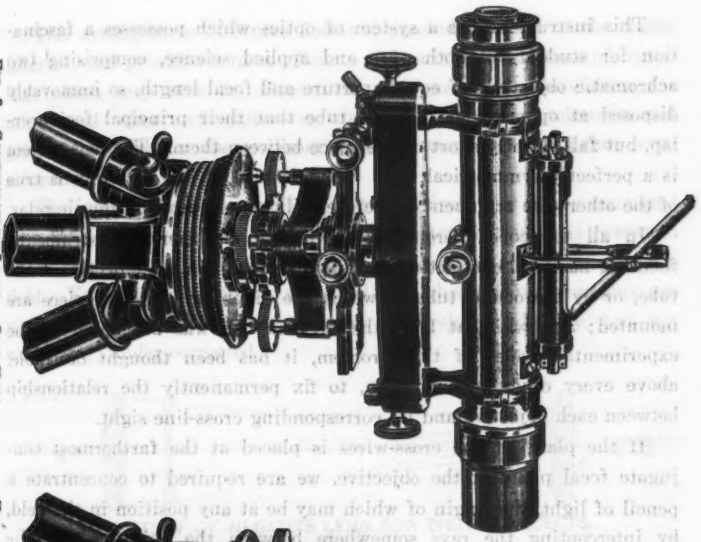

FIG. 3.—COMPENSATION LEVEL. SIDE VIEW.

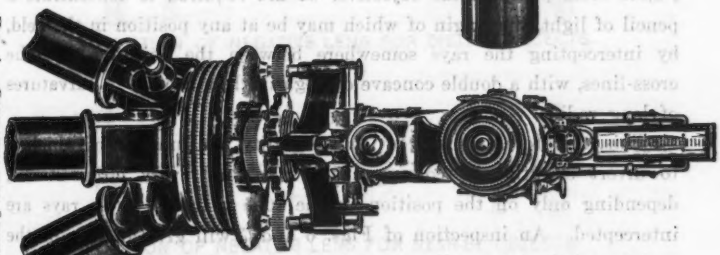

FIG. 4.—COMPENSATION LEVEL. END VIEW.

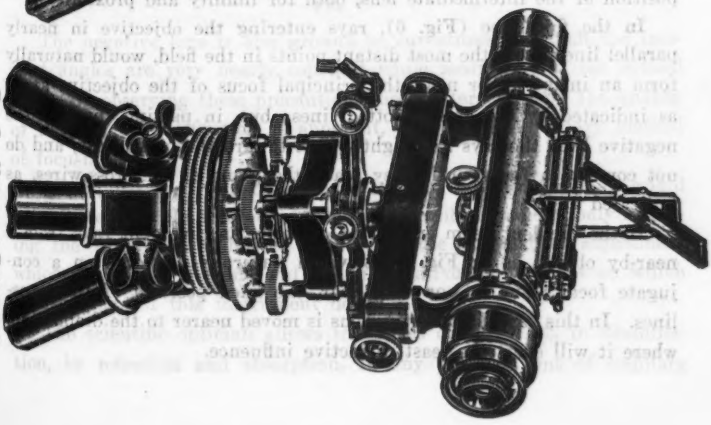

FIG. 5.—METHOD OF TRANSITION.

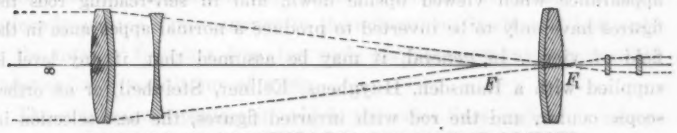
This instrument has a system of optics which possesses a fascination for students of both pure and applied science, comprising two achromatic objectives of equal aperture and focal length, so immovably disposed at opposite ends of the tube that their principal foci overlap, but fall slightly short of the space between them. The lens system is a perfectly symmetrical one. What is true of one direction is true of the other; the argument, therefore, will be conducted in the singular.

In all telescopes heretofore applied to engineering instruments, focusing has been conducted either by movement in the objective draw-tube, or by the ocular tube in which the diaphragm and eye-piece are mounted; and while at least the first method was attempted in the experimental stages of this problem, it has been thought desirable, above every other consideration, to fix permanently the relationship between each objective and its corresponding cross-line sight.

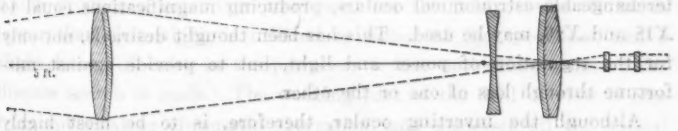
If the plane of the cross-wires is placed at the farthermost conjugate focal plane of the objective, we are required to concentrate a pencil of light, the origin of which may be at any position in the field, by intercepting the rays somewhere between the objective and the cross-lines, with a double concave or negative lens ground to curvatures of long radius.



This, therefore, is a lens of low sensibility, the function of which is to divert slightly the convergent rays to suit every circumstance, depending only on the position in the tube at which these rays are intercepted. An inspection of Figs. 6 and 7 will give an idea of the position of the intermediate lens, both for infinity and proximity.

In the first case (Fig. 6), rays entering the objective in nearly parallel lines, from the most distant points in the field, would naturally form an image at, or near, the principal focus of the objective at F, as indicated by the longer dotted lines; but, in passing through the negative lens, the rays are slightly bent toward the prism base, and do not come to a focus until they reach the plane of the cross-wires, as indicated at F_1.

If the incident beam enters the objective in divergent rays from a near-by object, as in Fig. 7, it would naturally converge on a conjugate focal plane, at, or very near, the fixed position of the cross-lines. In this case the negative lens is moved nearer to the diaphragm, where it will exert the least refractive influence.



This arrangement of lenses does not preclude the use of the stadia interval, and provides a most efficient and satisfactory means of focusing, which may now be adopted in tachymeters or theodolites for mines and other such purposes, where an impervious telescope and greater security in the collimation adjustment are of prime consideration.

The intermediate negative lens is of relatively low power compared with that of the objective, and the whole system of lenses is corrected for aberrations, as a single combination, for a mean distance in the field. For very long sights, spherical and chromatic aberrations are very slightly over-corrected, and for short sights, slightly, but not noticeably, under-corrected.

POSITION OF NEGATIVE LENS FOR DISTANT OBJECTS.

FIG. 6.

POSITION OF NEGATIVE LENS FOR NEAR-BY OBJECTS.

FIG. 7.

The negative lens is also ground to curvatures in which the incident angles are very nearly constant while moving it in the optical axis. By observing these precautions, no greater effect on the quality of the image or definition is apparent, than in the ordinary method of focusing.

As applied to leveling instruments, the intermediate lens would suggest, to a highly theoretical mind, the possibility of not only subduing the illumination, but of modifying the collimation adjustment which constitutes the one and only imperative requirement on which the accuracy of this instrument depends.

The scientific optician allows for a loss of about 8% in illumination, by reflection and absorption, in any polished lens of ordinary

thickness; but this phenomenon is apparent only to a trained eye, and may be nearly corrected, without making a sacrifice to other optical qualities, by increasing the diameter of the objective 4 or 5 per cent. In this instrument, as illustrated in Figs. 3, 4, and 5, there are no more lenses than are necessary in any terrestrial telescope commonly used by the American engineer for most azimuth instruments and for many types of levels.

To favor light conditions, under these circumstances, it has been thought desirable to consider, by preference, the astronomical (inverting) ocular which is most advantageously suited for leveling instruments, whereas it might cause some annoyance in transits or theodolites.

When the target rod is used, the target itself is not changed in appearance when viewed upside down, and in self-reading rods the figures have only to be inverted to produce a normal appearance in the field of view. In general, it may be assumed that, if any level is supplied with a Ramsden, Huyghens, Kellner, Steinheil, or an orthoscopic ocular, and the rod with inverted figures, the best selection in the character of the outfit has been procured.

The optical arrangement in this instrument is such that two interchangeable astronomical oculars, producing magnifications equal to $X18$ and $X26$, may be used. This has been thought desirable, not only for the regulation of power and light, but to provide against misfortune through loss of one or the other.

Although the inverting ocular, therefore, is to be most highly recommended, it is not impossible to utilize the erecting type, as shown in connection with Fig. 10, by which a magnification of $X20$ is secured. With this eye-piece, the superlative optical qualities, with respect to illumination and size of field, cannot be expected, but it has been designed as an option for those who are confused by an inverted image. The erecting eye-piece, together with an erroneous idea that the accuracy of the sight is proportional to the length of the optical axis, are the factors which determine the unusual length of the modern Wye-level. The use of an erecting eye-piece, with the instrument under consideration as a substitute for the inverting ocular, increases the length of the telescope 40%, in-

FINE CROSS-LINES ETCHED ON SURFACE OF CROWN LENS

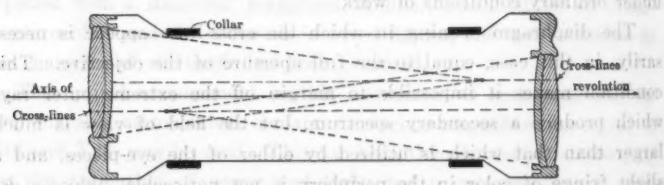
FIG. 8.

creases the weight of the instrument 20%, and reduces considerably the brightness of the image.

After much experimentation with a new three-ring diaphragm (which was finally discarded), it was decided, inasmuch as the objectives were immovably and permanently fixed in the tube, that each, in turn, could be made to serve as an excellent substitute for a glass diaphragm for the other optical system.

With this in view, it became necessary to design an elaborate collimating apparatus especially for this instrument. Where the optical axis of each objective passes through the other, a microscopic cross is etched on the outer surface of the crown lens, with a fine diamond point, somewhat as shown in Fig. 8. If the elements which enter into the collimation adjustment, therefore, are fixed, we may rationally assume a permanency in the adjustment itself, and look only to the interior focusing lens for such derangements as are possible under ordinary conditions of work.

The diaphragm opening in which the cross-lines appear is necessarily, in this case, equal to the full aperture of the objective. This condition makes it impossible to margin off the extreme outer rays which produce a secondary spectrum, but the field of view is much larger than that which is utilized by either of the eye-pieces, and a slight fringe of color in the periphery is not noticeable, unless a deliberate search is made. The working part of the field of view is free from spherical or chromatic aberration, and possesses all the optical qualities which satisfy the most fastidious demand. There is nothing, however, to prevent the construction of a diaphragm of proper proportions as a part of the eye-piece mount, and so fulfill in this particular the uttermost requirement in the case.



The position of the plane of the cross-lines has been located arbitrarily where an image will be naturally produced by rays having their origin 5 ft. beyond the objective. For the shortest sight possible to be observed through either end of this instrument, 1.5 m. has been selected.

Particles of dust will inevitably settle on the outer surfaces of the objectives, and will be noticeable in the plane of the cross-lines under the magnifying effect of the eye-piece. Unless one is familiar with this construction, such a phenomenon will cause either wonder or con-

fusion. The glasses should be cleaned occasionally with a camel's hair brush.

The collimation adjustment consists of the fixation of the intersection of the cross-wires into the optical axis of the objective, as accomplished by some improvised axis of longitudinal revolution. The collimation line in this, or any ordinary, telescope may be slightly removed from this geometrical axis, depending on the amount of eccentricity which exists in the objective mount; but it will be parallel in any case.

A thorough investigation into the probable causes of collimation error, in reconciling one optical system with the other, induces the conclusion that the maximum total error in reading must be equal only to the amount of eccentricity in the objectives, which is not a progressive error in any event, and, if it occurs in the horizontal plane, is a negligible quantity, however great.

EFFECT OF ECCENTRIC MOUNTING ON COLLIMATION.

FIG. 9.

With the facilities of manufacture now at the disposal of the precise mechanic, we shall perjure the premises if we allow that, in mounting, a greater displacement than 0.1 mm. may occur on either side of the geometrical axis of the tube. Treating, however, with a most exaggerated case of this character, we shall have, after the separate adjustments for collimation, the conditions expressed in the diagram, Fig. 9, showing two possible sight-lines that must be either coincident with, or parallel to, the axis of revolution.

Eccentricity of mounting will reveal itself, after the collimation adjustment, if the telescope is revolved in the wyes. If the field of view appears to move in a small circle, there is eccentricity of mounting; but, if the collimation adjustment has been properly made, the intersection of the cross-lines will appear to move with the field.

There will be no such thing as an inclination of the optical axis

in the tube by virtue of an inclination in the objective itself. No error can possibly occur through oblique mounting, except that of astigmatism, but this is incidental rather than vital, and need not be considered in this, any more than in any other, instrument.

The chances for error induced by any lateral movement in the focusing lens have to deal first with the collimation adjustment (or the position of the optical axis as fixed by the cross-lines), then with the reproduction of the rod at the plane of the cross-lines, thus fixed.

In testing the accuracy of the collimation adjustment for either optical system, some very distant point in the horizon should be selected. If the test is made on a near-by object, it will not fulfill, in the highest theoretical sense, the requirements in the case. The infallible test for errors of this character is a check of the collimation on a near-by object after perfecting the adjustment on some very distant point. This necessitates moving the interior lens between the positions shown in Figs. 6 and 7; and this test ought to qualify, irrespective of eccentricities in mounting, as previously shown by D. A. Molitor,* M. Am. Soc. C. E.

An excellent collimator apparatus for use in the field may be arranged by placing the objectives of a level and a transit in juxtaposition so that a beam of light can pass directly through both optical systems. If the transit telescope is racked down to its shortest length, it will be necessary to focus the telescope of the level at, or near, infinity, in order to see the cross-wires of the transit diaphragm. This method brings an object, apparently at an infinite distance, into very convenient range, and the test may be made at night by placing a bright light immediately behind the transit eye-piece. The arrangement, as illustrated in Fig. 10, shows the level equipped with an erecting eye-piece and a special sunshade which may be used interchangeably with the inverting eye-pieces, and thus convert the telescope almost instantly from one type to the other.

The axis of revolution is established as between the bearings in the supports. It is desirable, therefore, that the caps should be only slightly loosened and that the telescope should not be removed from its supports, or reversed for the second test, except on the vertical axis. In making the collimation test by longitudinal revolution, it is not

Transactions, Am. Soc. C. E., Vol. XLV, 1901, p. 45.

absolutely necessary that the telescope should be horizontal; but the axis of revolution in the wyes must not be modified except as stated.

The possibility of securing permanently the collimation adjustment by fixing immovably the relationship between the elements which constitute that adjustment, commends itself at once, and, now that we

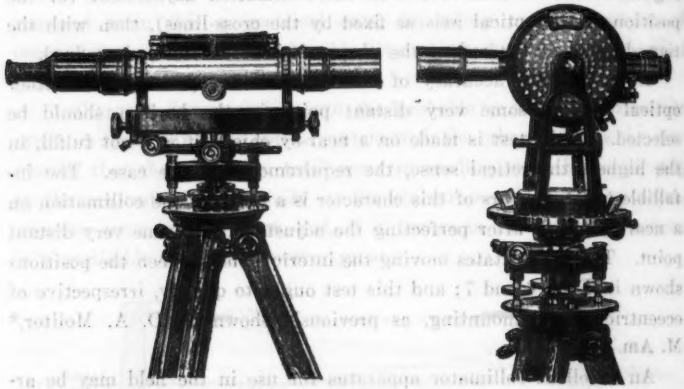


FIG. 10.—FIELD COLLIMATOR APPARATUS, SHOWING READING MIRROR REMOVED AND BEARING CLIPS LOOSENED TO FACILITATE LONGITUDINAL REVOLUTION.

may provide against any movement for either the objective or the diaphragm, we may mount them in a tube which is sealed against the intrusion of dust or moisture.

The telescope tube has been reinforced with three longitudinal ribs, cast, drawn, and turned down in one solid piece with the outer wall. The carefully machined ribs add lateral strength, prevent flexure, preserve alignment, and form a convenient skidway on which to slide the barrel in which the focusing lens is mounted. The contact surfaces between these ribs and the lens-barrel are the only movable parts on which the accuracy of the instrument depends.

FIG. 11.

If we safely allow that the error due to eccentric mounting of the objectives is a constant not exceeding 0.2 mm. for all distances, it may be regarded as a negligible quantity, and the proposition seriously concerns us only

so far as irregular motion in the focusing device may affect the reproduction of the field of view at the plane of the cross-wires.

This influence has been accorded a most careful theoretical and practical investigation, with results so satisfactory that it is recommended as superior in point of accuracy to either of the other methods of focusing now in common use.

A theoretical consideration of the effect produced on the optical axis by the negative focusing lens is one involving some of the simple laws of refraction. For the purposes of this demonstration, Fig. 12 represents an exaggerated condition of affairs.

Let it be assumed that an objective, O, and a reticule, R, are immovably placed with respect to each other. It is assumed that the negative lens, being in the position, N, when focused on infinity drops

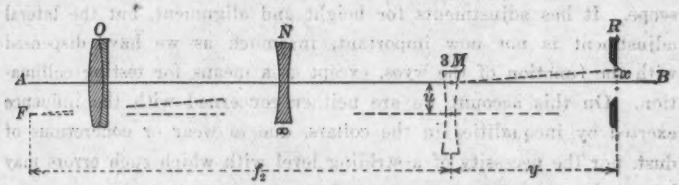

DIAGRAM SHOWING EFFECT OF LOST MOTION IN FOCUSING LENS.

FIG. 12.

out of alignment from the optical axis, AB, to the position, $3M$, through a displacement equal to u, when focused on an object, say, 10 ft. away.

In the position, $3M$, the axial ray from A will be deflected at an angle having a base equal to x, and the anterior focal point will drop accordingly to F. Let the total amount of deflection at the diaphragm be equal to x, and let the distance from F be equal to f_2. From similar triangles we have:

$$x : u :: y : f_2$$

$$x = u \frac{y}{f_2}.$$

In the very portable instrument under discussion, the focal length of the negative lens, f_2, is equal to 350 mm., and the mean value of y is equal to about 70 mm. Substituting, we have:

$$x = u \frac{70}{350} = \frac{1}{5} u.$$

In other words, for a level of this length, the displacement of the image at the diaphragm will be equal to about one-fifth of the deviation of the focusing lens from the optical axis.

The contact bearings of the inner lens-barrel can be made to move so accurately that, whether we consider the error of displacement, as applied to collimation adjustment or accuracy of pointing, we can only conclude that it must fall within the diameter of the sight line itself, and remain within the limbo of intangible quantities.

The mechanical process of focusing by this method necessitates only a movement of the interior lens between the telescope supports, where such a reapportionment of weight will not sensibly affect the center of gravity or destroy the equilibrium of the instrument.

The bubble tube is rigidly attached directly over the top of the telescope. It has adjustments for height and alignment, but the lateral adjustment is not now important, inasmuch as we have dispensed with the function of the wyes, except as a means for testing collimation. On this account we are neither concerned with the influence exerted by inequalities in the collars, due to wear or concretions of dust, nor the necessity of a striding level with which such errors may be tested.

If temperature fluctuations have any effect on the horizontality of the level vial, the elimination of such discrepancies is accomplished only by the process of end-for-end reversals, which forms a part of the prescribed routine in the performance of precise leveling with an instrument of this type.

The accuracy of results depends entirely and directly on the relation of the bubble axis to the amphidioptric sight line, and sudden changes in temperature will affect such work only as they are capable of disturbing this relationship.

H. M. Wilson, M. Am. Soc. C. E., concurs with Professor Molitor in the opinion that precise leveling does not differ materially from the ordinary kind, except in the character of the instrument; and that practically all residual errors are attributable to temperature changes.* It would seem, therefore, if we provide in the new instrument a ready means of testing the collimation, that temperature effects will compensate themselves on reversals, and that it will be no longer necessary

* *Transactions*, Am. Soc. C. E., Vol. XLV, 1901, p. 126.

to equalize forward or back-sights, unless it is thought desirable to do so on account of curvature and refraction.*

Although variations in temperature may affect somewhat the angular value of the graduations on the bubble vial, its capability to indicate a truly horizontal setting is not impaired if the same central segment of the graduated scale is used, as advocated by the late J. B. Johnson, M. Am. Soc. C. E.

At each side of the bubble tube are sockets for the reception of the mirror supports. The mirror frame is hinged at the center, so that the reflected image of the bubble may be viewed from either end of the telescope with equal facility. This method of observing the bubble was adopted on account of its peculiar fitness to the requirements of the case; but a stop has been provided that regulates the amount of inclination to approximately 40° each way, and also to prevent cracking the vial by reckless use.

Naturally, the longer the bubble the greater the amount of error, due to parallax in reading it by this method; but this constant, in a sensitive bubble, must necessarily be very small, and will neutralize itself in reversals. For ordinary leveling operations it may be disregarded entirely. It would seem, from the peculiar conditions and the requirements in the case, that by the process of end-for-end reversals every real or imaginary error, traceable to the bubble or its mounting, will be perfectly compensated and automatically corrected.

Our total anxiety, therefore, in the use of the instrument may be concentrated on the parallelism between the bubble axis and the biaxial sight-line to which it must be adjusted; but this can be tested at any time, within from 3 to 5 min., in a second observation, without moving out of one's tracks and without an assistant.

For ordinary leveling purposes, the operator will naturally make this test in the morning, as required of all assistants in the Coast Survey, and, when satisfied, he will apply the eye-piece to one objective and the sun-shade to the other, for continuous and accurate work. This instrument was designed only for use in more ordinary work, but the object of this paper is to show that the construction is such that the most precise results may still be secured by two sets of

*See L. S. Smith, M. Am. Soc. C. E., in *Bulletin*, Univ. of Wis., Vol. I, No. 5, 1895; W. S. Williams, Assoc. M. Am. Soc. C. E., in *Transactions*, Am. Soc. C. E., Vol. XLV, 1901, p. 176; "Plane Surveying," Professor J. C. Tracy, 1898, p. 273, etc.

double observations, on the assumption that the collimation and the bubble are both out of adjustment.

The instrument's first claim on the attention of the engineer is the wonderful facility with which the adjustment for parallelism may be tested, and the accuracy and speed with which it may be rectified. An unbiased, open-minded examination into those parts of the instrument which might be suspected of infidelity, develops the conclusion that, one by one, they may be reduced to negligible quantities.

The vertical adjustment device is an entirely new model, peculiarly adapted to the reversible qualities of this instrument. The upper element of the base-bar forms a channel encasement for the lower element, which is rigidly attached to the vertical axis.

The telescope and bubble are mounted on the upper element in non-adjustable supports. The upper element, with telescope and bubble, revolves through short arcs in the vertical plane, on a conical pivot or an eccentric worm gear at the center of the bars, some 55 mm. below the axis of the telescope.

This is an improvement over the method of placing the pivots at one end, but nothing essential would be gained by a further modification of the mechanical equipment, in order to get the pivots in the horizontal plane which is coincident with the longitudinal axis of the telescope. The reversion principle in this level demands that we shall place the pivots at the center, in order that the height of instrument shall not be modified in the second observation. If the instrument, considered in this paper, was intended for the measurement of small vertical angles by a micrometer screw, it is agreed that the longer base secured by placing the pivots at the opposite end would contribute to the efficiency of the construction; but in the 10-in. (25-cm.), instrument herein described, the micrometer is not adaptable, and it is proposed, further, that the micrometer method of securing precise results shall be superseded by the process of reciprocal vision herein described, or by the three-wire method already adopted.

The mechanical construction of the "vertical adjustment" in this design cannot be adapted for use as a gradienter because the value of one division on the drum would change constantly in the different positions of the eccentric gear. For convenience of manipulation, we are required to communicate a slight vertical movement through a horizontal bar revolving on its own axis.

The horizontal bar terminates in milled-heads, symmetrically placed directly under each successive position of the eye-piece, so that, whether in direct or reverse position, the final delicate setting of the bubble can be accomplished without inconvenience or confusion. This method is quite unique, and is well adapted to this construction.

The upper base-bar is not always necessarily parallel with the lower, nor perpendicular to the vertical, axis. A normal position, however, may be quickly determined in reversals on the vertical axis by correcting half of the bubble displacement in the leveling base and the other half in the "vertical adjustment." In one of two such trials the bubble should remain centered during an entire revolution.

The mechanical separation of the connection between the telescope and the vertical axis distinguishes this instrument at once from the dumpy type, and places it formally in the precise class, irrespective of its numerous other claims to this distinction.

On precise levels of the Coast Survey type, a circular-box bubble has been attached to the lower element of the base-bar to secure a nearly vertical setting of the vertical axis, without regard to the relationship of the upper portion of the instrument, and independent of the more sensitive vial which is mounted on the telescope, but in the comparatively small instrument herein described a "normal adjustment" is of such easy accomplishment that it has seemed preferable to dispense with the circular bubble, which has no given sensibility or means of adjustment.

This alternative seems the more to commend itself inasmuch as the "vertical adjustment" is constructed on an endless worm gear in which the total amount of elevation or depression cannot exceed 1.8 mm. on either side of the normal line. If either milled-head were turned continuously, the telescope would only rise and fall in uninterrupted oscillation. The operator will become quickly accustomed to the effect produced in the mirror by turning the milled-head either to the right or left, and this effect will be the same when viewed from either end of the instrument.

The tangent release mechanism is also a new idea, absolutely without precedent, so far as the writer knows. As shown in Fig. 5, the nose-piece, instead of being rigidly attached to the lower bar, is removable and adapted to engage a spring-slot at either end of the instrument, as shown. In reversing the instrument, the clamp-screw to

the vertical axis need not be thrown open, as usual, but the whole clamp-and-tangent arrangement may be allowed to remain, so that it can be manipulated with the right hand in either position of the upper portion of the instrument.

When looking through either end of the telescope, the focusing screw, the vertical adjustment, the clamp screw, and the tangent screw, may be manipulated by either the right or left hand, as desired, depending on the habits of the operator, and, in fact, all other details in both the optical and mechanical equipment are symmetrical, interchangeable, and in perfect equipoise.

The type of three-screw base shown in the various illustrations is also a new model, which is attachable to the ordinary form of tripod, is applicable to the ordinary type of transit or level, and is provided

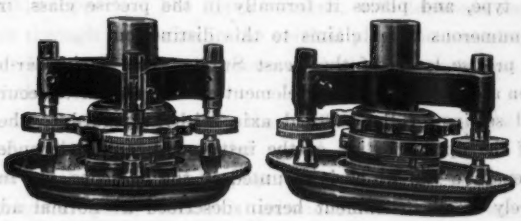

FIG. 13.—NEW THREE-SCREW BASE WITH SHIFTING CENTER.

with the regular type of shifting center such as the American engineer has used since 1858. For leveling instruments, the shifting center is not necessary, but in azimuth instruments, which are required to be centered over a given point, the appliance is almost indispensable. Referring to Fig. 13, the spring, which accommodates a universal movement through the center of the instrument, is no longer attached to an awkward spring-bar of the European model, but snugly contained in the central capsule of the shifting plate.

Every movement in each of the three leveling screws is compensated automatically at the center, and the tension in the leveling arms is equalized. Unequal strain in varying temperature, which has a subtle influence on the bubble, is eliminated, and the longer radial arms, with larger thumb-screws in German silver, provide a more sensitive control. This type of leveling base, while very convenient, is not indispensable to the instrument herein described, or to any other pro-

vided with a "vertical control," but, to the ordinary dumpy level, it adds greatly to ease of manipulation and efficiency of operation.

While in use, the coarsely-knurled clamp ring is to be loosened, but, for transportation, it is to be screwed down against the flange, in order to lock the instrument securely against the lower base.

One quickly becomes used to the three-screw system, and it is not too much to say that, if one of the screws is placed directly beneath the intersection of the two lines marking the longest axis of the bubble tubes in a transit, the bubbles may be centered simultaneously with remarkable speed.

In leveling up such an instrument as described, first secure the normal position of the bubble, then place the telescope parallel to any two of the leveling screws. After centering the bubble in this position, revolve the telescope 90° and center the bubble once more, using the third leveling screw alone.

Paper No. 1269

TESTS OF CREOSOTED TIMBER.

By W. B. Gregory, M. Am. Soc. C. E.

In a previous paper,* under the same title, the writer reported the tests of fourteen beams, which were taken from a trestle of a railroad near New Orleans, and, at the time of the tests, had been in use for 26 years. The specifications for treating this timber with creosote were given in the former paper, and need not be repeated here.

Recently, other beams, having been in use more than 29 years, were removed from the trestle and tested to destruction. The material was similar to that tested previously, and consisted of southern pine stringers having a cross-section approximately 6 by 16 in. and a length of 30 ft. For the purpose of testing, each beam was cut into two parts, each about 15 ft. long. It is the purpose of this paper to report the recent tests.

Method of Testing.

The tests were made exactly as in the former case, using a Riehlé 100 000-lb. machine, in the Experimental Engineering Laboratory of Tulane University of Louisiana. In order to make this discussion complete, the methods as stated in the former paper are repeated here:

"The machine is provided with a cast-iron beam for cross-bending tests. The distance between supports was 12 ft. The method of support was as follows: Each end of the beam was provided with a steel roller which rested on the cast-iron beam of the testing machine, while above the roller, and, directly under the beam tested, there was a steel plate 6 by 8 in. in area and 1 in. thick. The area was suf-

ficiently great to distribute the load and prevent the shearing of the fibers of the wood. The head of the Riehlé machine is 10 in. wide. A plate, ⅜ in. thick, 6 in. wide and 18 in. long, was placed between the head of the machine and the beam tested.

"The deflection was measured on both sides of each beam by using silk threads stretched on each side from nails driven about 2 in. above the bottom of the beam and directly over the rollers which formed the supports. From a small piece of wood, tacked to the bottom of the beam at its center and projecting at the sides, the distance to these threads was measured. These measurements were taken to the nearest hundredth of an inch. The mean of the deflections was taken as the true deflection for any load.

"In computing the various quantities shown in Table 1, the summary of results, the load has been assumed as concentrated at the center of the beam. While it is true that the load was spread over a length of about 12 in., due to the width of the head of the machine and the plate between it and the beam tested, it is also true that there were irregularities, such as bolt-holes and, in some cases, abrasions due to wear, that could not well be taken into account. Hence, it was deemed sufficiently accurate to consider the load as concentrated. Besides the horizontal bolt-holes, shown in the photographs, there were vertical bolt-holes, at intervals in all the beams. The latter were ¾ in. in diameter, and in every case they were sufficiently removed from the center of the length of the beam to allow the maximum moment at the reduced section to be relatively less than that at the center of the beam. For this reason, no correction was made for these holes. The broken beams often showed that rupture started at, or was influenced by, some of the holes, especially the horizontal ones."

In the previous paper the writer made some comparisons of results with those of large timbers tested elsewhere. The conclusion was:

"The number of tests was not sufficient to settle questions of average strength or other qualities. It will be seen, however, that the treated timber 26 years old compares favorably with the new untreated timber."

Although the tests now reported give average results slightly lower than those in the former paper, the maximum breaking load occurred in the recent tests, and the minimum of all breaking loads was found in the first set of tests. In view of these facts, it appears that the conclusions apply to the later tests of this material, which, as stated previously, has been in use more than 29 years.

The writer is indebted to his colleague, Professor J. M. Robert, of Tulane University, for valuable assistance in this work.

Paper No. 1270

IRRIGATION AND RIVER CONTROL IN THE COLORADO RIVER DELTA.*

By H. T. Cory, M. Am. Soc. C. E.

With Discussion by Messrs. L. J. Le Conte, Morris Knowles, Francis L. Sellew, Elwood Mead, W. W. Follett, R. H. Forbes, R. S. Buck, F. T. Robson, Andrew M. Chaffey, C. E. Grunsky, Clarence K. Clarke, U. S. Marshall, and H. T. Cory.

From almost every point of view, the Lower Colorado River, and particularly the Colorado Delta, is extremely interesting. Ever since its examination and description by members of Lieut. Williamson's exploration party in 1850, the various features, geological, geographical, anthropological, engineering, and otherwise, have been written about. In 1905 the diversion of the Colorado River into the Salton Sea and the events which followed it were so spectacular as to result in world-wide notoriety.

While engaged in re-diverting the river, the writer became impressed with the fact that the experience and information obtained should be made available to the Engineering Profession, and since then he has constantly been gathering data to that end. In February, 1907, a general paper on the subject† was contributed to this Society by C. E. Grunsky, M. Am. Soc. C. E., then Consulting Engineer to the Secretary of the Interior in United States Reclamation Service matters; so that, before giving detailed information, it seemed best to wait until time should have revealed the strong and weak points

* Presented at the meeting of January 8th, 1913.

† "The Lower Colorado River and the Salton Basin," *Transactions*, Am. Soc. C. E., Vol. LIX, p. 1.

of construction and methods. Since then, experience with the control of the Lower Colorado River, and as local executive head of the immense irrigation project of the Imperial Valley, has brought the conclusion that the various possible vicissitudes of irrigation enterprises in the United States have been so well exemplified in the region as to justify setting forth such experience in considerable detail.

Ordinarily, more information is secured from failure than from success; consequently, no apology should be due for pointing out failures as well as successes in a paper, the functions of which are primarily to furnish useful engineering information.

The Colorado River.

The United States Geological Survey has observed the discharge of the Colorado and its several tributaries since 1895, and the results are to be found in its Annual Reports and later in the Water Supply and Irrigation Papers, especially Nos. 249 and 269, on the Colorado River Basin. At various times 169 gauging stations have been maintained, and there are 76 at present.

General Discharge Characteristics.—From the data obtained at these stations, the discharge characteristics of the tributaries and main Colorado River are pretty well determined. The discharge records of the Green River, at Green River, Utah, the lowest gauging station above its mouth, and where the drainage area above it is 38 200 sq. miles, indicate a maximum flow of about 75 000 sec-ft., a minimum flow of about 700 sec-ft., and an average annual run-off of about 5 000 000 acre-ft. The greatest discharge is in June, averaging about 1 600 000 acre-ft.; the annual rise starts about April 1st, reaches its peak in the middle of June, and has passed by August 1st.

The data obtained on the Grand River indicate a proportionately great run-off and very much the same distribution throughout the year. The records, taken at Turley, N. Mex., on the San Juan River until December, 1908, and since then at Blanco, indicate an ordinary flood maximum of about 15 000 sec-ft., a minimum of 75 sec-ft., and an average annual discharge of 1 000 000 acre-ft., but with a much longer period of summer flood than in the Green and Grand.

The maximum flood discharge of the Little Colorado when it enters the Colorado River is not known, but is probably about 50 000 sec-ft. The floods are short and violent, and carry large quantities of silt in

suspension, in which regard the stream is similar to the Gila and Salt Rivers.

The Gila at Yuma is often dry, and has a maximum flashy flood discharge of probably 185 000 sec-ft. with a total average annual run-off of 2 750 000 acre-ft. Flashy floods have been known to occur in every month of the year except May, June, and July, at which times the Colorado has its maximum flow.

Power.—Excellent reservoir sites have been found on the headwaters and along the main channels of the various tributaries, by utilizing which a considerable portion of the flow could be stored for power and irrigation. Such storage would equalize the discharge, that for power having the greater relative influence. There are at present no water-power plants of any importance whatever in the whole drainage area of the Green River. A total of approximately 40 000 h.p. has been developed in the Grand, 7 000 in the San Juan, and 20 000 in the Gila Basin, in connection with irrigation construction. No data seem to be available as to the amount of energy which it is commercially practicable to develop under existing conditions on these various streams—it is obvious that there must be a vast difference between the figures for theoretically possible and for commercially feasible developments.

Irrigation.—The water of the streams making up the Colorado is already utilized for irrigation to a considerable extent. The oldest and largest development in the basin is perhaps that on the upper Green River, in Wyoming. Recently, large irrigation systems have been constructed in the Duchesne River Basin, and there is considerable irrigation around Vernal, and also Green River, Utah. Along the White and Yampa Rivers, in Colorado, meadow irrigation is extensively practiced, and projects are on foot for the irrigation of from 200 000 to 300 000 acres in this section.

Similarly, in the Grand Basin, there are extensive meadow lands in the upper part, and a half dozen small projects in contemplation for the Middle Basin which together would irrigate about 35 000 acres. In the Lower Basin is the Grand Valley Project, covering an irrigable area of 70 000 acres, and the Uncompahgre Valley Project, which, when completed, will irrigate about 150 000 acres, both by the United States Reclamation Service. Under other schemes, from 40 000 to 50 000 acres more will be irrigated.

FIG. 1.

Quite a little land along the San Juan, Animas, Pine, Florida, and La Plata Rivers, and the small tributaries of the San Juan, in Colorado, is now under cultivation, and also several thousand acres of valley land in New Mexico, but, as yet, irrigation has largely been confined to the bottom lands. The greatest probability of future irrigation development in this basin is in San Juan County, New Mexico, where it is said that probably 1 000 000 acres of fertile lands are excellently adapted for irrigation and for which the water supply is ample. The average annual run-off at Turley dam site is probably more than 1 000 000 acre-ft., the reservoir at that point having a capacity of 1 500 000 acre-ft., and the total stream flow at Shiprock, below the mouths of the Las Animas and La Plata Rivers, is more than 3 000 000 acre-ft.

In the Little Colorado River Basin there are scattered a few relatively unimportant patches of irrigated land, and the U. S. Reclamation Service has investigated and found feasible the irrigation of approximately 70 000 acres in the vicinity of Holbrook, by constructing storage reservoirs at St. John's and Woodruff, Ariz.

There are also irrigation possibilities in the Virgin River and Bill Williams Fork Basins, but their total area is relatively unimportant, as far as concerns their effect on floods, or the irrigation of lower lands.

There are excellent opportunities for irrigation in the Gila River Basin, chief of which are the projects examined by the U. S. Reclamation Service in the vicinity of Alma and Lordsburgh, N. Mex. At the latter point there are 250 000 acres of almost unbroken and very fertile land which could be irrigated by the stored water of the Gila River, although at considerable expense. Other good storage sites exist at San Carlos on the Gila, and at Roosevelt on the Salt, the latter having already been utilized by the U. S. Reclamation Service by building the famous Roosevelt Dam, behind which can be stored 1 100 000 acre-ft. of water. With this water, about 200 000 acres of land will be irrigated directly, and power will be generated for pumping water to nearly 60 000 acres more. In addition, there is an excellent reservoir site on the Verde River above McDowell, and large tracts of land on the Gila River in the vicinity of Solomonville and of Florence, Ariz., are now irrigated.

Along the Colorado River itself there are storage sites at Bullhead Point and at another point about 6 miles above the Laguna Dam

near Yuma, while there are irrigable lands between Mohave and Yuma aggregating some 400 000 acres.

Table 1 is a summary of the areas above Yuma which are now irrigated, in a technical sense, although much of this territory, no doubt, is watered in a very unsatisfactory manner.

TABLE 1.

District.	Acres.	Acres.

Colorado, below Mohave and above Yuma	.....
Total	10 150 000 +

It must be borne in mind that all the figures in Tables 1 and 2 are for developments which are theoretically possible, and they would

have to be more or less seriously reduced to be correct for commercially feasible developments, on account of the excessive cost and the formidable character of the silt problem.

Discharge at Yuma.—Observations of the gauge heights of the Colorado River have been made by the Southern Pacific Company on its bridge at Yuma since 1878. The U. S. Geological Survey has maintained a gauging station at this point since 1895, using rating curves for discharge reductions until 1902, since which time careful current-meter observations have been made every 3 or 4 days. Table 3 contains the data thus collected for the 18-year period, 1894 to 1911, reduced to averages.

TABLE 3.—ANNUAL DISCHARGE OF COLORADO RIVER, AT YUMA, ARIZONA, FROM 1894 TO 1911, INCLUSIVE.

Year.	Mean, in cubic feet per second.	Total acre feet.
1894	7 400	5 390 000
1895	9 900	7 162 000
1896	9 000	6 515 000
1897	12 400	9 039 000
1898	9 100	6 581 000
1899	12 200	8 870 000
1900	9 400	6 798 000
1901	11 700	8 495 000
1902	8 400	6 127 000
1903	15 600	11 329 000
1904	13 900	10 119 000
1905	27 300	19 710 000
1906	26 800	19 475 000
1907	35 100	25 500 000
1908	18 900	13 700 000
1909	35 800	26 000 000
1910	19 700	14 335 000
1911	24 600	17 839 000
Mean	17 070	12 388 000

The minimum annual discharge was observed in 1894, and the maximum in 1909. The discharge has been strikingly greater since 1902 than for previous years, but too much dependence should not be placed on the data obtained prior to 1902, at which time very frequent current-meter observations were commenced. The lowest discharge was probably 2 400 sec-ft. in January, 1894, the average for that month being only 2 510 sec-ft.; the greatest was 149 500 sec-ft. on June 24th, 1909. The smallest total discharge for one month was 154 100 acre-ft. in January, 1894, and the greatest was 6 250 000 acre-ft. in June, 1909.

TABLE 4.—MEAN MONTHLY DISCHARGE OF COLORADO RIVER, 1894 TO 1911, INCLUSIVE.

Month.	Cubic feet per second.	Total, mean monthly, in acre-feet.
January	7 340	450 400
February	8 370	466 900
March	12 830	787 800
April	16 380	973 200
May	34 280	2 104 200
June	50 500	3 000 000
July	29 630	1 819 200
August	13 560	832 700
September	9 880	586 900
October	8 460	519 000
November	6 660	395 900
December	7 060	433 200
Totals	17 080	12 369 400

The record for 1908 is given by months in Table 5 as typical of the monthly variation. The lesser disturbances caused by the floods from the Gila in the autumn are very well shown; in this case, the maximum discharge from this source occurs in December, instead of from the Colorado in June.

Necessity for Storage.—The figures for the discharge at Yuma show that, in an ordinary dry year, the Colorado, without regulation, will serve an area not greatly exceeding 500 000 acres. On the other hand, in

an ordinary dry year, with fairly complete regulation—that is, with 2 000 000 acre-ft. of water storage—this river will serve 1 500 000 acres, and any supply held over from wet to dry years would add to the reserve. It is conservative to assume at present that no reservoir site on the Colorado below the Grand Cañon can be utilized, on account of the apparent absence of rock foundations for dams in the river, and, even if other things were favorable, the tremendous quantity of silt in the water means a heavy reduction in the reservoir capacity which could be obtained. Indeed, it has been seriously suggested that by the construction of a series of such dams, the silting up would in time create large areas of excellent land, one above the other.

Above the Grand Cañon, the Kremmling Reservoir site, on the Grand River, and the Brown Park Reservoir site, on the Green River, would together store approximately 4 500 000 acre-ft., and thereby add much more than 1 000 000 acres to the irrigable lands of the Arid West. When it is considered that the present irrigated area of Southern California, exclusive of the Imperial Valley, is less than 300 000 acres, the potentiality of storage along the Colorado is startling.

Another very important feature of water storage along the river is the marked effect it would have in decreasing the difficulty of controlling the Lower Colorado River. Levee construction and bank protection must obviously be designed to guard against maximum floods, and it is these which the storage basins would affect to the greatest degree. The completion of the Roosevelt Dam, which will hold back 1 100 000 acre-ft. on the Salt River, will in future undoubtedly reduce to a considerable extent the dreaded floods from the Gila River.

Rise of the Bed at Yuma.—If the measured discharge of the river at various heights is used in making a rating curve, and this curve is extended back, by means of the gauge readings, to 1878, the results would indicate that the quantity of water formerly passing Yuma was materially less than at present. As a matter of fact, the average low-water plane has constantly risen, and a comparison of the gauge heights by 10-year periods beginning with 1878 shows the following average elevations:

1878 to 1889	114.5 ft.
1890 " 1899	116.6 "
1900 " 1909	117.4 "

The low-water plane at the end of 1909, however, was 3½ ft. lower than during any of the six preceding years, which included the period of diversion into the Salton Sea. Indeed, it was lower, by more than 1½ ft., than 20 years ago, and only 0.8 ft. higher than during 1878-79. The reasons for this interesting condition of affairs will be considered later.

Following conventional practice, the endeavor was made for a long time to establish a rating curve for the Yuma gauging station, but this was found to be impossible. The reason is that the bed is eroded during high water and silted up during lower stages, thus fundamentally changing the cross-section, not only for different gauge heights, but for the same gauge heights at the beginning and end of

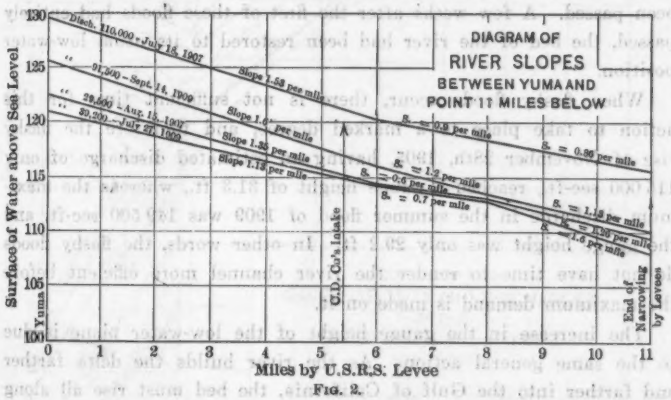

Fig. 2.

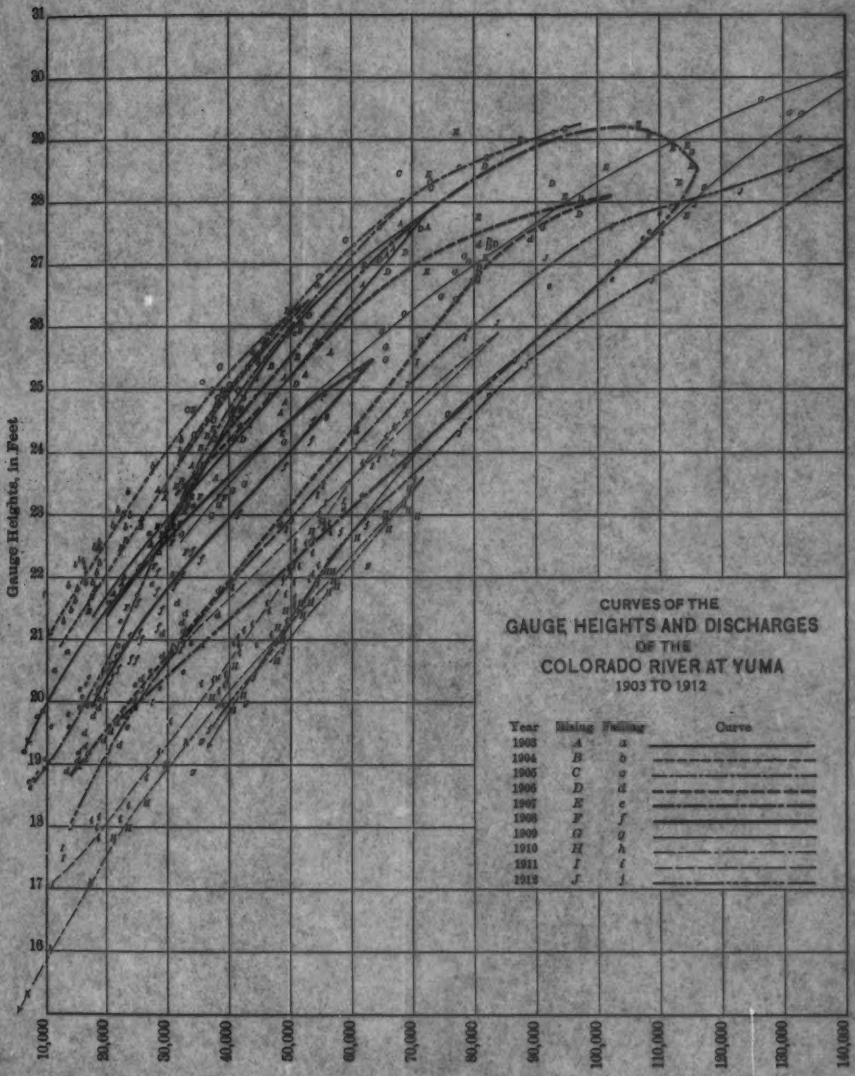
a high-water period. The reason for the exaggerated extent of such action is as follows: The Colorado at all times carries considerable silt, the quantity and character, of course, depending on the velocity of the water. Assuming a given discharge, and conditions of equilibrium, the bed of the river will have a given slope, the water will have a certain velocity, and will carry a certain quantity of sediment, none of which will exceed a definite size or specific gravity. If the volume of water increases, the water section and hydraulic radius will increase, and will result in greater velocity, which will give greater silt-carrying capacity. Conditions at the outfall or mouth are determined and temporarily unchangeable, therefore it follows that the grade of the river will automatically tend to flatten itself by



picking up additional quantities of silt and carrying them along. When the volume of water decreases, the velocity will slacken, resulting in carrying less silt, and the bottom will rise with increasing slope until equilibrium is again established. This condition of affairs results in surprisingly great changes at Yuma during long periods of high water. In 1907 and again in 1909 it was found that for an increase of 10 ft. in the gauge height there was a lowering of the bed of approximately 30 ft., making the total increase in depth of water almost 40 ft. In other words, the grade line drawn from the bottom of the channel at Yuma to the average water surface in the Gulf of California had 30 ft. more fall, from Yuma down, at the beginning of the summer floods of 1907 and 1909, than when the peaks had just been passed. A few weeks after the first of these floods had entirely passed, the bed of the river had been restored to its usual low-water position.

When flashy floods occur, there is not sufficient time for this action to take place to a marked degree, and therefore the flashy rise of November 28th, 1905, having an estimated discharge of only 115 000 sec-ft., reached a gauge height of 31.3 ft., whereas the maximum discharge in the summer flood of 1909 was 149 500 sec-ft. and the gauge height was only 29.2 ft. In other words, the flashy floods do not have time to render the river channel more efficient before the maximum demand is made on it.

The increase in the gauge height of the low-water plane is due to the same general action. As the river builds the delta farther and farther into the Gulf of California, the bed must rise all along the line, of course, taking averages of considerable periods of time. According to Capt. J. H. Mellon, of Yuma, Ariz., who for a great many years navigated the Lower Colorado, the delta fan has extended out into the Gulf more than 6 miles in the past 40 years. Assuming the fall of the river in the lower reaches at 1.2 ft. per mile, the rise in the bed should average 1.2 ft. in 6⅔ years, or approximately 0.2 ft. per year. These figures are about what the hydrographs seem to show, namely, 2 ft. per 10-year period.

Effect of 1909 Flood.—The fact has been mentioned that the low-water plane at the end of 1909 was only 0.8 ft. higher than during 1879, and this becomes much more striking when the general elevations for the entire period are shown by a curve. There were two

IRRIGATION AND RIVER CONTROL.
COLORADO RIVER DELTA.

factors which tended to produce such a result: first, the diversion of the river through the Abejas to the west during the summer flood of 1908, and the lowering of the river bed at that point; and second, the effect of the Laguna Weir basin, which existed as such for the first time that year.

It seems very probable that the Abejas diversion was the smaller influence, in spite of the fact that at the time it was generally considered to be the only factor of importance. Undoubtedly, the bed of the river, and consequently the surface of the water, lowered rapidly while the diversion was becoming an accomplished fact. The amount of such lowering could not have been more than a very few feet at most, although it probably seemed much greater to nervous and frightened observers.

Doubtless it was an important factor that the Laguna Weir had been completed just before the beginning of that year's summer flood, and created a reservoir having a capacity of perhaps 20 000 acre-ft. The waters of the Colorado, heavily laden with silt, were here stilled and their contents deposited. The large volume of water which passed over the dam—the greatest ever recorded on the river itself—contained little more silt than it would ordinarily during low-water stages. Consequently, it picked up and carried along the silt to an unprecedented extent. As the waters receded, the bed was built back to a very much less extent, because there was still an extraordinarily small quantity of silt in the water. Indeed, during this one season, the basin formed by the Laguna Weir was completely filled and some 20 000 acre-ft. of mud were deposited out of the Colorado at this point instead of being spread along the river bed thence to the Gulf.

Unfortunately, no sediment observations were made at Yuma during this flood period. Had this been done, the influence of the Laguna Basin on the low-water plane would doubtless have been approximately ascertainable. In any event, the gauge heights at Yuma, for discharges of 30 000 and 10 000 sec-ft., respectively, platted as ordinates, with the times as abscissas, as in Fig. 3,* for the period of 1902 to 1912, show very clearly that there has been no serious grade recession at Yuma due to the Abejas diversion.

* This method of platting seems to be the only one possible to show much relation, if any at all, between gauge height, discharge, and time at the Yuma gauging station.

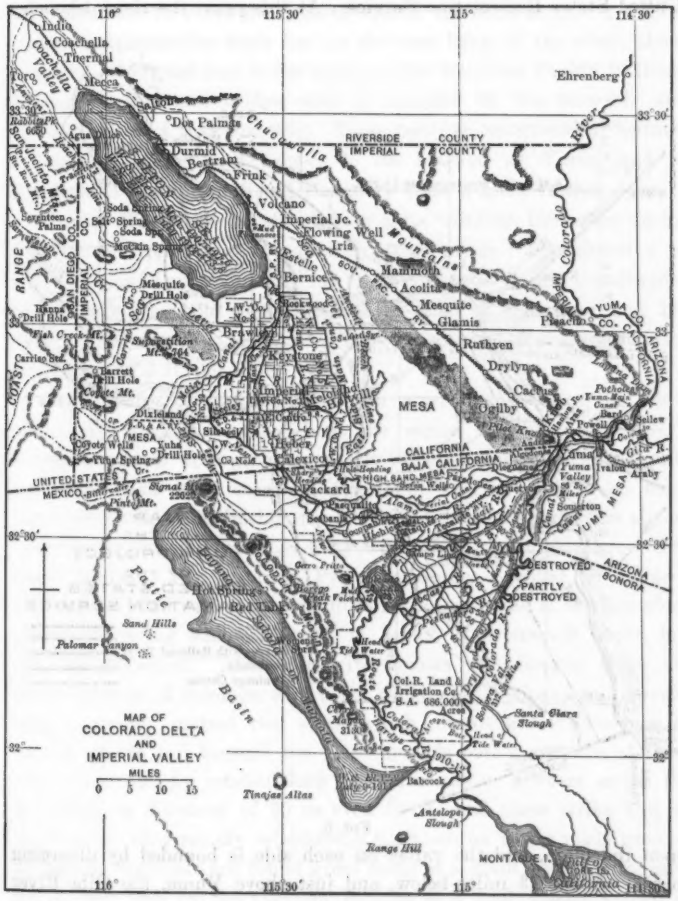
Silt.—Professor C. B. Collingwood, of the University of Arizona Agricultural Experiment Station, examined the silt contents of the Colorado River water at Yuma for a period of 7 months, beginning with August, 1892. One pint of water was taken each day and evaporated, and the sum of the daily residues for each month was then weighed and analyzed. The results varied from a minimum of 1 part of sediment to 613 parts of water in January, 1893, to a maximum of 1 to 97 in October, 1902, and an average of 1 to 388, the ratio of dry material to weight of water being 1 to 277. The corresponding ratio in the Mississippi is 1 to 1 500; the Nile, 1 to 1 900; the Danube, 1 to 3 060. The average value of the fertilizing material was computed at $3.22 per acre-ft.*

Later, January 1st to December 31st, 1904, Professor R. H. Forbes, now Director of the same Experiment Station, made a careful study of the quantity of silt,† and the relation of irrigating sediments to field crops.‡ It was found that the quantity of silt varied from 84 to 3 263 parts per 100 000 by weight, and from 250 to 9 800 parts per 100 000 by volume, or roughly $\frac{1}{1\,200}$ to $\frac{1}{30}$ part by weight, and that 1 acre-ft. of river water contained from a minimum of 1.14 tons to a maximum of 44.42 tons, and an average of 9.62 tons, of silt. Obviously, the total quantity of sedimental material cannot be obtained by multiplying the average sedimental contents by the total annual discharge, but the investigations were carried out in such detail that it was possible to compute the quantity of solid material from the discharge at the time, and in this way it was found that the total solid material carried past Yuma that year was 120 961 000 tons. The total discharge of the river during that year was 10 119 000 acre-ft., and the annual average for 1894 to 1911, inclusive, was 12 388 000 acre-ft. It would seem conservative to estimate that the average quantity of material would be as much larger than that delivered in 1904 as the discharge, on which basis the result would be $120\,961\,000 \div 10\,119\,000 \times 12\,388\,000 = 148\,084\,000$ tons. The specific gravity of the Colorado sediment is 2.65 and the weight of dry soil is 93 lb. per cu. ft., so that this quantity of material would make approximately 71 800 acre-ft. or 112 sq. mile-ft. of equivalent dry alluvial soil.



* These results are given in Bulletin No. 6 of the Arizona Agricultural Experiment Station.
† Bulletin No. 44.

Navigability.—In a technical sense, the Colorado River is navigable from its mouth up to Laguna Weir, and again from there to The Needles. This navigability was recognized when Mexico and the United States entered into the treaty of 1848 regarding the International Boundary Line. By the provisions of this treaty, neither country was to permit works which would interfere with navigation throughout that part of the river which is a common boundary. In a subsequent treaty (1853) this provision was abrogated, but the United States guaranteed in lieu thereof a free and uninterrupted passage of vessels and citizens as far as the river forms a common boundary. As a matter of fact, the swift, shoal waters and the shallow depth over bars in the river itself, together with a tidal bore at the mouth, where the range of tide exceeds 30 ft., has resulted in practically no commerce on the river below Yuma since the Southern Pacific Railroad completed its track in 1876. At various times the U. S. Army engineers have investigated the situation, but have always reported that the navigation interests were not sufficient to justify any expenditure for river improvement.

An Act approved April 21st, 1904, authorized the Secretary of the Interior to divert water from the Lower Colorado River for irrigation purposes and to construct a diverting weir across the river at The Potholes, or Laguna, in which no provision whatever is made for navigation.

Delta of the Colorado.

The Delta of the Colorado River of the West, at the head of the Gulf of California, lies approximately between the parallels of 32° and 33° N. and the meridians 114° 30′ and 115° W. It is partly north of the International Boundary Line between the United States and Mexico, and in larger part south of that line. Its area, including the Pattie Basin and the Cocopah Mountains, is approximately 6 000 sq. miles. It extends practically from the mouth of the Gila River, at Yuma, westward to the rocky walls of the San Jacinto Mountains and south to tide water of the Gulf, while on the north it blends with the depressed area below the sea-level, from which the ocean has been cut off by the deposits of the stream. Its general deltoid form is shown on Fig. 4, together with the course of the main stream and principal branches, sloughs, and overflow channels.

The Lower Colorado River.—The Lower Colorado River may be considered as that portion lying below the last narrows, at what is known as The Potholes—the location of the Laguna Weir, of the United States Reclamation Service. At this point the river debouches

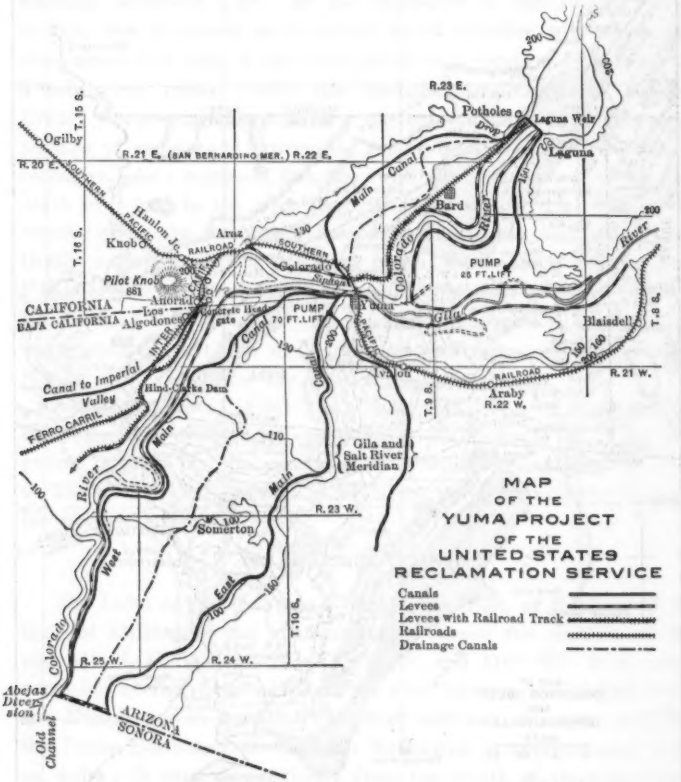

FIG. 5.

upon the plain, and the valley on each side is bounded by diverging mesas. About 13 miles below, and just above Yuma, the Gila River joins it. The present location of this portion of the river is shown on Fig. 5.

Alignment.—Below The Potholes there are two controlling points: one is a peculiar knob of indurated clay at Yuma through the center

of which the river channel has passed since the first advent of the whites; the other is the granite hill known as Pilot Knob. The small eminence at Yuma covers about 40 acres, and reaches a height of not more than 100 ft. above the general level of the delta plain. A similar though much smaller knob lies on the east bank of the river, about 1 000 yd. below and just to the south of the Southern Pacific Railroad Company's line and bridge, and is occupied by the reservoir and settling basins of that company. These peculiar topographical features control the river, with respect to its location at Yuma, and at Andrade, at the International Boundary Line, 8 miles farther down.

Grade.—The course of the river is quite winding, like every flashy, silt-bearing stream with a relatively steep grade. The elevation at The Potholes is approximately 140 ft. above sea level, and the distance by the river is about 100 miles to the head of tide-water and 114 miles to the mouth at the Gulf. Thus the general average fall is approximately 1.3 ft. per mile.

Remarkable Vegetation.—Attention must be called to the dense and varied vegetation throughout the region subject to the river's overflow. Arrow weed grows in nearly impenetrable jungles; mesquite and screw-bean trees occur in forests of varying density on older established soil, while freshly deposited mud flats and banks are almost immediately covered with seedling willows which quickly grow into heavy timber. For instance, Professor Forbes counted on an area 5 ft. square 1 500 willow sprouts up to 20 in. high, and in another older growth 90 young willow trees 20 ft. high.* Cottonwoods occur, but are not abundant. Along the river banks and sloughs there are dense thickets of common wild cane, which the Mexicans call *carrizo,* with a densely matted root stock which affords great resistance to erosion of the soil because the plant spreads both by means of these root stocks and by sending long slender stems or runners across the mud flats to distances of 20 or even 30 ft., and these strike root at every point, thus rapidly establishing the plant on newly made ground. In marshy locations are found great fields of a plant with an immense edible bulb used by the Cocopah Indians as a food, locally known as *tule.* In addition there is the *sesbania,* or so-called wild hemp, which is limited strictly to ground subject to overflow. It comes up from seed

* "The Lower Courses of the Colorado," R. H. Forbes, in *The Great Southwest,* Yuma, Ariz., Vol. 1, Oct., 1906, p. 2.

annually after the subsidence of the summer floods, stands in dense thickets from 5 to 20 ft. high, and is often square miles in area. This plant is also of interest because of its industrial possibilities. In general, the vegetation of the delta is remarkable for the manner in which plants of a kind mass together in areas, almost to the exclusion of other species, and for the remarkable density and immense areas occurring in continuous bodies, strips, and patches, particularly of willow, arrow weed, wild hemp, and *carrizo*.

Line Changes.—The entire Colorado River Delta has been said to consist of alluvial silt. When the river is low the water wanders in a devious way, along a very wide shallow bed in many places, and is everywhere confined by banks seldom exceeding 10 or 12 ft. high. During high stages these banks are overflowed at many points, and in the case of severe floods such overflow is practically general. The banks are thus wet and softened, and, when the river falls, caving and side-cutting proceed wherever the current is thrown at an angle against the confining banks, and often with startling rapidity. At the same time, the overflow water, being very heavily charged with silt, is checked by the dense, matted growth, and at once deposits its heavier particles, the smaller sizes being dropped a little farther down stream, and so on. Thus the country is built up most rapidly at the banks, and the land slopes away from the river at a constantly decreasing rate. Indeed, the theoretical cross-section of the land surface away from the stream is a hyperbola. Of course, these slopes are not identical at any two points along the river, but instrumental data at present available show the general average fall to be about 1½ ft. in the first 100 ft.; 3 ft. in the first 300 ft., and from 5 to 8 ft. in the first 3 000 ft.

Although the coarser silt deposits are thus found immediately at the river bank, there are several reasons why this has little practical significance. The overflow water gathers in little channels which follow the line of greatest slope and in general approximately away from and down stream, the direction being the resultant of the general grade parallel to the river, and of the slope locally from the river's banks to the abeyment on either side. Such overflow channels build up their miniature beds and banks exactly like the main channel; they join to form overflow creeks, and these in turn form the overflow rivers.

As the level of the river rises higher and higher by such overbank deposition, it is obviously only a question of time until an unusual flood will produce sufficiently high velocities in some of these overflow channels to cause a recession of their grades extending through the river bank, thus diverting a portion of the water through the new route. Ordinarily, as the flood recedes, such breaks are clogged with drift and sediment, but sometimes the clogging action is not rapid enough to counteract the opposing forces successfully, and in this way radical and extensive changes of the river's course throughout the delta occur. Usually, these changes are in the nature of cutting off bends and thus shortening the channel.

At first thought it would seem that a diversion to the west would be a very probable occurrence during any great flood, because, with the constant extension of the delta southward, the gradient in that direction has become less, and to the west, more, until the fall toward the Gulf is much less than half as great per mile as that along former courses to the Salton Basin. As a matter of fact, however, though the overflow waters go down these channels with considerable rapidity, the cross-sections for many miles from the river are exceedingly inefficient, due to the dense vegetation, drift in the water, and occasionally, no doubt, to beaver dams.

In addition to the foregoing, there is another factor of importance: The bed of the main stream for quite a distance on each side of the International Boundary Line is excessively eroded during flood periods and filled up during lower water stages, as has been fully explained, so that, with a given flood discharge in the river, the water going over bank constantly decreases in quantity, in depth, and in velocity, and it is only the overbank flow which is important in connection with the overflow channels.

Character of Local Silt Deposits.—These various actions result in the formation of numerous little pockets throughout the inundated areas, in which water is left standing after the recession of each flood. Wherever this occurs the very finest of the silt settles out and, on becoming dry, cracks in large, somewhat hexagonal, irregular cakes. If the deposit is very thin, these cakes curl up when thoroughly dried and are broken up and carried away as dust by the wind; but when very thick the cracks are sometimes 6 in. and even more in width at the top and extend down 4 or 5 ft. Dust and vegetation accumulate in

such gaping cracks, and the next flood deposits another layer of sediment. Then, the heavier materials having settled first, the result is that the pockets are arched over, thus producing underground interstices which must be carefully guarded against in levee and other earth construction for holding back water.

The character of such deposits depends on the nature of the silt carried in the overflow water, and thus it happens that it is usually possible by examination to determine whether a deposit was made by a flood from the Colorado, or from the Gila proper, or from the Salt River.

The rate of such local deposition is sometimes startling. One instance the writer observed was due to the flood of 1905 which caused the diversion of the river into the Salton Sea. This filled in the ground on the left-hand side of the break about 3 000 ft. from the old river bank over quite an area to a depth of 6 ft., or almost to the roof of an Indian's *ramada*.

In this manner the Colorado River, from its exit from the Grand Cañon near The Needles, Cal., to about 3 miles south of Yuma, Ariz., has wandered about between its eastern and western abeyments, and, where these were any distance apart, has built up alluvial valley stretches which are practically level transversely.

The Principal Overflow Channels.—The overbank flow of the Colorado on the east side does not gather into channels of importance because the eastern abeyment is near by, except far down the stream, where there is what is known as the Santa Clara Slough. This, doubtless, at one time was the river's main channel, and during the severe summer flood of 1907 it carried so large a volume of water that for a time it seemed probable it would again become the main outlet of the river to the Gulf. This slough is about 40 miles long, and empties into the Gulf about 20 miles southeastward from the present mouth. This and the other smaller high-water channels on the east side are of no material importance in the engineering operations along the river.

By far the greater portion of the delta cone lies on the west side, where there are five inundation channels of considerable importance. These are shown on Fig. 4. In their order down stream from Andrade, they are known as the Alamo, New, Paredones, Abejas, and Pescadero Rivers. Without a thorough knowledge of them and their relation-

FIG. 6.—TYPICAL SURFACE OF CRACKED ADOBE SOIL.

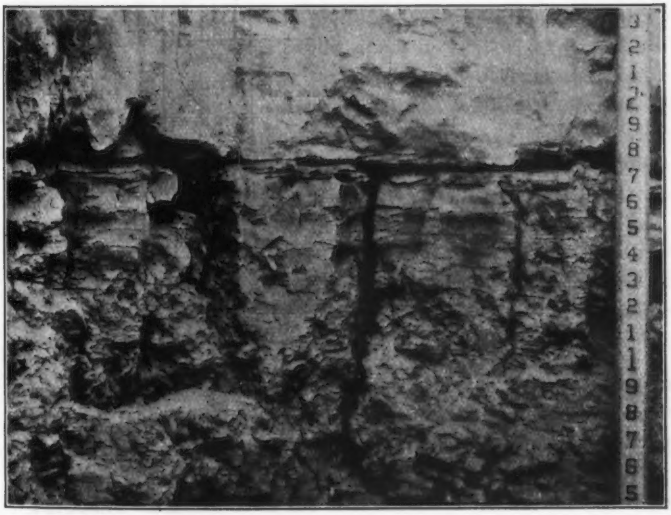

FIG. 7.—TYPICAL SUBSURFACE OF CRACKED ADOBE MATERIAL. THE BOTTOM OF THE ROD IS 5.3 FEET BELOW THE SURFACE.

ship to the Colorado flood-waters, no satisfactory understanding of the problems of the Lower Colorado, and the endeavors to handle them, is possible.

The Alamo River, which was formerly often called the Salton or Carter's River, has its gathering ground in the northerly edge of the delta cone immediately south of Andrade. It follows somewhat closely the southern end of the sand hills, at times in a well-defined channel and again spreading out in broad swamp sections, known locally as

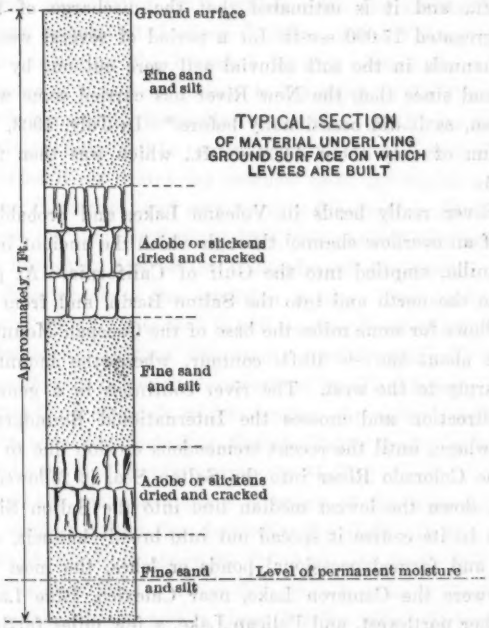

FIG. 8.

lagunas. About 40 miles west of the Colorado it crosses the International Boundary Line, and occasionally its waters were doubtless carried clear into the Salton Sink. The swamp areas, *Las Lagunas*, were also drained in part by the Quail River, which emptied into the Paredones. Farther down the Alamo there is a low area to the south and west through which the overflow waters from the great flood of February, 1891, broke over from the Alamo into the New River, the main point being at what is known as Beltran's Slough. The latter

runs into the low region between the Paredones and the Alamo, and this drains into New River through the Garza Slough. It seems probable that in 1891, for the first time in many years, the overflow waters reached the New River channel directly *via* the Alamo, rather than *via* Volcano Lake. During this flood from the Gila and the later annual summer flood of the Colorado, sufficient water reached the Salton Sea *via* the Alamo and the New Rivers to cover approximately 100 000 acres in the bottom of Salton Sink to a depth of about 6 ft., and it is estimated that the discharge of both these rivers aggregated 17 000 sec-ft. for a period of several weeks. Well-defined channels in the soft alluvial soil were cut out by both these streams, and since then the New River has carried some water every flood season, as it did occasionally before.* In July, 1903, it reached a maximum of only about 4 000 sec-ft., which was then the largest since 1891.

New River really heads in Volcano Lake, and probably is what remains of an overflow channel through which the ancient inland lake, Lake Cahuilla, emptied into the Gulf of California. At present its grade is to the north and into the Salton Basin, and from the lake's edge it follows for some miles the base of the Cocopah Mountains until it reaches about the + 10-ft. contour, where the mountains turn rather sharply to the west. The river continues in a general northwesterly direction and crosses the International Boundary Line at Calexico, where, until the recent tremendous erosion due to the diversion of the Colorado River into the Salton Sea, it followed a gentle depression down the lowest median line into the Salton Sink. At a few places in its course it spread out into broad channels, a few feet in depth, and formed occasional ponds or lakes, the most important of which were the Cameron Lake, near Calexico, Blue Lake, a few miles farther northwest, and Pelican Lake, a few miles farther on. It is now a great barranca, averaging from 40 to 80 ft. in depth and 1 000 ft. in width, from a point about 6 miles southeast of Calexico to the Salton Sea.

The Paredones is the first drainage channel on the southerly slope of the delta cone, and within quite recent years had direct connection

* Old settlers in the vicinity agree in saying that in 1840, 1849, 1852, 1859, 1862, and 1867 large quantities of water reached the Salton Sea. In 1862 that body of water attained unusual size, and the flow in New River that summer was so great that it stopped the mail stage-line service between Yuma and San Diego for several weeks, and a flatboat was built to ferry across it, near Calexico.

with the Colorado River. This connection was automatically reduced to the very small channel which existed in 1906, when the levee construction then done fundamentally changed overflow conditions. The Paredones gathers the overflow water from a large area, and a few miles from the river becomes a channel of considerable width and depth, following thence along down an element of the delta cone. During the extraordinary conditions existing in 1905-06, it carried a very large quantity of drift, which, with the assistance of some beaver dams, accumulated about 7 miles above Volcano Lake, and resulted in enlarging the branches leading toward the south. The overflow water of this river gathers to the south in the Pescadero, and to the north joins with the similar water from the Alamo and runs in part to Volcano Lake and in part through Garza Slough to New River.

The Abejas River drains the overflow from the region immediately south of the Paredones, and empties into the western side of Volcano Lake. Since the summer flood of 1908, this channel has been carrying the entire low-water flow of the Colorado and the greater portion of the flood flow, which is the condition to-day. The reasons for this diversion and the efforts to stop it will be considered at length later.

The Pescadero, another important overflow channel, drains the region immediately below that unwatered by the Abejas. It empties into a network of channels which conduct the water from that part of the delta cone and including Volcano Lake, finally gathering into Hardy's Colorado and emptying into the Gulf.

Volcano Lake may be another remnant of the waterway through which the ancient Salton Sea drained to the Gulf. It is a flat basin, the bottom of which is about 22 ft. above sea level, and its high-water stage is about 35 ft. At such a stage it extends about 10 miles northwest and southeast, and is about 6 miles wide. It is fed by the Paredones and Abejas Rivers, the latter since 1908 being the course of the Colorado proper, and by the system of sloughs which form the Pescadero network and also serve as an outlet. It is on the summit of the low, flat divide between the Salton Basin on the north and the Gulf on the south, and thus its discharge is both toward the north and the south. From the size of the outlet channels it is obvious that the greatest discharge has in recent times been southward. Since 1908 a line of levees has prevented any water from passing into the New River and thence into Salton Sea; the lake's waters, therefore, go to

the Gulf through Hardy's Colorado, which is an important channel, averaging perhaps 500 ft. wide and 20 ft. deep at maximum stages, with a fall varying with the stage in the lake from less than 15 to more than 30 ft. in a distance of from 45 to 50 miles.

The engineering operations which resulted in the irrigation of the Imperial Valley and its threatened destruction by inundation at various times since, have in very large measure been concerned with the overflow channels just described.

Diversion to the West.—Regardless of the tendencies for and against a fundamental diversion toward the west, the Colorado continued to flow in its regular bed to the Gulf until 1905. There can be no doubt that the operations of the California Development Company, and particularly in making an artificial cut from the Colorado River into the Alamo Channel and the utilization of that channel as a main canal, rendered the diversion to the west at that point, when it broke through in 1905, very much easier and more probable of immediate occurrence. Nevertheless, the behavior of the river since that time indicates pretty clearly that a diversion to the west somewhere within the first 25 miles below Pilot Knob was just about due, under natural forces alone. The conditions of equilibrium had become unstable to a degree, and this is the condition in which they are to-day.

Mesa and Delta.—The high mesa land which forms the eastern abeyment below Yuma extends therefrom almost south and into Mexico. The river turns, crossing the valley almost from east to west for about 5 miles, until it reaches the foot-hills forming the west abeyment; then it turns more than a right angle, hugging these hills, to the International Line; and thence it flows for 80 miles, in a remarkably direct general line, but little west of south, to the Gulf. On the west side of the valley the foot-hills end at Pilot Knob, a small mountain at the International Boundary Line, and the low mesa begins. The edge of the latter runs southwest for 4 miles; then it turns sharply directly west for 25 miles; then again it turns sharply to a little west of north for 50 miles—the latter edge forming the east side of the cut-off portion of the Gulf, Lake Cahuilla.

It is thus in a sense almost proper to say that the Colorado Delta begins practically at the International Boundary Line between California and Lower California, and that, for the first 14 miles below that line, the river is running on the very edge of the divide of the delta

cones, on one side sloping northwest to the Salton Sea and on the other to the Gulf. Furthermore, from that point the river (until 1908) was in a ridge of its own making, which it was raising constantly, and which is quite close to the eastern abeyment.

Pilot Knob.—Pilot Knob is a small, detached, and relatively abrupt mountain lying just above the International Boundary Line on the west bank of the river, and is one of the landmarks of the region. One of its rocky arms extends almost to the present west bank of the river. Fifty years ago the river had a pronounced bend, shown by the dotted line on the map, Fig. 13, and hugged this rocky point until passing it. The time when the shift of the river took place is not definitely known, but, very fortunately, at present the alignment here for several miles is almost straight.

It is quite significant that Pilot Knob is the lowest point along the river where a canal can be taken out for the diversion of water, with the diverting structure resting on solid rock. For this reason, it has been considered as a strategic factor in the irrigation of the Imperial Valley, but, in the writer's opinion, quite erroneously. The engineering fetish of a solid rock foundation for structures for irrigation and other purposes confining water, has resulted in needlessly spending amounts of money in the United States alone which must aggregate a tremendous sum. Perhaps no case is more spectacular than that of Pilot Knob and its relation to the irrigation system of Imperial Valley.

Early Suggestions Regarding Salton Sea.—Almost the very first explorers were interested in the Salton Basin and its various possibilities. The ability to create an inland sea by diverting into it the water of the Colorado attracted much attention, and it was very seriously suggested because of a supposed advantageous effect that it might have on the climate of the entire region. On the other hand, the possibilities of irrigating the Colorado Desert by the waters of the Colorado, which has since been accomplished, were not overlooked, work having been done on many more or less serious propositions at various times.

Later Irrigation Projects.

In 1891 and 1892, the Colorado River Irrigation Company was formed. Mr. C. R. Rockwood was placed in charge of the engineering work, and, under his direction, the entire problem of irrigating the Colorado River Delta was carefully examined and the important

features fully worked out. The financial stringency of 1893 put an end to the operations of this corporation, and in 1894 Mr. Rockwood was forced to sue the company for his unpaid salary. In partial satisfaction of the judgment which he obtained, the engineering records and data were taken over by Mr. Rockwood, and the Colorado River Irrigation Company ceased to exist. Nevertheless, it is interesting to consider the plans then evolved by that corporation, or, more properly speaking, by its engineer, Mr. Rockwood.

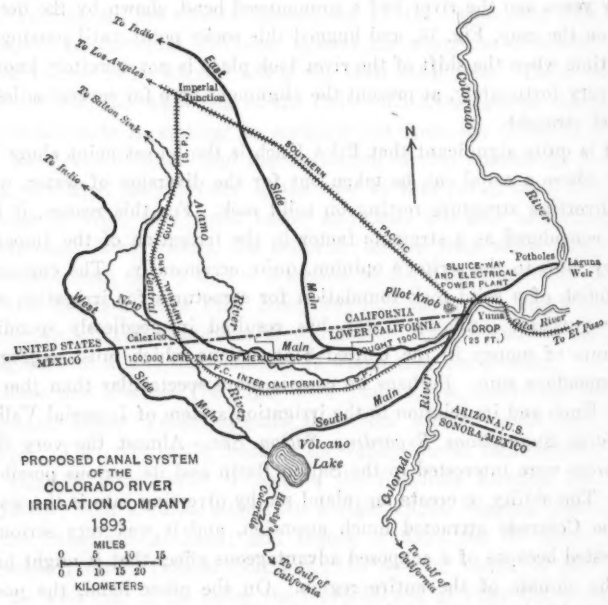

FIG. 9.

Plans of the Colorado River Irrigation Company.—These plans are outlined diagrammatically in Fig. 9, and show what is probably the ideal system of diversion and canals for watering all the land irrigable by gravity with the waters of the Lower Colorado. Events, however, shaped themselves so that the water for Imperial Valley has been, and is now being, diverted at Pilot Knob, and the U. S. Reclamation Service has built a diversion weir at The Potholes or Laguna to put water by gravity on all except the mesa lands in the so-called

Yuma Valley. Mr. Rockwood contemplated taking water out at The Potholes and installing in the main canal near Pilot Knob a sluiceway with which he intended to flush out the silt in the canal above which escaped being deposited in and removed by hydraulic dredges from a short enlarged section of the main canal immediately below the diversion point, where the velocity of the water would be reduced. The dredges were to be operated by electricity generated at the sluice-way. The maps showing the detailed surveys of these canals are now in the files of the California Development Company at its Calexico headquarters.

The California Development Company.—Mr. Rockwood, being thoroughly imbued with the practicability and advantages of the project to irrigate the Colorado Desert with the waters of the Colorado, undertook to carry it through, and finally did so by means of the California Development Company, under the engineering direction of, and with funds supplied by, Mr. George Chaffey, of Los Angeles, Cal. At the present time it is only important to say that, because of financial considerations, the engineering features were radically modified to diverting the water at Pilot Knob and utilizing a large part of the Alamo overflow channel as a main canal to carry the water around to the Imperial Valley, essentially as suggested by Lieut. Bergland in 1875-76. In this way the diversion work at The Potholes was eliminated, and a very cheap and quick method of getting water into the valley was arranged. By this decision the inclusion of the Yuma Valley as a part of the project was abandoned.

The Yuma Project, U. S. Reclamation Service.—As early as 1895 the Hydrographic Branch of the United States Geological Survey began stream gauging in California, starting with an allotment of $5 000. More recently, the California Legislature has aided in the work on the basis of appropriating sums equal to those set apart by the United States. At the present time daily discharge observations are made on about fifty typical streams. Hydrographic investigations throughout the Western States, not only helped to prepare the way for national irrigation, but resulted in acquiring such hydrographic data that when the Reclamation Act was passed, in 1902, the best opportunities for national irrigation projects were pretty generally outlined. On account of legal and social complications elsewhere throughout California, the Yuma Project was finally selected as the first to be

commenced by the Reclamation Service in that State. On April 8th, 1904, a board of seven engineers recommended this project; on April 21st, Congress authorized the Reclamation Service to take water from the Colorado and divert it by a weir which would close it to navigation permanently above Yuma. On May 10th, 1904, the Secretary of the Interior gave his approval, and an allotment of $3 000 000 was made.

There are approximately 75 000 acres of irrigable land under this project in Arizona, and 15 000 in California. Of this area, 98% is subject to the provisions of the Reclamation Act, the owners of private lands having signed the necessary agreements to limit their holdings to the size of the farm unit to be determined, and otherwise to conform to the regulations required by the Service. A Water Users' Association, consisting of the land owners of the project, handles the affairs of the district, from the farmers' point of view, and has contracted with the Secretary of the Interior to accept and use the water under the usual conditions fixed in such cases by the Government.

The Imperial Valley should logically have been included as a part of this project, particularly from an engineering point of view. However, water had been delivered into the Imperial Valley for almost 3 years when the Secretary of the Interior approved of the Yuma Project. In addition, there were complications—largely over-estimated and far more apparent than real—due to the fact that it is practically imperative to go through Mexican territory with canals to serve the American Imperial Valley. The project, therefore, was limited, for the present at least, to the irrigation of the Yuma Valley.

Fig. 5 is a map of the restricted Yuma Project. As it occupies a position on the river above that of the California Development Company's constructions, and for that reason in many ways has had a very important influence on the whole irrigation of the Colorado delta proper and related engineering problems, its essential features will be briefly described first. These are a diversion weir, and the levee, canal, and drainage systems. The diversion is by an overflow weir of the type developed by British engineers in their irrigation work in India, and improved and used later on the Nile. It is of loose rock, rests on a bed of river silt, is almost a mile long, very wide, quite low, and is in general an exceptionally interesting and expensive construction.

The next most unusual and interesting feature is the necessity for about 74 miles of levees to protect, from the overflow waters of the river, the greater part of the land to be irrigated. The canal system, with the exception of the siphon under the Colorado, is nothing out of the ordinary, and the same is true of the drainage system.

THE YUMA PROJECT, U. S. RECLAMATION SERVICE.

The project has proved very much more expensive than was originally contemplated, the estimated cost being $3 000 000, whereas, the construction expenditures up to June 30th, 1910, were $3 617 472.71,* exclusive of maintenance and operation charges and $100 000 of the preliminary survey costs more properly chargeable to general investigations along the Colorado River than to the Yuma Project itself. Work on the project was reported as 80.8% complete, but this estimate was revised in April, 1911, and changed from 81.6 to 52.4%, making the proper percentage completed on June 30th, 1910, about 51.8. On this basis, the total cost will be $6 964 233, or approximately $77.25 per acre of irrigable land.

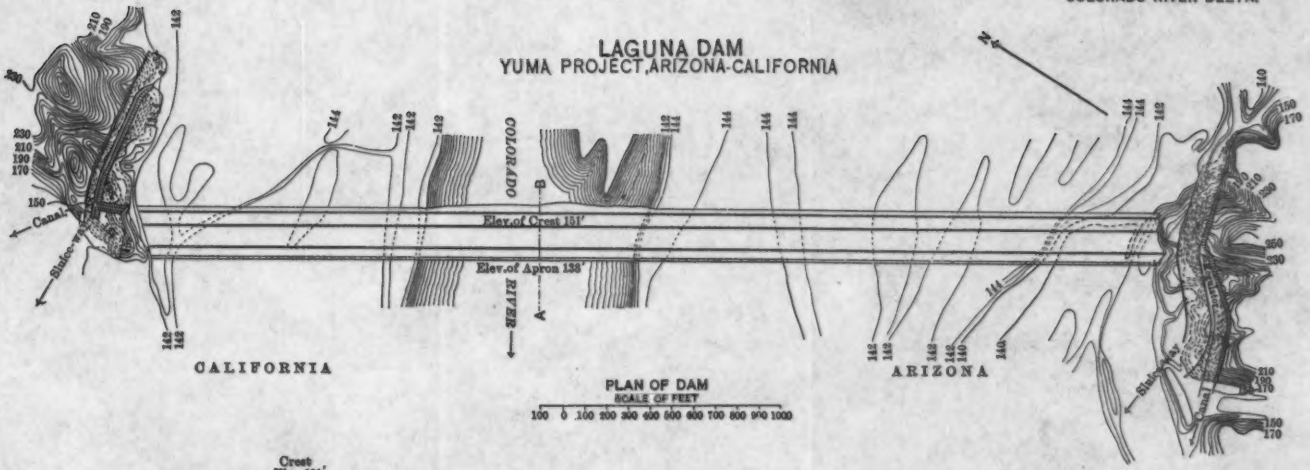
Laguna Weir.—The location and general design of this noted structure were determined by the character of the bluffs on each side of the last narrow point of the Colorado Valley, where they were almost a mile apart, and the fact that borings disclosed no bed-rock at reasonable depths in the river bed. Accordingly, it was decided to build a low, wide diversion weir of the so-called "Indian" type. The original design, as shown by Plate XLIII, was constructed with practically only one modification, namely, the interchange of the principal diversion from the Arizona to the California side.

Purpose.—The purpose of this structure, primarily, was to provide for silting out the heavier particles carried by the river, during flood periods especially, where such deposits could be sluiced out from time to time and in such a way that river floods would certainly carry them down stream.

Consideration will be given later to the silt problem, but it may be said that the only way of keeping the large, heavy, valueless particles of silt from getting into the distribution system, and clogging it, is to provide a settling basin where the water for a short time will either be practically still or the velocity reduced to not more than

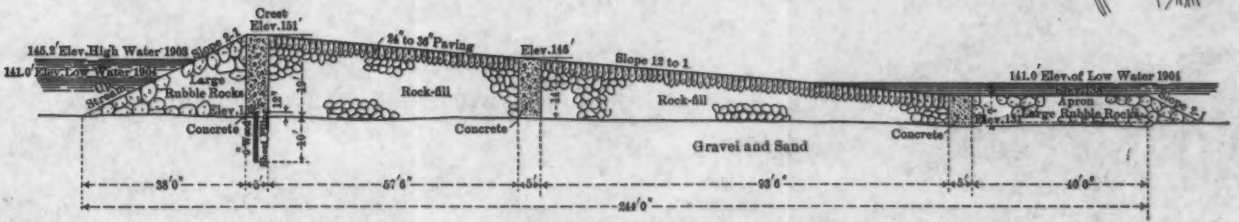
* Ninth Annual Report, U. S. Reclamation Service, Washington, 1911, p. 81.

0.5 ft. per sec., with freedom from eddy currents. Such deposits may be removed either by sluicing out with large volumes of water at a high velocity, or by using pumps, dredges, or some other kind of machinery. It was estimated that in the main canal, originally designed to carry 1 600 sec-ft., the volume of wet silt to be removed therefrom daily was approximately 17 000 cu. yd. The sluice-way method of doing this means a higher initial cost and certainty of success, as compared with the very much lower cost, greater maintenance and operation charges, and somewhat less certainty of operation, for removal by machinery. The Laguna Dam (or rather weir) consists essentially of sluice-ways at each end of the structure, with a barrier between to hold up the water and afford a head for sluicing.



Sluice-ways.—The sluice-ways are controlled at their lower ends by large, vertical, steel-plate gates which are raised and lowered by electric machinery. The method of operation is to close the gates and cause the water in the sluice-ways above them to become practically still. The water thus held back quickly drops its heavier silt, while the canals are supplied through flash-board regulator gates in the outer sides of the sluice-ways, these gates being so long that a thin stream of water running over the tops suffices, and no water from near the bottom, where the sediment is greatest, is ever taken. From time to time, as may be necessary—and this varies greatly, depending on the stage of the river and the quantity of heavier silt particles carried—the gates are rapidly raised, and, with a fall of about 10 ft., the water rushes through the sluice-ways carrying away the silt deposits and dropping them a short distance below. During the annual and other floods, these deposits are taken up by the river and carried down stream. These sluice-ways are built through rock, their floor elevations being 13 ft. below the crest of the weir. They are lined and paved with concrete, and constitute a very massive and beautiful piece of work.

The Weir.—Between these sluice-ways the weir is built, the slope of the face being very flat, only 1 to 12, and capped with a concrete pavement, 18 in. thick, except a small portion which is paved with rough stones from 2 to 3 ft. thick. The crest was 10 ft. above the low-water mark at the dam when the structure was started,* and the top



* See discussion of variation in elevation of river bed at different times and different seasons, and the consequent low-water mark.

of the down-stream wall is 3 ft. below; thus the total fall of the face is 13 ft.

The weir was constructed simultaneously from each end, and a gap of 800 ft. was left in the center of the river channel. The original plan for completing this gap was by building upper and lower coffer-dams with piling, brush, and sand bags, but this was changed and finally the barrier rock fill dam, developed by the operations of closing the first and second breaks described later, was utilized. Before the central section was filled in, the sluice-ways had been excavated and completed, the total capacity being more than enough to carry the low-water flow of the river. Rock was obtained in part from the excavation of the sluice-ways, and in part from the hills on each side; it was loaded on cars with derricks and steam shovels, and hauled by dinky locomotives to the various portions of the work. Coffer-dams made of quarry spoil were extended out into the stream, and inside these large pumps were used to clear of water. As much excavation as possible was done with teams and scrapers, and the remainder was taken out by suction dredges and pumps. Sheet-piling and the parallel concrete walls were then built, and the rock filling between was put in, followed up by the concrete surfacing. The actual quantities used exceeded the original estimates considerably; they are given in Table 6.

TABLE 6.

Rock excavation	444 640 cu. yd., or about	146%	of estimates.
Earth excavation	346 930 " " " "	123%	" "
Rock in dam	375 018 " " " "	123%	" "
Concrete*	76 066 " " " "	280%	" "
Sheet-piling	82 779 lin. ft. " "	156%	" "
Rock pavement	Insignificant—decrease.	100%	" "

* In place of rock paving, the concrete surface was substituted.

On March 15th, 1905, bids for the construction of the Laguna Weir were opened, but those submitted were rejected and the work was re-advertised. Proposals were again opened on June 5th, and on July 6th, 1905, the contract was awarded at the following prices:

Rock excavation	$1.30	per cu. yd.
Earth excavation	0.30	" " "
Rock in dam	0.35	" " "
Concrete	4.00	" " "
Sheet-piling	0.40	" lin. ft.
Laying pavement	1.00	" sq. yd.

The contract required the work to be finished within 2 years, which would mean just at the time of the peak of the summer flood of 1907. These prices, on the estimated quantities, made the bid amount to $797 650. There were seven other bidders, whose figures ranged up to $1 030 117.50. The Reclamation Service, under the specifications, supplied the cement to be used. On February 28th, 1906, the same firm was awarded the contract for furnishing and erecting the sluice-gates, regulator-gates, and operating machinery for the main sluice-ways and head-gates, the bid being $65 900. The contractors began work on July 19th, 1905, and a year later had completed 26.4% of the work.

As the quality of the rock obtained was much poorer than had been anticipated, the Board of Engineers of the Reclamation Service modified some requirements in the specifications and contract which resulted in increasing the contract price by $331 486, or to $1 129 136, and extended the specified time for completing the structure from July 19th, 1907, to January 19th, 1908. On January 23d, 1907, when about 34% had been completed, the work was taken over by the Reclamation Service direct. On July 1st, 1907, 52% of the work had been finished, a year later 77% was done; and it was practically completed in March, 1909, just before the summer flood of that year began.

The Reclamation Service gives the following costs* of the Laguna Weir and the sluice and regulator works:

Laguna Weir	$1 672 168.20
Sluice and regulator works	345 295.92

Other recent operations along the river have shown that a structure serving every purpose of the Laguna Weir could have been built by methods now well known at far less cost. The building of rock fill dams in the bed of such a stream as the Lower Colorado was considered impracticable until the work of re-diverting the river developed such method. However, it is now evident that it would have been far simpler, quicker, and cheaper to have developed rock quarries, thrown trestles across the bed of the stream, and dumped rock therefrom to form a wide rock fill dam, without any concrete walls whatever, and covered the top with concrete. There would be no difficulty in beginning the construction of such a dam in the center of the stream and causing the river itself to excavate its bed opposite the rock fill as the latter should be built forward. In this way the excavation

* Ninth Annual Report, United States Reclamation Service, Washington, 1911, p. 82.

would have been made to a little greater depth than the bottom of the concrete walls actually put in. The rock for such a purpose would by preference be graded, so that quarry spoil would in no way be objectionable, and rock material obtainable in the adjoining hills could be blasted out in large quantities, loaded with steam shovels, and consequently obtained and handled very cheaply. A structure having essentially the same top dimensions and surface covering, and extending deeper into the river bed than the existing one, would in this way have cost far less and be even more secure from failure. There would be practically no seepage through or under such a dam or weir, as the similar constructions, very much thinner and sustaining much greater heads, which closed the first and second breaks, seem to be absolutely water-tight.

To the cost figures should be added the proportional share of the total administrative and general expenses. Such administration figures are given as $179 021.43, to which should properly be added at least $75 000 of the item: "Preliminary surveys previous to selection of project—$174 735.83," or a total of $254 021.43. These are probably the approximate general expenses to be distributed over expenditures totaling $3 717 472.71, or 6.89 per cent. On this basis, there should be added to the cost, for general expenses, $114 243.24, or a total for the Laguna Weir proper of $1 786 411.44, and to the sluice and regulator works $23 583.71, making their total $368 879.63, or a total of $2 155 291.07, not including the loss of $400 000 said to have been sustained by the contractor, which would raise the total to $2 555 291.07.

The result is a magnificent and permanent head-works for taking water from the Colorado to irrigate by gravity about 75 000 acres of land in the Yuma Valley; and, at some future time, this structure may serve as well for diverting water to irrigate the entire Colorado Delta. Its very great cost, however, raises the question as to whether the silt problem could not have been solved in a more economical and equally satisfactory manner by pumping depositions thereof, in an enlarged section of the canal, back into the river, with suction dredges. This question cannot be determined until the maintenance costs of the sluice-ways and diversion weir are shown by experience, and the total costs and results of handling the silt with dredges, as is now being done at the California Development Company's head-works, have been ascertained for a considerable period.

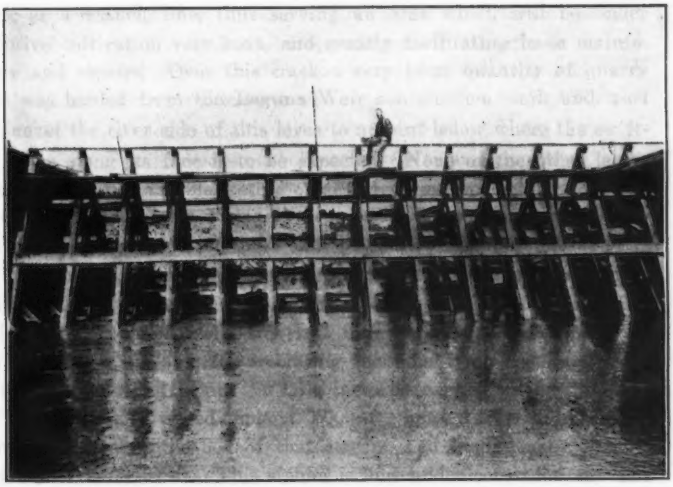
Levee System of the Yuma Project.—Practically all the valley lands in the Yuma Project are subject to overflow, so that a general and comprehensive system of levee protection is necessary. Fig. 5 shows this system, practically all of which has been completed. In general, the designs were for dikes 4 000 ft. apart along the Colorado and 3 200 ft. apart along the Gila, with a height of from 4 to 5 ft. above the high-water marks; as constructed, however, there are long stretches along the Colorado where the levees are only from 1 600 to 1 800 ft. apart.

The first levee construction was in accordance with the usual Mississippi River practice. The ground was cleared, stumps and roots were grubbed out, the base was plowed, and the levee was built with earth taken from borrow-pits on the river side. These borrow-pits were about 400 ft. long in the direction of the levee, with cleared traverses between about 12 ft. wide; 40-ft. berms; allowable depths of pits, 2½ ft. at the side nearest the levee and 3½ ft. at the farther side; levee top width, 8 ft; side slopes, 3 to 1 on the river side and 2½ to 1 on the land side. No muck-ditching was done.

The first stretch of levee constructed was 10 miles long, extending south from Yuma along the eastern bank of the river. In this section the current along the levee face was generally as little as would be expected anywhere on the project. Nevertheless, experience soon showed the desirability of an elaborate system of brush abatis work, a sample of what was put in here being shown by Fig. 10. At many points where any considerable quantity of water had come against the face of the levee the borrow-pits had cut together, the traverses having quickly been cut through and the breach widened more or less seriously. As it was expected that the river would fill up these borrow-pits with silt in the first few floods, such a result was disappointing.

It seems that no trouble was caused by the absence of muck-ditch protection under the levee. This must have been due to the fact that the ground where the levee was located was uniformly favorable. In the fall of 1906, however, the levee system of the project was extended some miles southward along the river, and the flood which occurred on December 7th, 1906—which got under the newly constructed dikes on the west side of the river in many places and resulted in the second break or crevasse to the west—caused several breaks in this new section, due to the lack of muck-ditches in unfavorable ground.

FIG. 10.—TYPICAL ABATIS WORK ON LEVEES OF YUMA PROJECT, U. S. RECLAMATION SERVICE.



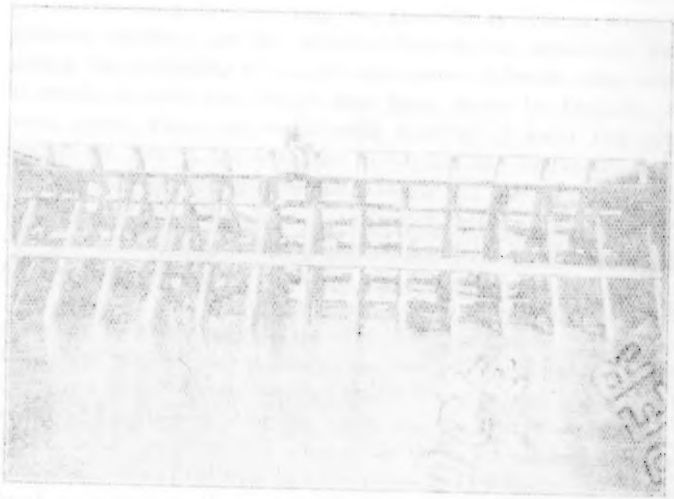


FIG. 11.—ORIGINAL INTAKE (CHAFFEY) GATE, IMPERIAL CANAL, COMPLETED IN 1901.

Experience with the levees, including the effect of this last-mentioned flood on the levee system of the project and on the levee work done on the other side of the river, caused a fundamental change in the design. In January, 1907, a Consulting Board of Engineers from the U. S. Reclamation Service was appointed to consider the matter of levee construction being done with money advanced by the Harriman interests on the west side of the river, and its recommendations are given later. Up to that date, 21 miles of levees had been constructed on the Yuma Project, extending from Yuma southward 15 miles and eastward along the south bank of the Gila 6 miles. All construction thereafter has been in accordance with the recommendations of this Consulting Board for the levees of the west side of the river, the essential features of which are "interrupted or checker-board borrow-pits" on the water side of the dikes, muck-ditches wherever test-pits show the necessity, and a large quantity of brush abatis work.

In 1907, a railroad track was laid in large part on the levee, from the Laguna Weir to Yuma on the California side of the river, chiefly for the purpose of hauling materials and supplies to and from the Laguna Weir. The Southern Pacific Company owns and operates this track as a branch line, thus serving an area which will be under intensive cultivation very soon, and greatly facilitating levee maintenance and repairs. Over this track a very large quantity of quarry spoil was hauled from the Laguna Weir construction work and used to blanket the river side of this levee to a point below where the swiftest water along its face is to be expected. None of the other levees of the project has any blanketing or any track on top.

Canal System of the Yuma Project.—Fig. 5 shows the general layout of the canal system of the Yuma Project as it is planned at present and in considerable measure constructed. The principal main canal is on the California side, and has a capacity of 1 700 sec-ft. The main canal on the Arizona side will irrigate only the land north of the Gila River. Water for irrigating the land lying east and south of the Colorado and below the Gila is to be carried under the river at Yuma in an inverted siphon, 1 000 ft. long, 14 ft. in diameter, about 50 ft. below the bed of that stream, and having an estimated capacity of 1 400 sec-ft. This siphon is now under construction. The original plan was to serve this territory with water taken from the

Arizona end of the dam and carried across the Gila River in four reinforced concrete tubes with a combined capacity of 1 300 sec-ft. and laid 3 ft. below the river bed. This crossing was abandoned because the difficulty of holding the Gila River banks at the ends of the underground siphon was considered too great. There is practically no danger of this kind in crossing the Colorado with the siphon, because of the little eminences of quite hard material which control the location of the river at this point.

The design of this siphon, the investigations of the material in which it is located, the first methods of construction used, the difficulties encountered, the changes in plans and methods, with the reasons therefor, the methods of doing the work finally adopted, and the time and cost figures, are all interesting in the extreme, but will not be given here for several reasons, chief of which is that, on the completion of the Yuma Project, it is hoped the work will be described at length in a paper by the Project Engineer, F. L. Sellew, M. Am. Soc. C. E., or some other engineer of the Reclamation Service. Only such general description is here given as seems desirable to make quite clear the effect of the project itself directly and indirectly on the irrigation of the delta.

The total acreage which will ultimately be irrigated by the Yuma Project is given in the reports of the Reclamation Service as 90 160. This includes 17 000 acres of mesa lands which lie too high to be reached by gravity from the principal canal system. It is intended to develop 1 000 h.p. at the drop in the main canal, and with this to operate pumps to raise water for the higher distribution systems.

At present the main canal from the Laguna Weir on the California side down to the California shaft of the river crossing at Yuma is under construction, and quite a little main and some lateral canals lying between these points and behind the line of the levees on the west side of the river have been completed and are in use. Such canal construction, and particularly the checks, head-gates, etc., are models of their kind, being of concrete and of the latest and most approved type. Up to the end of 1907, there were no canals on the California side of the river; indeed, practically all the area was contained in the Yuma Indian Reservation, which has since then in part been apportioned to individual Indians and in part, 6 500 acres, on March 1st, 1910, opened to entry and quickly taken up

by white settlers. Two weeks later water was turned into the reservation canals, and rapid progress is being made in developing the region. On the east side of the river below Yuma about 8 000 acres are being irrigated through small canal systems which have been in operation for a long time and were taken over by the Reclamation Service since the creation of the project. The total acreage of the project to which water could have been supplied was about 16 000 acres; about 10 000 acres were actually irrigated during the season of 1911.

Drainage System of the Yuma Project.—As has been said, a large acreage of the Yuma Project is subject to annual overflow, and lies behind the levees. The water-table throughout practically the entire region rises and falls with surprising rapidity during all floods which are long in passing. Thus it is that during May, June, July, and August particularly, the water-table rises so near the surface as to result in rather high alkalinity in the soil. The river water which will be applied for irrigation also carries a considerable, though not serious, quantity of soluble salts. Evaporation takes place from land surfaces very rapidly in such a hot country, and when water is on the surface, or approaches so near it that capillarity makes connection between the water-table and the surface of the ground, the quantity evaporated is excessive, and the salts contained are left behind, largely in the top layers. Therefore, efficient drainage is very important. It is made even more necessary because the rainfall is really inappreciable, having been less than 3 in. per annum for the past 15 years, and causes very little leaching and washing away of alkaline deposits. In passing, it is important to say that, very fortunately, the alkali of the valley lands is peculiarly a surface accumulation, often being confined to the very upper layers, usually to the first 2 ft. in depth, and seldom being found at depths exceeding 6 ft.

The Yuma Project, therefore, includes plans for an elaborate and efficient system of drainage canals which will be doing the maximum amount of work during the annual summer floods of the Colorado. It is planned, where necessary, to pump such drainage water over the levees and back into the river. This drainage system has not been constructed, and indeed the detailed plans may not yet have been worked out, but it is desired to state here that arrangements have been made for drainage in the Yuma Project, and results along that line must be obtained in the Imperial Valley sooner or later.

Imperial Valley Irrigation Project.

In 1893, Mr. Rockwood found himself in possession of much engineering and other information regarding the irrigation of the Colorado Desert with the water of the Colorado River, in lieu of salary for a considerable time as Chief Engineer of the Colorado River Irrigation Company, and had a firm conviction of the project's possibilities. For more than 7 years he endeavored to finance the work, both in the United States and abroad. Many people suggested the irrigation of the Colorado Desert, as already mentioned, but Mr. Rockwood and associates actually brought it about. His very interesting story of the enterprise,* unfortunately, is accessible to relatively few people. In spite of his later mistakes, Mr. Rockwood is certainly entitled to much credit and reward for his efforts, which, practically speaking, were finally crowned with complete success.

Engineering Features.—The engineering features of irrigating the Imperial Valley from the Colorado River can now be much better understood than was possible in 1900. The experience of 10 years is always of value, and was particularly so in this case. The fall of the ground was known, and to divert the water and conduct it to the broad, ideally lying tracts of land to the west of the sand hills was obviously practicable. There were, however, two especially serious problems: the danger of diverting water from a wide, erratic stream flowing through a shifting channel along the top of a ridge of loose alluvial silt; and the difficulty of keeping open canals which carried water so heavily charged with silt.

Diversion.—The impossibility of properly financing the enterprise absolutely forced the abandonment of the idea of diversion at The Potholes, with its opportunities for settling basins and sluice-ways to care for the silt *en route,* and made the diversion at the rocky point of Pilot Knob practically unavoidable. It was always the idea to have a head-gate founded on solid rock. At the last, it was found impossible to obtain the money, even for this construction, but the diversion point was located there, with the intention of utilizing this rocky point of Pilot Knob for head-works, in the very near future, when the financial status of the company might permit.

* "Born of the Desert," by C. R. Rockwood, in the Second Annual Magazine Edition, *Calexico Chronicle*, Calexico, Cal., May, 1909.

Flood Protection.—It does not seem to have been realized, at the time, or indeed by any one until the diversion into the Salton Sea was actually an accomplished fact in 1905, that there was any really appreciable danger to the Imperial Valley by flood-waters from the Colorado. The writer hopes especially, that the discussion will bring out any contradiction of this statement which may be successfully maintained. Of course, it was known that large quantities of water had been carried through the New and Alamo Rivers into the Salton Sea in 1891, and also by the New River earlier, especially in 1862, but the channels had not eroded to any marked degree at the gathering ground along the Colorado River bank, but, on the contrary, had automatically closed. Instrumental data regarding that portion of the delta cone which is subject to overflow were entirely lacking, and indeed, little other reliable information about the region was available. It was planned to build levees along the river side of the canal with the material taken from the latter, but the purpose of these levees was to protect the canal itself from danger, and not to keep the flood-waters which might enter this waterway from enlarging it to a dangerous degree. Of course, any risk of the river being diverted into the Salton Sink, and soon inundating the entire Imperial Valley, involves the same risk to the irrigation project as such. Otherwise, such risk should obviously not affect an irrigation company in any way, unless its operations and constructions have an appreciable effect on such river diversion.

Silt.—With this means of diversion it was necessary to let the silt-laden river water enter the canals directly, and depend on keeping them open by dredging, erosion, etc. The chief difficulty obviously must occur in the first stretches of the waterway, due to the rapid deposition of the heavier or sandy particles of silt which the river water carries during flood stages of excessively high currents, and which drops down almost at once when the velocity decreases to, say, 3½ ft. per sec. After such clarification, it is possible to design and operate canals in the Colorado Delta, as well as in India and elsewhere, so as to insure the carriage of the remaining finer silt into the smaller laterals and to the irrigated land. The first mile of the canal, therefore, was designed with a large cross-section so as to secure the deposition of this heavier silt there, where it could be removed by dredges.

Alkaline Lands.—From a farming point of view, a difficulty which was not given very serious consideration was the relatively high alkalinity in the upper layers of the soil throughout practically all the Imperial Valley. Wherever water came in contact with the ground, it was observed that vegetation at once sprang up like magic, and it was assumed, from this and from the obvious methods of its occurrence, that the soil must be exceedingly fertile and admirably adapted for general agricultural purposes. In one sense, a very serious mistake in this way was not made, for agriculture of almost unparalleled success has been followed for the past 10 years, with only at rare intervals a very slight thinning of crops indicating the need for proper drainage and the reduction of the excess of alkalinity.

In 1893 the Director of the Agricultural Experiment Station at the University of California was asked to investigate the agricultural possibilities of the land in the Imperial Valley. At that time it was proposed to provide an expedition properly equipped in order that the Director, Professor E. W. Hilgard, the great American authority on soils, might explore the region personally. The financial difficulties of the Company prevented carrying out the plan at the time, but a few samples of water from the lakes and of soil taken superficially, proved that the latter were very similar to that of the immediate bottom of the Colorado River, which previous analyses had shown to be of extraordinary intrinsic fertility.* In 1896 and 1897, some additional samples of soil and water were sent for examination. These corroborated the previous conclusions, but showed that a considerable quantity of alkali salts was present in the soils as well as in the waters, and thus indicated the desirability of a thorough examination of the region, from the soil standpoint. The subsequent soil investigations in the Imperial Valley and their effect on the fortunes of the region will be considered later.

Drainage.—Though the country as a whole lies ideally for irrigation and ordinary irrigation water drainage, the natural waterways are so far apart and so small and ill defined as to make the construction of an efficient, comprehensive drainage system almost as difficult and expensive as the irrigation canals. In the engineer's report to the Colorado River Irrigation Company, it was stated that the construction of a drainage system (though almost as expensive as the proposed

* Report, Agricultural Experiment Station, University of California, 1882.

irrigation system) was essential, but, some years later, when the work to be done was trimmed to the lowest practical minimum, it was decided that a general drainage system was not immediately necessary and possibly might never be required. This latter opinion was not as radical as might at first be assumed, because, even to-day, there are probably not more than 5 miles of drainage ditches in the valley. It is being realized in a general way that at some time provision for drainage must be begun, and within the next few decades doubtless a fairly comprehensive plan will be developed. The diversion of the Colorado into the Salton Sea in 1905-06 resulted in eroding the beds of the Alamo and New Rivers into deep wide channels which will be the controlling features in the design of the ultimate drainage system for the valley, and thus produce a benefit which in the end must certainly exceed the total damages resulting from such diversion.

Climate.—The climate of the region, with its long, hot, dry summers, is peculiarly favorable to agricultural luxuriance. Thus it is that here the very earliest grapes, fruits, and vegetables are produced for the United States market, with the consequent advantage of commanding the highest prices. This is notably true of the Imperial Valley cantaloupe, now famous all over this country, and of the early grapes, asparagus, etc. On account of the very low humidity and gentle winds which blow much of the time in hot weather, the sensible temperature—which is indicated by the wet-bulb readings and gives the measure of heat felt by the human body—is much less than the actual temperature as measured by the dry bulb. It is conservative to say that a temperature of 110° in Imperial Valley is not more uncomfortable than 95° in Los Angeles or 85° in the more humid sections of the Eastern States. Furthermore, the nights are always cool, the low humidity resulting in rapid and large daily temperature variations.

At the same time, the heat in the Colorado Desert and at Yuma was proverbial, and one of the difficulties which the project had to encounter was the supposedly frightfully hot summers; indeed, the project would otherwise have been financed very much earlier. Since the control of the diversion canal was lost in 1905, the impression has become general that the project of irrigating this region was rejected by capitalists as involving too great engineering risks. As a matter of fact, the chief difficulty was the fear that the torrid climate would render colonization very difficult. It was for this reason only that Mr. George

Chaffey declined to consider Dr. Wozencraft's solicitations to undertake the enterprise as early as 1885, and it was Mr. Chaffey's subsequent experience in successfully establishing an irrigation enterprise in the interior of Australia, where a maximum temperature of 125° Fahr. was often reached, which led him to undertake the work here in 1900.

The International Boundary Line at the Sand Hills.—Perhaps, everything considered, the location of the International Boundary Line and the Sand Hills which lie to the west of Pilot Knob and overlap into Mexico for several miles, constitute the most important features of the irrigation, and protection from inundation, of the Imperial Valley. It is this which makes it impossible for the people of American Imperial Valley to organize to protect themselves under the laws of California. The menace is entirely on Mexican territory, and, apart from the difficulty of dealing with the problem as one of engineering and statecraft, is the worst feature of all, namely, the seeming injustice of compelling American citizens to protect their homes against a menace originating entirely on foreign soil.

Aside from the danger of the diversion of the Colorado to the west and into the Salton Basin, the important result of the present location of the International Boundary Line is that, practically speaking, water cannot be taken from the Colorado River and carried in canals lying wholly on American soil to the areas in American Imperial Valley susceptible of irrigation by gravity. It could be done, but it would require approximately 12 miles of a closed conduit running under the sand hills and costing at least $10 000 000, a sum practically prohibitive.

Water Rights.—Due to the divided authority of the National and State Governments with respect to permission for taking water from the Colorado River as a navigable stream, water appropriation notices then, as now, had to be posted and filed, under the laws of the State of California, and arrangements had to be made with the United States War Department as well, if such diversion interfered with navigation. It appears that no attempt was made to obtain permission from the War Department for taking water from the river, because it was almost impossible to cause any "interference with navigation." This failure to secure permission from the War Department, however, had a very serious result later.

Ideal Plans.—The ideal way to carry such a project through is now quite obvious. All the engineering features should have been carefully worked out, elaborate soil surveys should have been made by well-recognized authorities, and experimental farms should have been established. The irrigation system should have been built in sections and colonized before additional areas were covered by canals. Water rights, entirely free from any possibility of attack, should have been obtained. In the light of experience, the writer believes that, by all means, these should have been obtained from the Mexican Government, and the diversion should have been made on Mexican soil, or the development should have been made under the Carey Act.

Dealings with Mexico would have meant the abandonment of the idea of diversion works founded on solid rock, but a structure with a wooden caisson foundation extending under the gates proper and the wing-walls would have been just as safe as the concrete head-gate actually put in later, and would have cost little more money, if indeed as much.

The ownership of all private interests in the Salton Sink ought to have been acquired, and such permission obtained from proper Government authorities that this naturally depressed basin would ever be available without question as a receptacle for the seepage, drainage, and waste water from the irrigated lands and canals. Data as to silt deposition and the cost of removing it from canals and intakes should have been obtained from experiments carried out on a commercial scale. Various details of the project, in short, should have been worked out very carefully and adhered to.

However, as in many irrigation and other projects in the West, the garment had to be cut according to the cloth. The sum total of events resulted in carrying out the project along lines which were far from ideal, but which later proved to be possible of execution with a remarkably small amount of money, everything considered.

The California Development Company.

The first practical step toward the actual irrigation of Imperial Valley was the incorporation of the California Development Company, under the laws of New Jersey, on April 26th, 1896. After two years of vain endeavor to obtain permission from the Mexican Government for the American corporation to hold land and acquire rights

of way for the main canals into American Imperial Valley, it was found necessary to form also a Mexican corporation. The California Development Company has a capital stock of $1 250 000, divided into 12 500 shares of $100 each; the Mexican Company—*La Sociedad de Riego y Terrenos de la Baja California, Sociedad Anonima*—has a capital stock of $62 500, all of which is owned by the California Development Company. Hereafter in this paper the California Development Company will be referred to as the C. D. Co., and the subsidiary Mexican corporation as the Mexican Co.

The general practice throughout the West was, and still is, the sale of the "water right" to settlers at a definite price per acre—usually the right to buy water thereafter at specified prices. The arrangement adopted in this case was the formation of mutual water companies which would receive water wholesale and distribute it to their stockholders, the capital stock of such mutual companies constituting the water right.

Organization Under the Carey Act.—It would undoubtedly have been much better if the desert land in the United States had been segregated, and if the project, as far as American territory was concerned, had been carried out under the Carey Act. This Act, however, had not been passed when the original investigations were made, and, when financial arrangements were concluded, the California Legislature had adjourned and would not meet for nearly two years. Such delay was deemed too great.

Water Appropriations.—Water filings were made on April 25th, 1899, on the right bank of the Colorado River about 3 000 ft. above the International Boundary Line, by Mr. C. N. Perry, on behalf of the C. D. Co., appropriating 10 000 sec-ft., of the flow of the Colorado River to be used for the irrigation of American lands in the Imperial Valley. No serious attempt was made to obtain water rights in Mexico—in Mexican territory there was no chance to found diversion works on rock, and money for the first work of promotion would have been difficult to obtain with a projected intake in that country.

Rights of Way.—The C. D. Co. purchased 316 acres of patented land along the river just north of the International Boundary Line and these included the rocky point of Pilot Knob; and the Mexican Co. acquired 10 000 acres in Mexico, belonging to Gen. Guillermo Andrade, and lying generally south of the Boundary Line, as shown

in Fig. 9, together with the bed of the Alamo River, which extended beyond the boundaries of this tract. In the American Imperial Valley (all the land belonging to the Government except Sections 16 and 36, belonging to the State of California, and known as "school sections") rights of way could not be purchased outright, but easements therefor were easily obtained as at present by application to the Secretary of the Interior, accompanied by maps and descriptions of the proposed constructions. All rights of way and property required for the construction of the project were thus arranged.

Contractual Relation of the C. D. Co. and the Mexican Co.— The two companies entered into a contract by the terms of which the C. D. Co. turned over to the Mexican Co. all the water to be diverted from the Colorado River by the former where the canal crosses the International Boundary Line at Algodones; the Mexican Co. agreed to deliver water to water users in Mexican territory as required and the remainder of the supply—the larger part by far—to the American water users at points on the International Boundary Line from 40 to 50 miles west of the river, and, from the water users of both countries, to collect for the water furnished, on a quantity basis; the C. D. Co. agreed to build, maintain, and operate all the Mexican Co.'s irrigation construction in Mexico; the Mexican Co., in consideration thereof, agreed to pay the C. D. Co. all sums received by the former for water rights, water stock, and water rentals from water users in the United States. These agreements were limited to water for lands which were irrigable by gravity from the system of canals beginning at the head-works constructed. It was stipulated, further, that no contract should be entered into with the Mexican Co. giving any person or corporation superior right over any other water user by reason of priority in date of contract or otherwise, and that the C. D. Co. should not be responsible for failure to deliver water to the Mexican Co. from any cause beyond its control, although admitting obligation to use due diligence in protecting canals and maintaining the flow of water therein.

By this arrangement, the Mexican Co. retains the money received from the water delivered to Mexican water users, and is put to no construction, maintenance, or operation expense whatever. This arrangement, however, is not as advantageous as at first appears, because the gross annual water rentals from Mexican water users did

not amount to $10 000 gold per annum until the beginning of the ninth year, while the right of way contains at least 2 500 acres of land and includes 50 miles of the Alamo River channel, which is utilized as a main canal. It will be a number of years yet before the receipts of the Mexican Co. will be sufficiently large to make the contract an unusually profitable one.

Mutual Water Companies.—Next to the general plan of arranging to require the purchase by settlers of the water right usual in such cases, the fundamental idea was delivery of water to mutual water companies instead of individuals, the mutual companies to be operated by the holders of stock, namely, the farmers in their respective districts. The various mutual companies thus run their own local affairs and join together, through the C. D. Co. and the Mexican Co., in a community main canal leading from the river to the settlement west of the Sand Hills.

Triparty Contracts.—The mutual water companies required the construction of a distribution system, and ought or ought not to have paid a bonus for the contract to receive water at the International Boundary Line, depending entirely on the conditions under which the water should be delivered and the price to be paid for it. A triparty contract was entered into between the Mexican Co., the C. D. Co., and each of the mutual water companies, under the terms of which the Mexican Co. agreed to supply water to the mutual water companies "on demand" and at definite points on the International Boundary Line in the Imperial Valley for 50 cents per acre-ft., to be used only on lands within the respective districts; provided, however, that the aggregate quantity of water necessary to deliver under the contract should not exceed four times the number of acre-feet per annum that there were shares of capital stock in the mutual company; the mutual company agreed to order and pay for at least 1 acre-ft. of water each year for each share of its stock sold and located, regardless of its use by the mutual company or by its stockholders; the C. D. Co. agreed to build the distribution system of the mutual company and to maintain certain definite portions of the canal thereof perpetually, reserving the right to develop and use the water-power that might be obtained from the waters running through any of the canals, including those of the mutual company; a provision was made that at the end of 3 years the loss of water to the C. D. Co. in evaporation from

the canals of the mutual company should be determined, and such an extra allowance of water be supplied, as so determined, to the end that only the net quantity reaching each half section of land should be paid for; and the mutual water company turned over all its capital stock to the C. D. Co. and agreed to locate such stock on any lands within the exterior boundary lines of its district on order of the C. D. Co. The C. D. Co. sold the capital stock of these various mutual companies to the settlers, and with the proceeds built the main canals in the United States, the canal system in Mexico which belongs to the Mexican Co., and the distribution systems which became the properties of the various mutual water companies.

There were eight of these triparty contracts; they were essentially similar, though no two were exactly alike in every detail. The contract between the Mexican Co. and the C. D. Co., and the triparty contract as just outlined, together with the by-laws of the mutual companies, show the contractual relation of the water user to the organizations on which he depends for water. These by-laws, in general, provide that each share of stock shall represent the right to purchase water for the irrigation of 1 acre of land; that stock issued shall have written on its face a description of the land on which it is located; that no stock shall be located on any lands outside those described in the articles of incorporation; that one share and no more shall be located on each acre of land which can be served by the ditches of the company; that owners of stock issued but not located shall not be entitled to receive any water represented thereby, but shall, nevertheless, be liable for all assessments, the same as other outstanding stock of the company; that the shares may be transferred; and that acceptance by any stockholder of a certificate of stock shall be considered as a ratification by him of any and all contracts between the mutual company in question and the C. D. Co.

The inter-relations of the water users and the various corporations have been given in detail because of a general impression that the plan was devised for the purpose of taking advantage of the settlers. In its operations it has resulted in no unfairness of any importance to any of the parties concerned. Considering all the circumstances, the prices charged for water rights were very low—$5.75 at the beginning, up to $20 at present, and averaging $12 per acre as the total cost to the settler, on easy terms—and the total annual water rental from the

Net earnings	$4 471.84	$8 114.59
Taxes	$197.76	$1 134.88

water users in the valley will not suffice to pay maintenance, operation, and general expenses, properly figured, until such time as about 700 000 acre-ft. of water are sold annually. At the end of 9 years the sales have not yet reached that figure. Fig. 4 shows the boundaries of the lands of the various mutual water companies in the valley and under whose distribution systems lie all the lands which are as yet irrigated.

Operation of Triparty Contract.—For 3½ years the writer was General Manager for both the C. D. Co. and the Mexican Co., and handled all matters between these companies and the various mutual water companies. During the latter portion of that time, the protection of the Imperial Valley from inundation by the Colorado had become quite as important as its irrigation, and, for this protection, of course, no provision was contemplated in these contracts. Except for that, the arrangement proved to be very satisfactory, and produced a smooth and comfortable relationship unusual in irrigation enterprises. As a result of litigation, the Supreme Court of California has just declared the whole scheme practically legal. The Imperial Irrigation District was created several months ago, and the directors thereof have decided to take over only the functions which the C. D. Co. and the Mexican Co. now perform, and will not interfere in any way with the mutual water company plan of organization, or the water companies themselves.

TABLE 8.—Statement of Earnings and Expenses of La Sociedad de Irrigacion y Terrenos de la Baja California.

	November 5th, 1909.	5 months, ending November 30th, 1909.
Gross Earnings	$641.20	$5 127.39

Imperial Land Company.—The parties who were induced to back the enterprise financially were afraid of the colonization end, and would have nothing whatever to do with it. Accordingly, it was necessary to form a colonization company—the Imperial Land Company—which was incorporated under the laws of California in March, 1900, and consisted in part of some of the promoters of the C. D. Co. and in part of other people. This corporation contracted to do all advertising and colonizing and sell all water stock in consideration of having the exclusive privilege of town sites and a commission of 25% on water stock sales. By using Government land scrip, this company obtained immediate ownership in fee simple of tracts of land in various parts of the valley and subdivided them into town sites. These town sites were covered with water stock in order to obtain water for domestic and municipal use through the assistance of the mutual companies, because no wells, except some very deep and unsatisfactory ones quite recently sunk on the east side of Imperial Valley, have ever been possible for domestic supply. The Imperial Land Company thus established the town sites of Mexicali, in Mexico, and Calexico, Heber, Imperial, and Brawley, in California. The other town sites—El Centro, the county seat, Holtville, Seeley, Dixieland, and several smaller places were platted and put on the market by other parties later.

TABLE 9.—OPERATING EXPENSES OF CALIFORNIA DEVELOPMENT CO., JANUARY 1ST, 1908, TO MARCH 31ST, 1909.

	1908, 12 months.	1909, January, February, and March.
Maintenance, canals and structures	$71 419.94	$18 177.32
Maintenance, levee	10 260.35	647.24
Maintenance, equipment	18 528.09	4 182.21
Distribution of water	15 613.42	4 559.10
General expense*	75 162.82	12 277.76
Construction of canals	73 765.12	27 859.47
Construction of levees	32 303.09	33 297.84
Totals	$297 053.43	$99 500.94

* Of this sum, $30 665.28 was litigation expenses and costs.

During 1911 the total net deliveries of water to the mutual water companies in the United States were 597 178 acre-ft., or $298 490.98.

This colonization company in general was successful, but not to the extent which would be expected, considering the unprecedentedly rapid settlement of the region, and the contract was certainly a fair one to

the C. D. Co., up to the time of its abrogation in 1906. Water stock was sold to the settlers for small cash payments and notes payable in five yearly settlements at 6% interest, such notes being secured by a pledge of the water stock purchased. Many of the settlers had scant means and only a filing right on the land, so that the water stock was not made appurtenant to the land, but left as personal property. The initial payment went to the Imperial Land Company, and was by it used for advertising and other essential purposes, the collateral notes secured by the water stock being taken by the C. D. Co.

TABLE 10.—AVERAGE DIVERSION AND DELIVERIES OF WATER BY THE CANAL SYSTEMS OF THE C. D. CO. AND THE MEXICAN CO. FOR THE WEEK ENDING JANUARY 19TH, 1912.

Gauge at Yuma		15.3 ft.
Gauge opposite intake		105.9 "
Elevation of bottom of diversion gate		98.0 "
Average flow of Colorado River at Yuma		4 000 sec-ft.
Diversion from Colorado River at Andrade		1 559 " "
Used in Mexico	37 sec-ft.	
Used in United States	894.6 " "	
*Wasted at Rositas waste-gate	321.3 " "	
Total		1 252.9 sec-ft.
Total loss, Andrade to Sharps		306.1 sec-ft.

* 171.1 sec-ft. of this passed through the plant of the Holton Power Company *en route* to this waste-gate for developing electrical energy.
This loss equals 19.6% in about 46 miles of main canal, chiefly the bed of the old Alamo River, or 0.43% per mile on the average—an extremely low figure.

Management of the C. D. Co.—Delta Investment Company.—Until the water rentals became of importance, these collateral notes constituted the only receipts of the C. D. Co., and these assets were looked on with considerable suspicion by the financial institutions of Los Angeles. Nevertheless, they might have been taken as collateral at about 25 cents on the dollar had not the merit of the entire enterprise been rendered questionable in various ways, as explained later. When this occurred the Delta Investment Company was formed—in the fall of 1901—with assets consisting solely of C. D. Co. and Imperial Land Company stock contributed by the wealthier people of the enterprise. This company was given a contract to take over all the C. D. Co.'s bonds at 50 cents on the dollar, and all its collateral notes and mortgages at the same discount. By this arrangement, the Delta Investment Company practically controlled the C. D. Co., although the amount of the C. D. Co. stock held by it was much less than a majority.

TABLE 11.—ANNUAL EXPENDITURES OF IMPERIAL WATER COMPANY NO. 1 FOR 1911.

Capital stock = 100 000 shares, all of which have been sold, and are located on 100 000 acres of land. Total length of canals = 373.25 miles.

Maintenance:		
Superintendence	$7 000.00

Imperial Water Company No. 1, expense		$169 303.11
Water Bought (from the C. D. Co.) 305 183 acre-ft., less 10% allowance for seepage and evaporation, at 50 cents per acre-ft., on net amounts		137 332.50
*Total expenditures**		$306 635.61

*The expenses of the company were almost exactly $1.70 per acre, and the water rentals paid to the C. D. Co. $1.37 per acre. The total cost to the farmers, therefore, averaged $3.05 divided by 2.747, or $1.11 per acre-ft.—a very low figure for water in California, where the "water right" averages $12 per acre, or indeed much more.

It must be admitted that the Delta Investment Company took over such securities at a larger price than could have been obtained from any other source. Nevertheless, the securities were really good, everything considered, and quite a few large and apparently strange and dishonest transactions were made between the two corporations. Money was forthcoming for construction purposes, but was costing the C. D. Co. $2 for every $1 obtained. The result was that in a couple of months serious dissensions arose, and in February, 1902, an adjustment was made cancelling the contracts with the Delta Investment Company and Mr. Chaffey, who thereupon retired from the enterprise. March 1st, 1902, therefore, found the C. D. Co. a going concern, and Imperial Valley a reality, but the parent company, with all its bonds gone, its

collateral notes and mortgages largely depleted, no money in the treasury, and deeply in debt. Shortly afterward actual results from farming under the project were so reassuring that the Company was able to borrow $25 000 from the First National Bank of Los Angeles.

The contract with the Delta Investment Company was a serious thing for the C. D. Co., but, to be perfectly fair in presentation, it must be borne in mind that the financial interests had their confidence in the project violently shaken by advance rumors of an adverse Government soil report (to be discussed later).

With the exception of the arrangement with the Delta Investment Company, no proper criticism can be made of the handling of the finances of the whole irrigation project, as far as any of the promoters of the irrigation company are concerned. The writer has had opportunity and occasion to investigate thoroughly the relationship of all the corporations, and in common fairness must state that, though the deals back and forth were many and diverse, they were otherwise with very few exceptions reasonable and fair, when the circumstances and reasons which produced them are given the proper weight. Furthermore, the general aims and plans which the company practically succeeded in carrying out do not merit any more criticism than those of the average Western irrigation project, if indeed as much. Had the break in the Colorado River never been allowed to get beyond control—and it never would have happened, in spite of all obstacles, had the loan of the Southern Pacific Company (referred to later) been arranged 6 months earlier than it was—the C. D. Co. would undoubtedly have proved to be one of the most successful private irrigation enterprises throughout the entire land.

Colorado River Land Company.—It is well at this time to mention the Colorado River Land Company and the New Liverpool Salt Company. The former is a corporation consisting principally of Southern California stockholders, incorporated under the laws of Mexico, and owning about 1 000 000 acres south of the International Boundary Line and west of the Colorado River. It owns all the Colorado River Delta west of the river in Mexico except 162 000 acres, the location of these holdings and those of other important Mexican land owners being shown on Fig. 4. The existence and operation of this corporation have lately become important as being the agency through which the United States Government has handled the river control work

recently done by it. The company will hereafter be referred to as the C. M. Co., as it is locally called.

The New Liverpool Salt Company.—This corporation was organized many years ago for the purpose of obtaining salt from the deposits in the bottom of the Salton Sink, and began operations in 1884. In 1904 its plant was reasonably satisfactory in its details and had a capacity of 1 200 tons of salt per month. The actual value of the plant and the salt beds, taking into consideration the excellent quality of the salt,* the conditions under which the Company operated, and the competition it had to meet, is of course impossible to determine without access to the company's records. It appears, however, that negotiations at that time were pending for its sale, the figures being $150 000 asked and $100 000 offered. When the water began to come into the sink in large quantities, negotiations were dropped, and the entire plant was soon buried by the Salton Sea.

Operations of the California Development Company.

When the C. D. Co. was ready to begin operations, there was on the lower river a dipper dredge with a 4-yd. bucket which had been built and equipped by the Hon. Eugene S. Ives, of Yuma, Ariz., and his associates, for digging irrigating canals near Yuma. This dredge was bought by the company in exchange for guaranteed bonds, floated down the river, and, in August, 1900, set to work excavating a canal along the lines marked "Original Intake" in Fig. 13 and then following the old Alamo overflow channel to a point 8 miles below. From that point the Alamo channel, with a little diking here and there, had sufficient capacity to carry for some time the water needed. From the beginning of actual construction until he left the enterprise (April, 1900, to February, 1902), Mr. George Chaffey was President and Chief Engineer of the Company.

About 500 ft. above the Boundary Line a temporary wooden head-gate, Fig. 11, known locally as the "Chaffey" gate, was put

*The published analyses of the deposit give the following average:

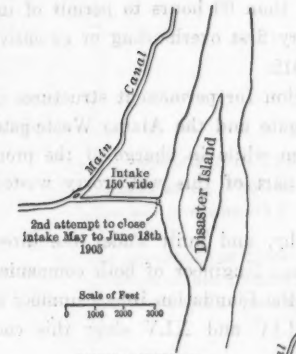
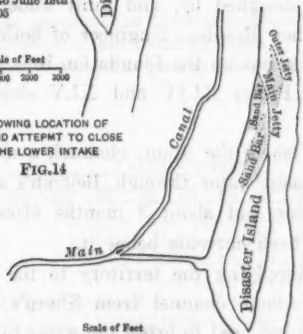
	100.00



The California State Mineralogist reports the value as $1 per ton.

in. This was a well-designed and well-built wooden, A-frame, flash-board gate, 70 ft. long, 15 ft. high, with a plank floor, and founded on piling. When it was built* nothing was known or even suspected with reference to the rapid and large variation in elevation of the river bed at varying flood stages and otherwise, and it is not surprising, therefore, that the floor was not put as low as it should have been, but, even so, it was not as deep as planned on account of an unnaturally early summer flood. The structure was made no larger, not because of cost, but because it seemed certain that when more water than the gate's capacity should be required, that fact would mean such revenues as to permit building the permanent concrete and steel diversion works at Pilot Knob, regardless of all other considerations. In passing, it may be said that the construction and design of this temporary head-gate was fully equal to that of any throughout the West, even to-day. The floor, however, was quite too high.

At what is known as Sharp's Heading, the Alamo channel was abandoned as the main canal, and the controlling works for the valley end were put in. These consisted of a wooden, A-frame, flash-board gate in the continuation of the Alamo, a similar gate at the head of the Encina or West Side Main canal, and a combined gate and drop, known as Sharp's Head-gate, from which leads off the Central Main, the chief canal in the valley.



This last structure is well worth describing in some detail. In the first place, it is a most vital part of the system, because, being a combination of a drop and regulating gate, were it to fail, the water in the Alamo or Main Canal above it would immediately be lowered far too much to permit taking out any whatever for the East and West Side Mains. To realize the consequences of this, it must be remembered that irrigation water is needed every day in the year, and that no stock and domestic water for the entire region, except for the Town of Holtville, can be had, except from the irrigation system and by being brought in by the railroad in water cars. In the second place, for several months consecutively, in each year since 1905, it has been taxed beyond the capacity for which it was designed, without developing any serious weakness. Furthermore, at intervals of about 18 months, since it was put in service in 1903, the canal above it has

* Nothing really was known about the changes in elevation of the river bed until 1907.

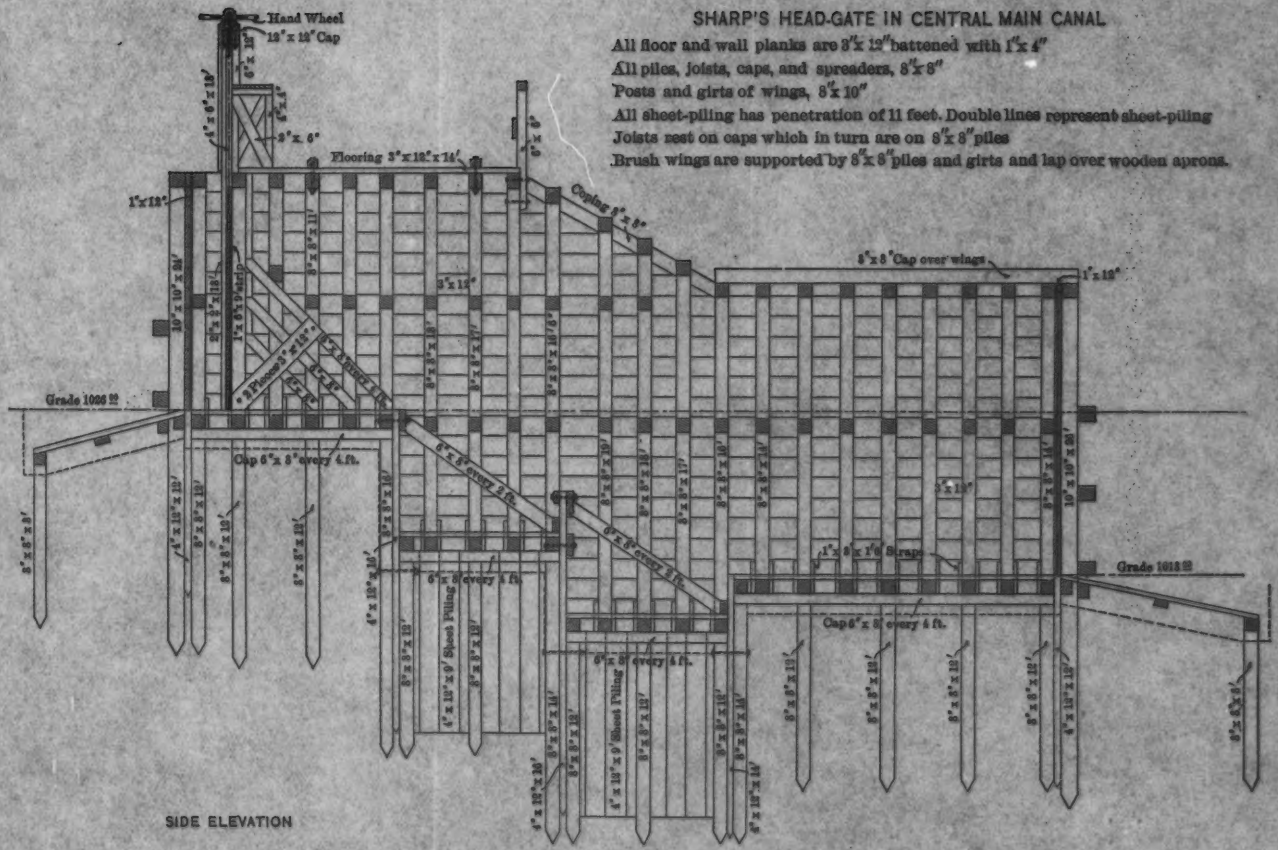
been emptied for periods of not more than 60 hours to permit of inspection and light repairs, but the very first overhauling or extensive repairs were begun on January 5th, 1912.

The writer confesses to a predilection for permanent structures of masonry, concrete, or steel, and this gate and the Alamo Waste-gate, built in 1905, were nightmares to him while in charge of the properties. It would seem that a large part of this was worry wasted, however.

Sharp's Head-gate was designed by, and built under the direction of, Mr. C. N. Perry, then Resident Engineer of both companies, the fundamental idea being to cut up the foundation into a number of water-tight compartments. Plates XLIV and XLV show this construction.

Where Beltran's Slough leaves the Alamo channel, a wooden, flash-board gate was built to waste water through Beltran's and Garza's Sloughs into the New River, but about 3 months after being put in service it failed, due to back currents below it.



The original plan for supplying the territory to the east of the Alamo was to utilize the Alamo channel from Sharp's Heading to Holtville, an earthen dam being used to bring the water to the surface of the land at that point. This dam soon failed, and the canal from there was connected with the Alamo at a point about 1½ miles above Sharp's, such connection being made in record time, with a cross-section only large enough for the demand. The idea was that erosion would enlarge it, which in general has been the case, although some blasting was required to assist the action. Originally known as No. 5 Main, the canal is generally called the East Side Main. It, as well as the West Side Main, is occasionally broken in places by the severe rain-storms—almost cloudbursts—which occur at infrequent intervals in the region. To provide absolute protection against such damage would be very expensive, and neither No. 5, which owns the exposed portion of the East Side Main, nor the C. D. Co., which owns all the West Side Main, has done so. Otherwise, they, as well as the Central Main, are quite satisfactory.

Main canals were constructed from Sharp's to serve the territory between the New and Alamo Rivers (the Central Main); a second, the West Side Main, crossed New River to serve territory west of that waterway, and a third, the East Side Main, to serve the territory

east of the Alamo. In 11 months, or in June, 1901, delivery of water was begun through the Boundary Canal as far west as Calexico, and the Central Main was put into service in March, 1902, or in 19 months.

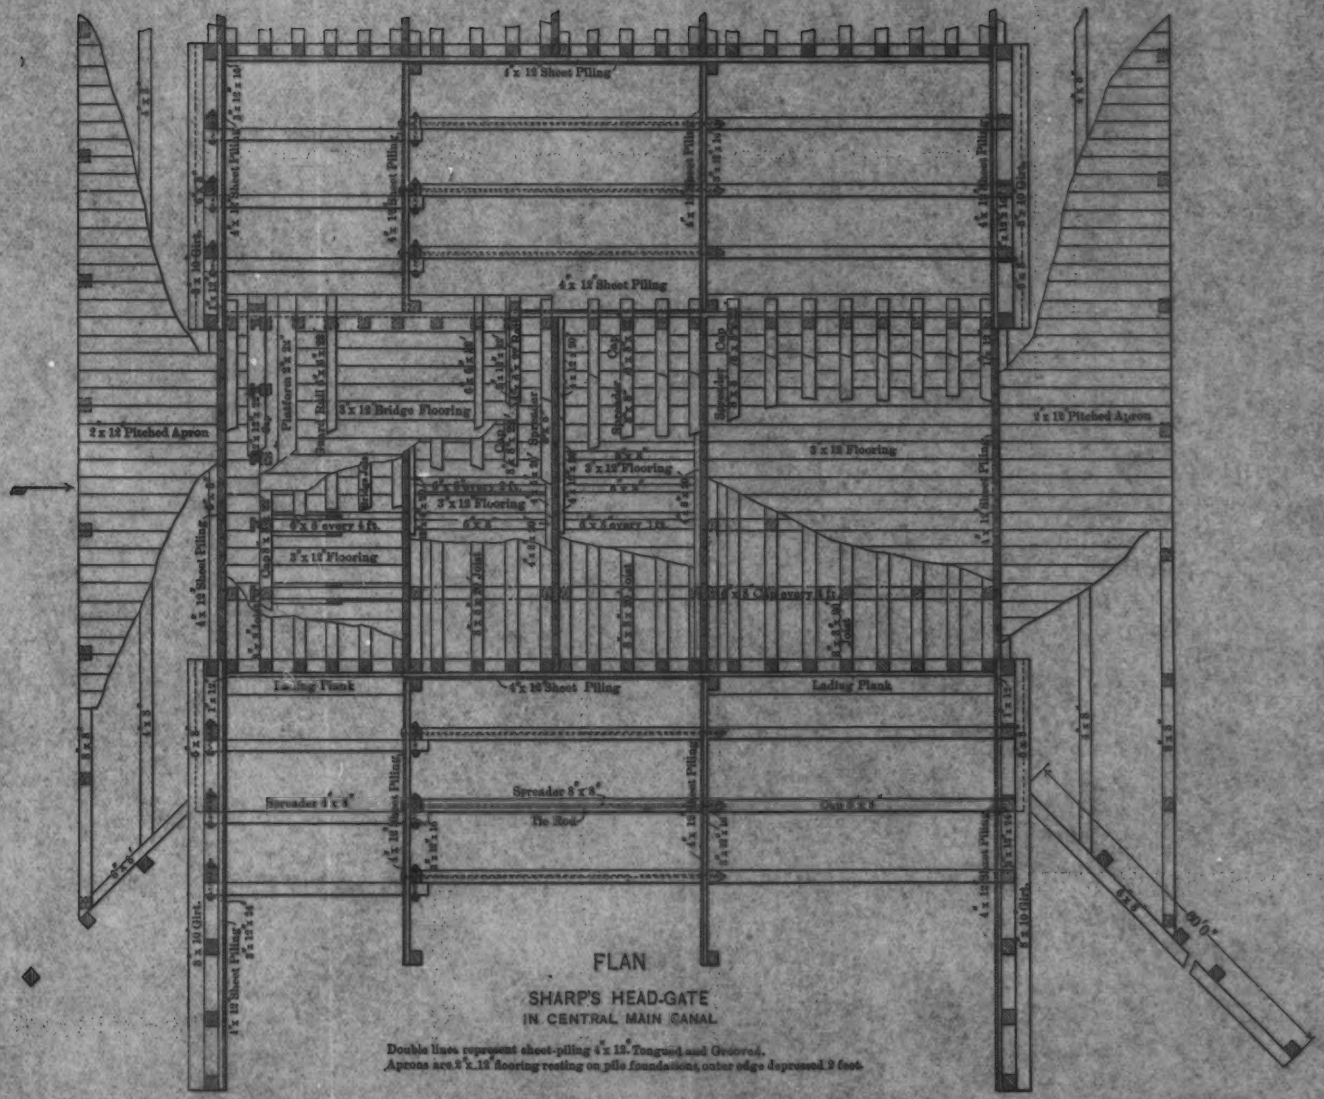
Imperial Water Companies Nos. 1, 4, 5, 6, 7, and 8 were formed, and triparty contracts were entered into with each. The C. D. Co. constructed the distributing systems for these districts, with the exception of that of Imperial Water Co. No. 7.* The total length of canals in all these distributing systems was approximately 700 miles on January 1st, 1905, and there were also about 80 miles of canal belonging to the C. D. Co. and the Mexican Co., making the total about 780 miles. During 1905 and 1906 relatively little canal building was done, because the river got beyond control; and, from 1907 to 1911, inclusive, the increase has been less than 20%, on account of excessive litigation following the vast expenditures for controlling the river, and because the canals existing on January 1st, 1905, covered 85% of the territory now under ditches.

With the exception of a permanent diversion gate at the river, two permanent structures replacing temporary ones in the valley, the building of the Alamo Waste-gate (Fig. 27), just above Sharp's Heading (June 25th to August 17th, 1905), and another in the Central Main at Station 134 (November 13th, 1904, to January 12th, 1905), that portion of the canal system completed on January 1st, 1905, has not been essentially changed or enlarged, and, with few exceptions, the original structures are still being used. There is a marked tendency on the part of the mutual water companies to replace wooden structures with permanent ones of reinforced concrete, but otherwise in general the canal systems are as satisfactory as any which could be devised.

The irrigation service afforded to farmers in Imperial Valley is the best of which the writer has ever heard. This has been the case with the exception of three short periods: the winter of 1904, 1 month (November) in 1906, and a total of 2 months in 1910, when there were shortages of water. Indeed, so accustomed are the water users

*The water rights for all the land south and east of the district of Imperial Water Co. No. 5 which could be irrigated by gravity from what was known as the Holt Heading—where the East Side Main heads—approximately 18 000 acres, were sold for $50 000. The purchaser, Mr. W. F. Holt, formed Mutual Water Company No. 7, constructing the distribution system and selling for his own benefit all the capital stock of this company. The fact that this deal was made at the rate of $3 per acre, including the consideration for the proportional cost of the controlling works in the valley and of the main canal thereto from the Colorado River, for one of the very richest sections of land, shows plainly the financial straits of the company at that time.

of this region to obtaining all the water they want whenever they want it, that a suggestion of delivery in rotation—which is done in almost all irrigation projects—would doubtless meet violent opposition.



A preliminary summary, issued on December 15th, 1911, by the U. S. Census Bureau, states that, in 1909, 2 664 104* acres of land were irrigated in California, of which 220 000 acres, or one-twelfth, were in Imperial Valley. The percentage irrigated of the whole number of farms was 44.6, or 39 352 acres. The area included in projects completed and under construction was 5 490 360 acres, or slightly more than double the present irrigated area. Probably there will soon be 450 000 acres under the Imperial Valley canals, or just about the same proportion of one-twelfth. Of the acreage irrigated in 1909, there were 400 acres (0.01%) under the canals of the U. S. Reclamation Service; 3 490 acres (0.1%) under the U. S. Indian Service canals; 173 793 acres (6.5%) under canals of irrigation districts; 779 020 acres (29.2%) co-operative enterprises; 746 265 acres (28%) commercial enterprises; and 961 136 acres (36.1%) individual or partnership enterprises. Of the irrigated acreage in 1909, 71% was watered by works controlled by the water users. Of the remaining 29%, almost one-third is under the canals of the C. D. Co. Aside from the very large area covered by the canals of this project, its relative importance is vastly increased by the vital necessity for continuous service every day in the year, which has no counterpart of which the writer knows, and the minimum daily demand in winter is one-fourth of the maximum.

Obstacles Encountered by the C. D. Co.

The settlement of Imperial Valley† took place more rapidly than any of the men interested in the project had even hoped, and constituted the most marvelous achievement of irrigation in the West, up to that date at least, and probably to the present time. On January 1st, 1901, with the exception of a party of surveyors, not a single white

* Undoubtedly, the greater part of this total is irrigated only after a fashion, so that the relative importance of the irrigated area in Imperial Valley is much greater than the figures indicate.

† The Imperial Land Company decided to use the name "Imperial Valley," for the region to be covered by the irrigation canals, instead of "Colorado Desert" or "Salton Basin," partly to distinguish between the reclaimed and unreclaimed areas, but chiefly for the effect of the name on readers of the colonization literature put out by the company. The name, "Imperial Valley," is firmly established as referring to the cultivated portion of the Colorado Delta west of the river, whether north or south of the International Boundary Line

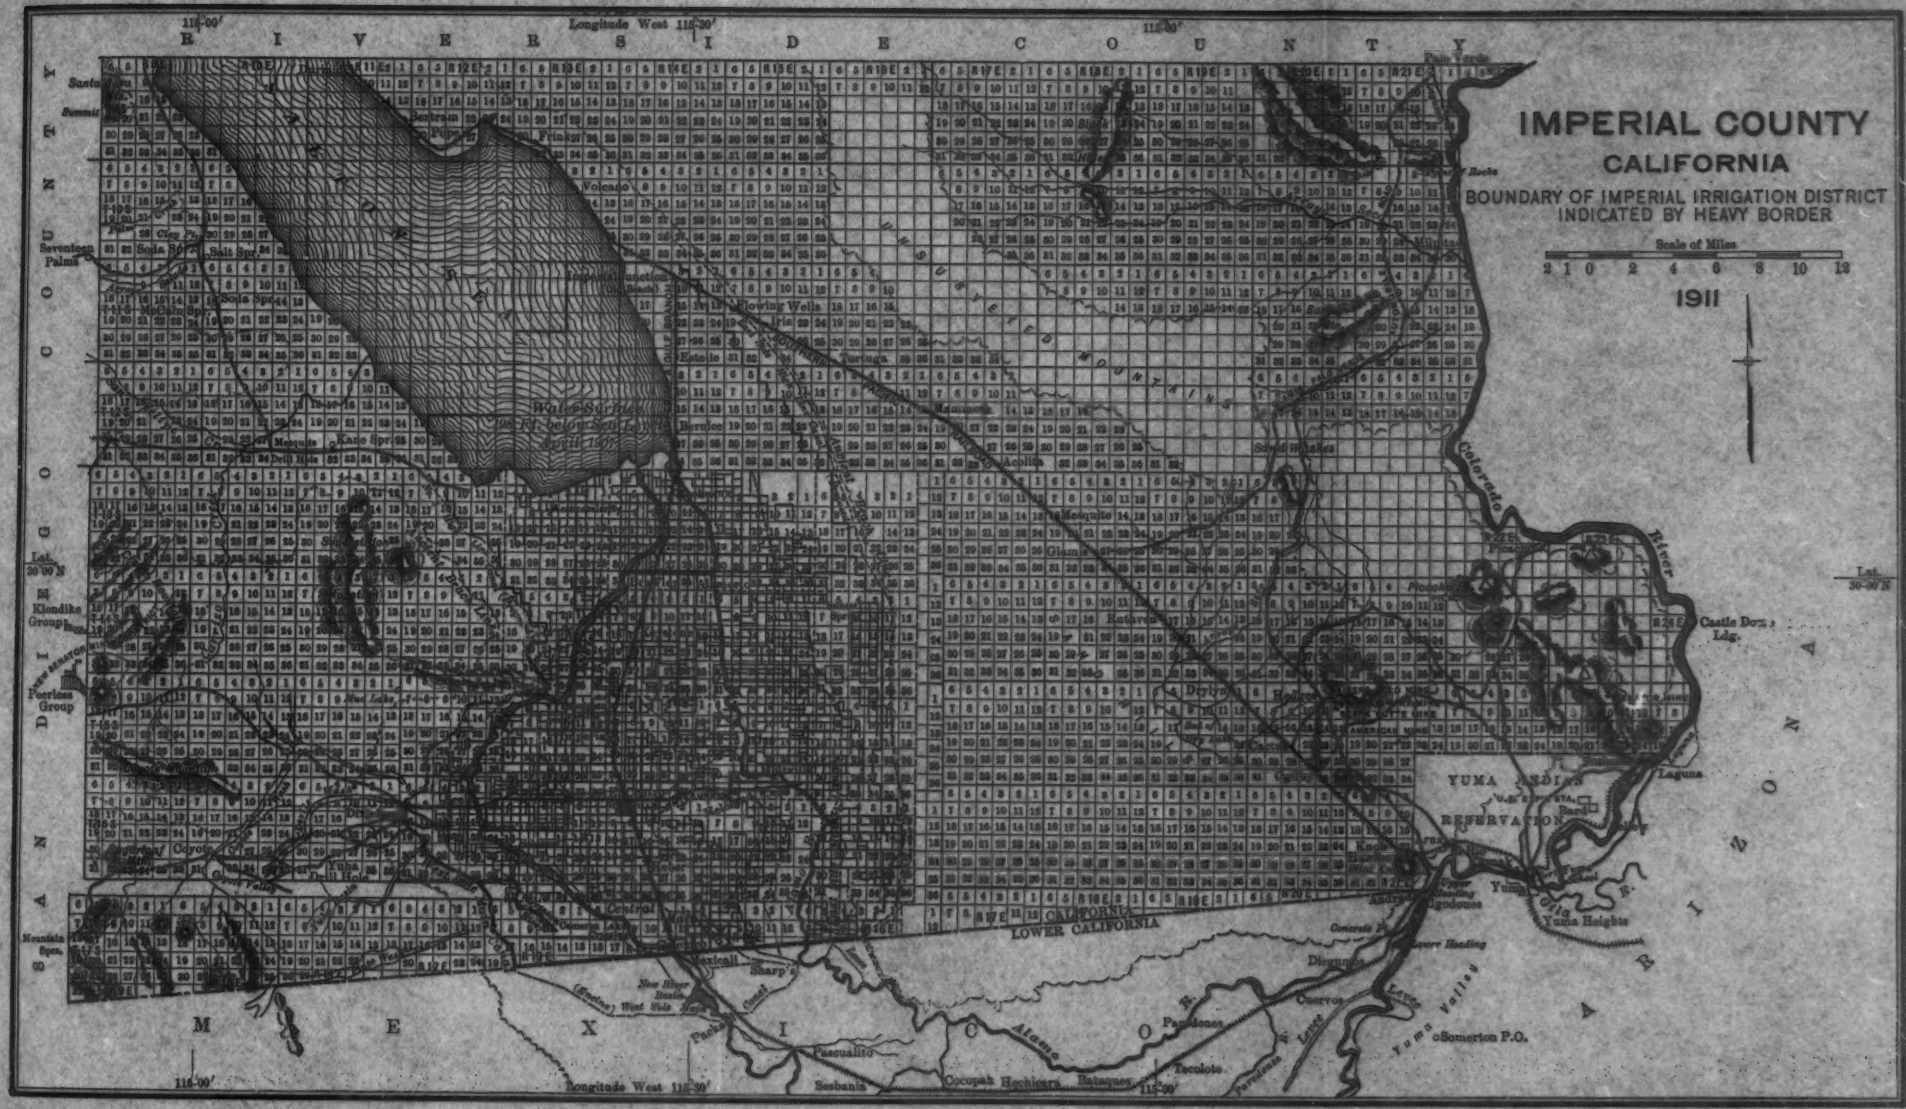
man lived in the whole region; by January 1st, 1903, 2 000 people had come in; by January 1st, 1904, probably 7 000 people had made their homes in the new district, and by January 1st, 1905, the population was between 12 000 and 14 000. As early as 1904 there was a branch railroad through the district from the Southern Pacific main line at Old Beach, since called Imperial Junction, and, at the beginning of 1905, there were seven towns, with stores, banks, etc., 780 miles of canals, about 120 000 acres of land under actual cultivation, and 200 000 acres covered by water stock.

This unprecedented and unexpectedly rapid development overtaxed the resources of the C. D. Co., and, in addition, there were several untoward factors which accentuated the difficulty. These were serious complications in the United States Government Land Survey of the region, an extremely unfavorable soil report by the United States Agricultural Department, agitation for the United States Reclamation Service to supplant the irrigation system of the valley, a question as to the right to divert water from the Colorado River, and troubles at the intake by silt depositions.



United States Land Surveys in the Imperial Valley.—That portion of the Imperial Valley north of the 4th standard parallel was supposed to have been surveyed in 1854-56. The maps and notes for it were accepted, but there is at least some question whether the survey was ever actually made in the field. Later, in 1880, after the International Boundary Commission had surveyed the Boundary Line between the United States and Mexico and marked it continuously with permanent monuments, the area south of the 4th standard parallel was surveyed, this being locally known as the "Brunt" survey. The colonization company, in April, 1900, put out surveying parties under the direction of Mr. Perry, now County Surveyor of Imperial County, to re-run the Government lines and establish corners so that settlers might have proper descriptions for the tracts of land they wished to file on, and also that the distribution systems of the various mutual companies might be located along the Government subdivision lines, as the topography of the land is such that this ideal canal location is generally feasible. Mr. Perry found nearly all the corners of the Brunt survey, and used the notes showing certain connections made with the survey of 1856 along the 4th standard parallel. In this way

the lines to the north were retraced, but, some time later, when the survey had extended farther and the work of retracing the lines east of the Alamo River was commenced, it was discovered, by encountering natural features given by the notes of the 1856 survey, 2 miles or more out of correspondence, that there were serious errors. Exhaustive search was then made for the 1854-56 survey stakes, but in an area of thirty townships only five corners were discovered which seemed to be authentic. These were widely scattered, and showed great errors. Between the 3d and 4th parallels the actual distance was found to be 25¼ miles, or an error of 1¼ miles in a 24-mile north and south line. East and west the error was approximately 2 miles in 30.

Throughout the territory, Sections 16 and 36, the school sections, had been given to the State of California by the United States Government for the benefit of the State school fund, the remainder of the land belonged to the United States, and this dual ownership increased the difficulty of making any adjustment. In June, 1902, the president of the colonization company and the chief engineer of the C. D. Co. went to Washington, explained the situation, and, on the advice of the General Land Office, an Act was prepared and passed in July, 1902, authorizing a resurvey of twenty townships of the land in Imperial Valley. The outside lines of these townships were re-run in 1903 and are known locally as the "Henderson" survey. It was more than 6 years, however, before the interior lines in these townships were re-run and the work was completed and approved.

In the mean time, it was impossible for the Land Office to issue patents to the settlers, and thus men practically owning from 160 acres to two and three times that area of extraordinarily fertile land, with a selling value of from $60 to $100 per acre, could offer no security for a loan with which to make permanent improvements. The United States land laws are extremely strict and severe with reference to a settler borrowing money with which to make final proof. Under such circumstances, the interest rate was naturally from 10 to 12% per annum, while the interest on deferred payments for the water stock was only 6%, so that the C. D. Co. suffered severely. However, it was not until 1909, more than 3 years after the control of the company was taken over by the Southern Pacific interests, that any suits were entered to foreclose on the collateral notes and mortgages secured by the water stock.

PLATE XLVI.

CORY ON
IRRIGATION AND RIVER CONTROL.
COLORADO RIVER DELTA.

Soil Surveys of the Imperial Valley.—In the fall of 1901 the Bureau of Soils, United States Department of Agriculture, made a soil survey of Imperial Valley. On January 10th, 1902, a preliminary report, "Circular No. 9," was issued covering the 169 sq. miles of territory which had been examined.* The report doubtless presented the only possible conclusions, according to the information at that time extant regarding alkaline soils of such depth as are found in the Imperial Valley. It was very unfavorable, however, and calculated to deter sensible people from settling in the region. For example, one statement was as follows:

"One hundred and twenty-five thousand acres of land have already been taken up by prospective settlers, many of whom talk of planting crops which it will be absolutely impossible to grow. They must early find that it is useless to attempt their growth. * * * No doubt the best thing to do is to raise crops such as the sugar beet, sorghum, and date palm (if the climate will permit), that are suited to such alkaline conditions, and abandon as worthless the land which contains too much alkali to grow those crops."

The warning was reiterated in a subsequent report.† It seems certain that, had the territory not been already settled in very large measure when these reports were sent out, Imperial Valley would yet be unreclaimed.

Agitation in Favor of a Reclamation Service Project.—When the United States Reclamation Service Act was passed, in June, 1902, the crops produced in the Imperial Valley were causing a return of confidence in the region, and the extraordinarily rapid development was being resumed. The irrigation possibilities on the Colorado River had already been examined by the United States Geological Survey, and in 1903 plans for the Yuma Project were outlined. The engineers of the Service were convinced that no diversion from the Colorado for irrigation could be permanently successful where provisions were not made for preventing the heavy silt from entering the canals—that it would take an impractically large amount of dredging to keep canals leading directly from the river open for reasonably satisfactory delivery of water. The cost of the Laguna Weir, borne by the land owners of Imperial Valley alone, constitutes a serious burden, but, if

* "Field Operations of the Bureau of Soils, U. S. Department of Agriculture, 1901, p. 587."

† "Soil Survey of the Imperial Area, California (Extending the Survey of 1901), Advance Sheet of Field Operations of the Bureau of Soils, 1903."

borne by all the irrigable land in both valleys, the cost per acre would be reduced to approximately one-fourth. Mr. William E. Smythe, of San Diego, who has been very prominent in the work of the National Irrigation Congress, and has written extensively on irrigation generally, urged the people of Imperial Valley to join with the Yuma Project; that the enterprise would then be backed by the Government with unlimited funds; that they would be required to pay to the Government only a small portion of the money they were obliged in one way and another to pay the C. D. Co., and that they would eventually attain the laudable desire of owning and operating their own system. The Imperial Water Users' Association was accordingly formed, with Mr. W. F. Holt, of Redlands, Cal., as its President, and negotiations were at once instituted with the C. D. Co. to acquire its canal system. Mr. A. H. Heber, President of the C. D. Co., who acted for it in the matter, knew that the estimates of the Reclamation Service for the canal line into Imperial Valley, lying entirely on American soil, were at least $10 000 000, on account of the sand hills. He believed that the Alamo River for 40 miles was a very satisfactory main canal, and that by owning the 100 000-acre tract of the Mexican Co., building another waterway through Mexican territory would require the consent of the Mexican Co.; consequently, his idea regarding the values of the property were excessively high.

As a natural feature of these negotiations, and with a view to tempering such ideas as to price, the right of the C. D. Co. to take water from the Colorado was challenged. The navigability of that stream suddenly assumed serious commercial, national, and international importance. As usual in such cases, these questionings were carried to unfortunate extremes.

In the course of events, at a mass meeting held in Imperial on July 30th, 1904, Mr. Heber offered to have the price fixed by arbitration, one man to be appointed by him, one by the Imperial Water Users' Association, and a third to be selected by these two. This was not done, but the Engineers of the Reclamation Service made an appraisal of the C. D. Co.'s plant. The Imperial Water Users' Association appointed a committee headed by its president, Mr. Holt, to represent it in all negotiations, and it agreed with Mr. Heber on a price of $3 000 000. Mr. C. D. Walcott, Director of the U. S. Geological Survey, and of the Reclamation Service, made a report to the Secretary of the

Interior in the matter on September 15th and again on October 1st, 1904, that

"from present knowledge of the conditions, a recommendation to pay three million dollars for the property and rights involved is not justified."

On being advised of this report, an endeavor was ostensibly made by the Committee and Mr. Heber to secure different action. It appears, however, that, without intimating to Mr. Heber that it had changed front, the Committee agreed with the Reclamation Service authorities against buying the property on the agreed basis. With such unpardonably bad faith on the part of the Committee, it is not surprising that the matter ended with relations between Mr. Heber and the Reclamation Service so strained that further negotiations were impossible.

In a further report made by Director Walcott on January 4th, 1905, to the Secretary of the Interior, it was advised that, even if there were no complications because of the unfavorable soil report by the Department of Agriculture and

"the present desperate situation of many of the inhabitants of the Imperial Valley, it was a matter of grave doubt whether it was wise to become involved in the situation.

"Much of the land filed on is unsuitable for cultivation owing to the large amount of alkali and other adverse conditions of the soil. The water supply is deficient, owing to poor construction and accidents to the canal system, and although during the fall months there has been ample water, it appears that the people will not utilize it, and from best information are not planting crops to any considerable extent. Difficulties of handling the silt are very great, and if the Government is to take up the project, it must make enormous expenditures at once to prevent the country lapsing into a desert condition."

Shortly after this, it was announced by the Secretary of the Interior that the Assistant Attorney General had concluded that no law existed whereby it could deal with the problem of carrying water through Mexico.

The effect of the entire incident was to render the people of the valley antagonistic to the company, and at the same time split them into several factions. More important, however, was the effect of the severe criticisms of the plant and water rights of the C. D. Co., which had been given wide publicity. The company's credit, which had slowly but steadily improved since 1902, was again destroyed in South-

ern California and in the larger financial markets of the United States. Consequently, early in 1905, when these negotiations ended, the company was almost on the rocks.

Water Rights Attacked.—Because of the attacks on the right to take water from the Colorado, then well under way, a bill was introduced into the House of Representatives in January, 1904, at the request of the C. D. Co., declaring:

"That the water of the Colorado River for the irrigation of the arid land that may be irrigated therefrom is hereby declared to be of greater public use and benefit than for navigation, and the diversion of the water from said river, heretofore made and that which may in future be made, for irrigation purposes, in accordance with the laws of the respective States and Territories in which such diversion has been or may be made, is hereby legalized and made lawful.

"Section 2. That any person, firm, or corporation be, and is hereby, authorized to divert, take, and appropriate water from the Colorado River for the purpose of irrigation, in such quantity, subject to and under the State appropriation of the State of California, as now in force under the laws of said State." (H. R. 13 627, 58th Congress, 2d Session.)

The U. S. Reclamation Service had filed on some of the flood-waters of the Colorado in order to fill four large reservoirs between The Needles and Yuma, then under contemplation, and such filings were practically second only to those of the C. D. Co., so that the effect of this proposed legislation, other than on the C. D. Co., was null. The bill was bitterly opposed by Mr. Smythe, as representing the majority of the settlers in Imperial Valley. No attempt was made to amend the bill with a view of protecting all interests in a fair and equitable manner, but instead, under date of April 8th, 1904, the Acting Attorney General, Mr. Hoyt, in an opinion addressed to the Committee on Irrigation on Arid Lands, to which the bill had been referred, said:

"In view of these provisions [from the Treaty of Guadalupe-Hidalgo, February 2d, 1848; of the Gadsden Purchase, December 30th, 1853; and the Boundary Treaty of November 12th, 1884, between Mexico and the United States] and of the important irrigation projects now and hereafter to be carried on by the United States Government, I seriously doubt the wisdom of a surrender by Congress at this time of all control over the waters of the Colorado River."

Accordingly, the Committee reported* requesting the Secretary of the Interior to investigate and report to Congress on the various questions involved in the use of the waters of the Lower Colorado River, with a view to determining their availability for irrigation, and recommend any legislation which might be necessary. Under this resolution, Director Walcott reported through the Secretary of the Interior, on December 24th, 1904, that governmental control of the waters of the Colorado River was absolutely necessary to obtain the best results; that, the river being navigable, water appropriations under the Arizona and California laws were not valid; suggesting that legislation be along the line guarding present navigation interests; confining diversions heretofore made to the extent of actual beneficial use of the waters diverted upon land capable of producing remunerative crops, and making the same appurtenant to specific tracts of land; and making the approval of the Secretary of the Interior necessary with respect to future appropriations.

Mexican Concession Secured.—Failing to secure an adjustment of water rights at the hands of Congress, Mr. Heber went at once to Mexico and quickly obtained a concession from President Diaz, which was ratified by the Mexican Congress on June 7th, 1904.

This concession authorized the Mexican Co. to carry, through its canal system in Mexico, 284 cu. m. per sec. (approximately 10 000 sec-ft.), to be diverted from the Colorado River in United States territory by the C. D. Co. and turned over to the Mexican Co. at the boundary line; to construct an intake on Mexican territory, and connecting with the said canal system, and divert through such intake 284 cu. m. per sec., to be used in the irrigation of lands in Mexico and in the United States, but with the proviso, "without injuring the rights of any third party nor the navigation as long as the river is destined for navigation"; that, of the water carried in the canal, enough should be used to irrigate the lands in Mexico susceptible of irrigation by gravity to an amount not exceeding one-half the total volume; that the Mexican Co. should begin surveys within 6 months, and within 12 months file, with the Secretary of Development, maps in duplicate of the proposed extensions and betterments, together with a descriptive report, and entirely complete the same within 7 years;

* House Joint Resolution Nos. 147, 133. State. 591.

that the company should pay into the Inspection Fund, as is customary in all concessions granted by the Mexican Government, a sum, in this case $300 (Mexican money), per month, and should be subject to inspection by an engineer appointed by the Secretary of Development; granting the company the right of eminent domain over private property and defining the process by which condemnation could be carried out—incidentally with minimum possible difficulty—and permitting importation once for all, free of customs or duty, all equipment and apparatus necessary for the construction of the proposed extensions and betterments, together with freedom from all taxes, except stamp tax, for a period of 10 years; stipulating that under no circumstances should the company sell or mortgage the concession to any government or foreign state, nor admit it in partnership; that the company should be subject to the laws and rulings now in force, and which in future may be enacted, for the supervision and use of waters; particularly specifying that the company and its assigns shall always be considered as Mexican corporations, though all or any of its stockholders should be foreigners; that the corporation should be subject to the jurisdiction of the Courts of the Republic in all affairs emanating within Mexican territory, and that such stockholders should never be able to allege the rights of foreigners under any circumstances, but have the rights and the methods of establishing the same as the laws of the Republic grant to Mexican citizens, so that, in any matters, diplomatic or foreign agents should not have any interference.

Condition of Plant in the Summer of 1904.

From the first, there was a great deal of trouble with the Chaffey Head-gate, chiefly because its floor was not down to the bottom grade line of the canal, as originally planned. As has been explained, this gate was a temporary structure, but well and substantially built. Just as it was being covered up by the operations of the dredge, *Alpha*, cutting the main canal into the permanent concrete head-gate from below, in 1906, the writer examined it carefully and found it in an excellent state of preservation. The floor was so high, however, that it was necessary, during the low-water seasons of 1902-03 and 1903-04, to cut a by-pass around the gate, and close it on the approach of the summer floods. When the Mexican concession was obtained, the first Mexican intake was cut from the river to the main canal, as shown in Fig. 13.

In the winter of 1902-03 there had been shortages of water in the valley, due to the fact that the main canal had not been completed to its final depth; and, with the apparatus and available funds on hand, it was impossible to keep the water supply up to the demands when the river fell exceedingly low. In the winter and early spring of 1904, another water shortage caused considerable damage in the valley, and claims amounting to $500 000 were presented to the company. Every one of these was settled out of Court, however, in 1905 and the early part of 1906, with a payment of less than $35 000, taken entirely in water and water stock, and the writer believes that every claim was fairly settled, at least as far as the settlers were concerned.

Below the intake the first 4 miles of the Main Canal caused much worry, due to the extent to which it silted up during floods, but, with this exception, the plant of the C. D. Co. was in quite satisfactory condition. The canals were generally well located and in fair condition, and the structures, though of redwood and not concrete, were substantially built according to good design, and were in excellent condition. The canals in the distribution systems of the mutual water companies were silting up constantly, on account of the muddy water. In part, this was unavoidable, but was largely due to uneconomical methods of water deliveries when dealing with muddy water, particularly in serving any settler on his demand, regardless of the very low velocity, if no one else wanted water from the lateral during the same time. The silt problem in the distribution systems of these companies, however, is as simple as it will ever be for any lands irrigated along the Lower Colorado. The financial status of the various mutual companies was quite good, and they had generally established a small but satisfactory credit with the local banks.

To avoid excessive silt depositions in the first 4 miles of the canal, in February and March, 1904, the Best Waste-gate, so-called, was put in 8 miles below the intake, where water could be wasted from the Alamo channel through the Quail River into the Paredones River and thence into Volcano Lake. This was a wooden A-frame, flash-board gate, 60 ft. long, but it was carried away in June, 1906, by the side-cutting of the banks while the Alamo channel was being enlarged by that year's summer flood. The idea was to divert a large quantity of water during the flood season of 1904, waste it through the Best Gate, and in this way scour out the upper portion of the canal. At

first the action was as expected, and some 2 ft. in the bottom were carried away. When the river reached its maximum height during the summer flood of 1904, however, and carried an excessive silt content, particularly of the heavier and sandy type, this scouring action was entirely overcome, and the bottom of this stretch was raised approximately 1 ft. higher than during the previous year.

The Silt Problem.—This action accentuated, and properly impressed on the engineers of the C. D. Co., the seriousness of the silt problem in diverting the Colorado River water. Generally speaking, during flood stages, the water carries all the silt it can transport, and the faster the current the larger the particles it picks up and carries along. It is certainly desirable, and probably essential, to provide settling basins at or immediately below the diversion point, in which water can be practically stilled and thus insure the deposition of the heavier silt having very slight fertilizing value, and the admission of only such partly clarified water into the canals. Unless some provision is made, as at the Laguna Weir, the diversion canal immediately below the head-gate must act as a settling basin, which is just what happened from the very beginning in the canals of the C. D. Co.

The results of such excessive silting were obviated in various ways, largely by the construction of new intakes, until the diversion of the entire river occurred, and the permanent head-gate was put in service in 1907. The clam-shell dredge, *Delta,* was utilized intermittently to remove the deposits until 1910; then a submerged weir was built across the river, to raise the water at the intake; and lastly large suction dredges were operated just below and just above the regulating gates.

Rather carefully kept records indicated that the bed of the canal at the Lower Heading was raised a little more than 5 ft. between March 1st, 1907, and March 1st, 1910, most of this taking place in the first 6 months. The bed of the Alamo near Sharp's Heading was raised approximately 2 ft. in the same time, and there is constant deterioration all along between these points on the Alamo channel. The reduction of capacity in the larger canals has been noteworthy, but the maximum effect is shown in the smaller laterals constituting the distribution systems of the various mutual water companies.

Mr. Robert G. Kennedy states* that on the Bari Doab Canal from the Punjab River, the canals in Sind from the Indus and Shwebo,

*"The Prevention of Silting in Irrigation Canals," *Minutes of Proceedings,* Inst. C. E., Vol. CXIX, 1895, pp. 281-290.

and the Mandalay canals in Burmah, it appears that in a non-silting and non-scouring channel the mean velocity is independent of the width, but increases with the depth of the channel, according to the equation:

$$V_0 = 0.84\, d^{0.64},$$

in which V_0 = the mean velocity of a non-eroding, non-depositing current; and d = the depth for fine sand-silt, the constants varying slightly with the kind of silt.

He also points out the exceedingly important deduction that during flood stages in the river, the diversion of large quantities of water in an effort to scour away silt depositions in the upper reaches of canals will have the opposite result, because of the excessive silt contents of the water diverted.

The same rule probably applies fully in the case of canals carrying Colorado River water when they are free of vegetation. In point of fact, however, rank growths of tules and willows spring up, on the banks and berms and along the edges out into the water, with such rapidity as to increase tremendously the deterioration of carrying capacity, particularly in the smaller canals. Furthermore, the rate of deterioration in these laterals increases with the decrease in channel efficiency. The maintenance of the district distribution systems, therefore, consists, in large part, in keeping down and removing the brush and tules.

The various distribution systems were ordinarily designed and built on the basis of a capacity of 1 sec-ft. per 120 acres of land thereunder, although in some cases the ratio was decreased to 1 sec-ft. per 93 acres (8 in. vertical depth of water in a month). It would have been just as well, indeed considerably better, and of course cheaper, to have made the canals much smaller, for they were put into service when only a small percentage of the land was in cultivation, and, as they carried only a fraction of their capacity, they very soon silted up badly. Removing the silt deposition and the accompanying tule growths is fully as expensive as the excavation of the original section.

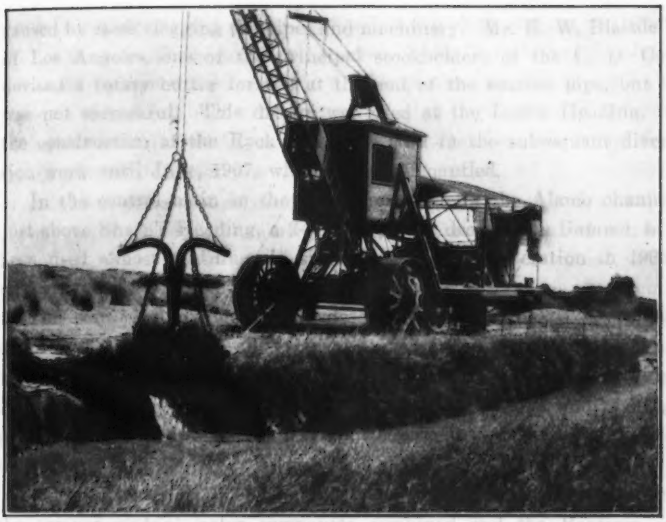
This needlessly large excavation was required by the contract provisions under which the C. D. Co. built the distribution systems of the various mutual water companies, and such provisions at the time were necessary to assure colonists that the water supply would be ample. In the construction of the first lateral canals built, however,

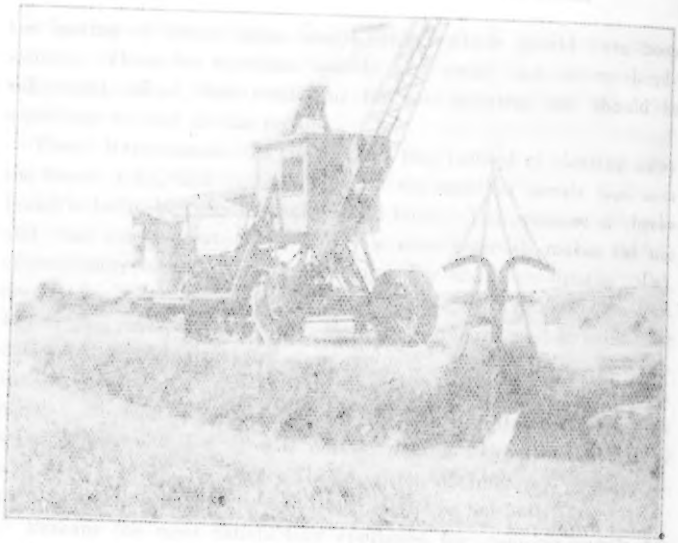
the leaving of inside berms was a defect which should have been avoided. These flat stretches, usually kept damp and seldom deeply submerged, afford ideal conditions for tule growths, and should be studiously avoided in this region.

Canal Maintenance.—In general, the best method of clearing away the brush, tules, and deposited silt in the smallest canals has been found to be by Mexican or Indian hand labor. The presence of checks and other canal structures at relatively close intervals makes the use of machinery of questionable economy. For the large canals, "V's", dragged by horses or traction engines, portable floating dipper-dredges, Lidgerwood cross-drags, portable clam-shell dredges, and a number of devices designed by local inventive geniuses have been tried with varying success. The results in all cases depend so greatly on the efficiency with which they are handled and the local conditions under which they work that it will not be profitable to attempt to give any cost figures—indeed, with the exception of Imperial Water Company No. 1, no cost-keeping worthy of the name has been attempted.

Perhaps the most satisfactory appliance for cleaning canals too small for floating dredges is a clam-shell bucket arranged on wheels so that it may follow along the bank. (Fig. 17.) The C. D. Co. has two of these machines, manufactured by the Stockton Iron Works, Stockton, Cal., which cost $5 000 each, f. o. b. factory. These consist of a clam-shell bucket having a capacity of 15 cu. ft., with a 40-ft. steel boom carried on an all-steel frame. The maximum width is 14 ft. The power is supplied by a 15-h.p. Atlas gasoline engine, manufactured in San Francisco, and the machine is self-propelling, with two speeds forward and one reverse. No definite figures, including deterioration and cost of moving from one job to another, are available, but it is understood that the cost of handling material with these machines is about 13 cents per cu. yd.

For handling silt in the upper reaches of the Main Canal along the river, the large 4-yd. dipper dredge, *Alpha*, used in the original construction, was perhaps the most efficient of all agencies for the first few years until the waste banks along the canal became too high to permit of its further use; it handled material for about 6 cents per cu. yd. A suction dredge, the *Beta*, equipped with a 12-in. Kroh centrifugal pump—manufactured in San Francisco—was tried very soon after the canals were put into service, but too much difficulty was





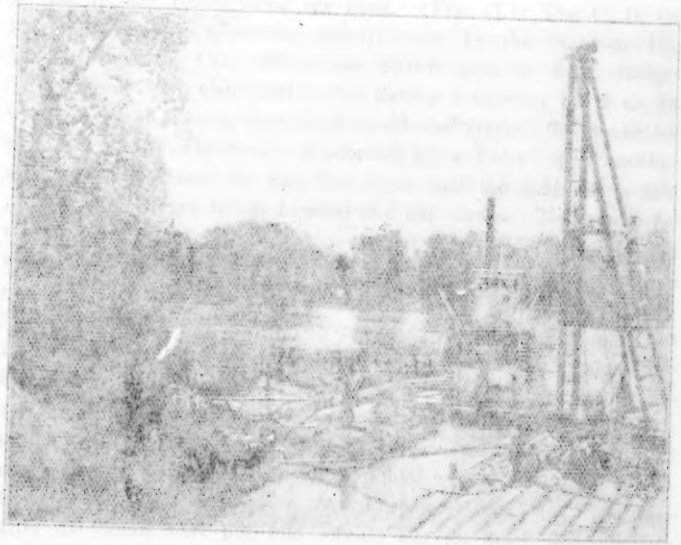


FIG. 17.—STOCKTON CLAM-SHELL DREDGE CLEANING CANALS IN IMPERIAL VALLEY.

FIG. 18.—THIRD ATTEMPT TO CLOSE BREAK AT LOWER MEXICAN INTAKE, JUNE 1ST, 1905.

caused by roots clogging the pipes and machinery. Mr. H. W. Blaisdell, of Los Angeles, one of the principal stockholders of the C. D. Co., devised a rotary cutter for use at the end of the suction pipe, but it was not successful. This dredge was used at the Lower Heading, in the construction of the Rockwood Gate, and in the subsequent diversion work until June, 1907, when it was dismantled.

In the central main in the valley, and also in the Alamo channel just above Sharp's Heading, a 2-cu. yd. dipper dredge, the *Gamma*, has been used almost continuously since it was put in operation in 1904, removing material at about 5 cents per cu. yd.

The clam-shell dredge, *Delta*, described in some detail later, has done excellent service in silt removal and incidental levee building, as well as in channel straightening, since its arrival on the work in November, 1906. It is now engaged in building cut-offs and making general channel improvements, rather than removing the silt deposits direct.

In the summer of 1910 an arrangement was entered into between the various mutual water companies combined and the Receiver of the C. D. Co. whereby the former were to furnish the money and build a suction dredge and rent it to the latter for 10% annually on its first cost. This dredge was built just below the concrete head-gate, and its operation is confined to the American side of the line, the contract being entered into with the North American Dredging Company, of Los Angeles, on December 10th, 1910, for the construction and equipment of an exact duplicate of one of the latter company's dredges in San Pedro Harbor, for $57 300. After being put into service it was found necessary to remodel the upper deck, in order to make the quarters of the crew suitable for the climatic conditions, at a cost of $950, and a bonus of $2 200 was paid for completion 11 days ahead of the contract time—4 months—making the total cost $60 450, exclusive of engineering, inspection, and legal expenses, which brought the grand total cost up to approximately $63 600. This dredge, the *Imperial*, has a hull 105 ft. long, 55 ft. wide, and 8 ft. deep, and is equipped with a 15 by 60-in. Kroh centrifugal pump driven by a vertical compound engine, steam being supplied by a 250-h.p. marine-type boiler. This dredge handles the silt deposits in the enlarged section of the canal below the head-gate at the rate of about 200 cu. yd. per hour lifted to an average height of 35 ft., at a cost of from 5 to 7

cents per cu. yd., exclusive of interest, taxes, and depreciation, using crude oil fuel at $1.40 per bbl., equivalent to coal at $5.60 per ton.

The *Imperial* was equipped with a cutter for stirring up the material, but this was found to be unnecessary for handling the silt deposits just below the head-gate, and the cutter engine, of vertical compound type, with 8 by 15 by 10-in. cylinder, was installed on the barge, *Silas J. Lewis,* mentioned later, in the canal above the head-gate to run the 10-in. Kroh pump formerly on the *Beta,* the resulting dredge being known as the *El Centro.* Under like conditions, the cost of handling material with the *El Centro* is approximately the same as with the *Imperial.*

With these two suction dredges, it is claimed that the bed of the Main Canal has been lowered approximately 5 ft. above and at the head-gate and for a distance of 3½ miles below, diminishing gradually to nothing throughout the next 2½ miles. If future experience confirms such results, it would seem that the periodic dredging of silt depositions from a settling basin near the intake, at a cost of from $30 000 to $40 000 per annum, will solve the silt problem in the Imperial Valley canal system, except for the very fine silt which cannot be gotten rid of except by allowing the water to be quiescent for some time.

The following general cost figures on maintaining the 373.25 miles of canals of the distribution system of Imperial Water Company No. 1 during 1911 are taken from the annual report of the Superintendent, R. S. Carberry, Assoc. M. Am. Soc. C. E.

Cleaning 465 miles of canal cost $60.64 per mile. The figures in 1910 are 562 miles at $43.81 per mile, and the average cost for the last 6 months of 1909 was $73.16. Clearing on 194 miles of canal cost $35.39 per mile. Cutting brush on 392 miles cost $20.71 per mile. The figures in 1910 were 346 miles at $43.47 per mile, and $60.65 per mile for the last 6 months of 1909.

In this report it is stated that canal "V'ing" is the best method for cleaning canals, generally speaking, and the company owns three "V's", each costing about $600, and three caterpillar traction engines to operate them, each costing $4 200. During the year, 363.8 miles of canal were "V'd" at $58.81 per mile, as compared with 362 miles in 1910 at $60.74 per mile, the details being as follows:

"V'ing"	$16.76
Repairs to engines	16.29
Repairs to "V's"	5.00
Fuel and oil	5.96
Mexican labor following "V's"	14.80
Total average cost per mile	$58.81

During the year, 1 415 miles of canal were worked on, so that the whole system was covered in various ways nearly four times during the year. A small portion of the system was not worked on at all, so that this statement gives some idea of the difficulty in maintaining the system.

The cost of building 117 new structures was $6 278.75, and the cost of repairing old structures was $4 145.05, making the total cost of structure maintenance and renewal $10 423.80. The average number of men employed per day (300 working days per year) was 162, or 0.43 man per mile of canal per day, in addition to teams and machinery. The bottom width of the canals constituting this system varies from 20 to 5 ft.

Canal Operation.—The mutual water companies have never considered delivering water to stockholders in rotation, but instead, without exception, supply any water user on demand, even though he may be at the very end of a long lateral and the only person desiring water from that lateral at the time. Thus, naturally, exceedingly small quantities of water are carried occasionally in every canal except the very largest laterals, and the result is low velocities and heavy silt deposition and canal deterioration. The feeling seems to be general that the additional cost of maintaining the various distribution systems is more than offset by the advantages or convenience of the water users in obtaining irrigation water at all times on 24 hours' notice. The amount which the maintenance cost of canals could be cut by adopting a rotation system of delivery is problematical, but must be between 35 and 65 per cent. This fact should be borne in mind in making comparisons with the cost data just given.

The Fourth or Lower Intake.

This is such a very important matter that the reasons for digging the lower Mexican intake and the method of handling it when

completed are given by quoting from Mr. Rockwood,* the man who did it.

"As soon as the summer flood (1904) dropped and I discovered that instead of the bottom being lower it was approximately 1 ft. above that of the year previous, we adopted the only means at our command to attempt to deepen the channel.

"Knowing the character of the material to be removed, we knew that with the dredging tools which we had (4-yd. dipper dredge *Alpha* and 12-in. suction dredge *Beta*), it would be impossible to dredge out this 4 miles of canal in sufficient time for the uses of the valley, providing the water in the river should drop as low as it had the previous year. The dredges were brought back, however, and put at work, but the result proved, as I had anticipated, that it would take practically all winter to dredge the canals; that is, it would take all winter to provide new machinery, even if we had the money; and in hopes, then, that it might possibly prove effective, I employed the steamer *Cochan*, and, placing a heavy drag behind it, ran it up and down the canal in hopes that by stirring up the bottom there would be sufficient velocity in the canal itself to move the silt deposits on below the 4-mile stretch to a point where I knew the water had sufficient velocity to keep the silt moving. A month's work, however, with the steamer proved that the work being done by it was inadequate.

"*The Great Problem.*—We were confronted then with the proposition of doing one of two things, either cutting a new heading from the canal to the river below the silted 4-mile section of the canal, or else allowing the valley to pass through another winter with an insufficient water supply. The latter proposition we could not face for the reason that the people of the Imperial Valley had an absolute right to demand that water should be furnished them, and it was questionable in our minds as to whether we would be able to keep out of bankruptcy if we were to be confronted by another period of shortage in this coming season of 1904-1905.

"The cutting of the lower intake, after mature deliberation, and upon the insistence of several of the leading men of the valley, was decided upon. We hesitated about making this cut, not so much because we believed we were incurring danger of the river's breaking through as from the fact that we had been unable to obtain the consent of the Government of Mexico to make it, and we believed that we were jeopardizing our Mexican rights should the cut be made without the consent of the Government. On a telegraphic communication, however, from our attorney in the City of Mexico, to go ahead and make the cut, we did so under the presumption that he had obtained the necessary

* "Born of the Desert—Imperial Valley In Its Making Not A Dream—A Brief History of the California Development Company." By C. R. Rockwood. Second Annual Magazine Edition. *Calexico Chronicle*, Calexico, Cal., May, 1909.

permit from the Mexican authorities. It was some time after this, in fact after the cut was made to the river, before we discovered that he had been unable to obtain the formal permit, but had simply obtained the promise of certain officials that we would not be interfered with, providing that plans were at once submitted for the necessary controlling structures to be placed in this heading.

"*Reasons Why.*—This lower intake was constructed, not, as is generally supposed, because there was a greater grade from the river through to the Main Canal at this point. The grade through the cut and the grade of the Main Canal above the cut were approximately the same, but the cut was made at this point for the reason that the Main Canal below the point where the lower intake joined it, was approximately 4 ft. deeper than the Main Canal through the 4 miles above this junction to the Chaffey gate, consequently giving us greater water capacity. In cutting from the Main Canal to the river at this point, we had to dredge a distance of 3 300 ft. only, through easy material to remove, while an attempt to dredge out the Main Canal above would have meant the dredging of 4 miles of very difficult material. We began the cut the latter end of September and completed it in about 3 weeks.

"As soon as the cut was decided upon, elaborate plans for a controlling gate were immediately started and, when completed early in November, were immediately forwarded to the City of Mexico for the approval of the engineers of the Mexican Government, without whose approval we had no authority or right to construct the gate. Notwithstanding the insistence of our attorney in the City of Mexico and various telegraphic communications insisting upon this approval being hurried, we were unable to obtain it until 12 months afterward, namely, the month of December, 1905.

"*Unprecedented River Conditions.*—In the meantime serious trouble had begun. We have since been accused of gross negligence and criminal carelessness in making this cut, but I doubt as to whether any one should be accused of negligence or carelessness in failing to foresee that which had never happened before. We had before us, at the time, the history of the river as shown by the daily rod readings kept at Yuma for a period of twenty-seven years. In the twenty-seven years there had been but three winter floods. In no year of the twenty-seven had there been two winter floods. It was not probable, then, in the winter of 1905, that there would be any winter flood to enlarge the cut made by us, and without doubt, as it seemed to us, we would be able to close the cut before the approach of the summer flood by the same means that we had used in closing the cut for three successive years around the Chaffey gate at the head of the canal.

"During this year of 1905, however, we had more than one winter flood. The first heavy flood came, I believe, about the first of February,

but did not enlarge the lower intake. On the contrary, it caused such a silt deposit in the lower intake that I found it necessary, after the flood had passed, to put the dredge through in order to deepen the channel sufficiently to allow enough water to come into the valley for the use of the people.

"This was followed shortly by another heavy flood that did not erode the banks of the intake, but, on the contrary, the same as the first, caused a deposit of silt and a necessary dredging. We were not alarmed by these floods, as it was still very early in the season. No damage had been done by them, and we still believed that there would be no difficulty whatever in closing the intake before the approach of the summer flood, which was the only one we feared. However, the first two floods were followed by a third, coming some time in March, and this was sufficient notice to us that we were up against a very unusual season, something unknown in the history of the river as far back as we were able to reach; and, as it was now approaching the season of the year when we might reasonably expect the river surface to remain at an elevation that would allow sufficient water for the uses of the valley to be gotten through the upper intake, we decided to close the lower.

"*Five Floods in One Season.*—Work was immediately begun upon a dam similar to the ones heretofore successfully used in closing the cut around the Chaffey gate. The dam was very nearly completed, when a fourth flood coming down the river swept it out. Work was immediately begun on another dam which was swept away by the fifth flood coming down during this winter season."

These closings of the by-passes or cuts around the Chaffey Gate were effected by throwing a barrier of brush across the cut and dragging earth over it with Fresno scrapers, pushing it into the water on the up-stream side, thus gradually rendering the barrier impermeable and then building it up as an earthen dam. In attempting to make the closure here mentioned, in March, a small pile-driver was rigged up on the end of the *Alpha*, and one line of 8 by 8-in. pine timbers, 3 ft. apart, was driven across the opening about 3 000 ft. west of the river bank, and an 8 by 8-in. waling was bolted to each pile above the water surface. Brush fascines were then made up, and all the sand bags available—about 10 000—were filled in readiness. Simultaneously from each side, brush fascines with the brush ends up stream, were piled above the piling and weighted down with sand bags, making alternate layers of fascines and bags, until the water was confined to a 30-ft. channel in the center. This barrier was about 20 ft. thick up and down stream. The opening was then spanned with long cottonwood timbers and a similar brush-sand-bag construction

was built upon them. The supporting timbers were then shattered with dynamite, letting the mass drop into the opening. At the same time a large quantity of brush was thrown in above and allowed to float into the opening to help close it. In this way the barrier across the opening was built above water and teams passed over it dragging in dirt from both sides, the flow being reduced so greatly that the dredge below it nearly went aground. With a few thousand more sacks of earth to place along the upper toe of the barrier, the work would have been successful. As it was, the structure was undermined, settled down, and eventually failed entirely.

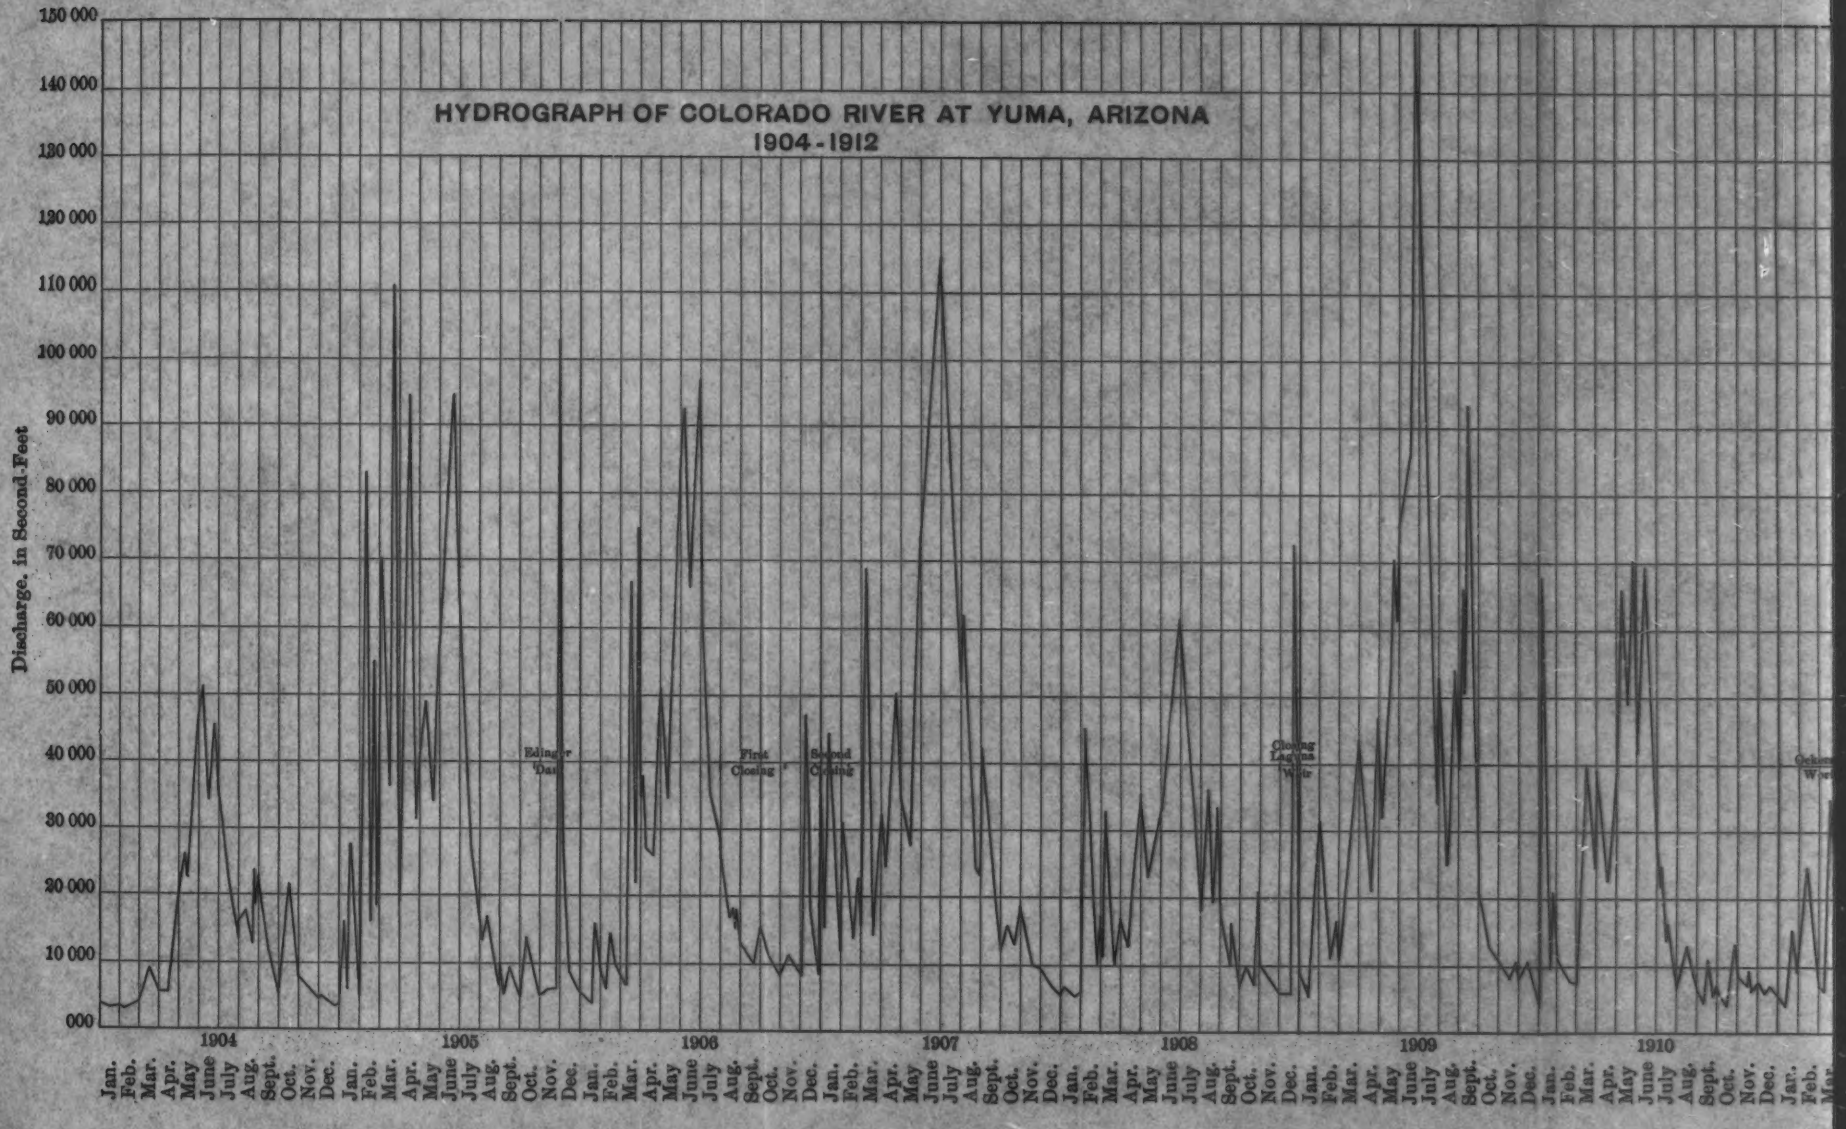
In this attempt 10 000 sacks were used, 8 days' time with the dredge at $100 per day, and 225 men-days time of Indian labor at $1.50 per day. This makes the total cost of closing about $1 800.

Instructions were then given to move the dredge up close to the river bank, where the soil was thought to be better, and make another attempt. The current through the break, however, was too swift, and instructions were given to go up the old Main Canal to the upper Mexican intake to stop it, which was done, using the method which had failed below.

A similar method was used to throw the water through the Alamo Waste-gate on its completion in June, 1905, 3 months later, 30 000 sacks of earth being filled in readiness and every one used. This barrier dam was thrown across the channel carrying 2 500 sec-ft. of water and with a total or final head of 10 ft. This has always seemed to the writer to have been a most remarkable achievement, the only equipment at hand being a skid pile-driver and Fresno scraper teams.

To resume Mr. Rockwood's narrative:

"About this time, I left for the East and at the earnest solicitation of the Imperial Water Company No. 1, which agreed to advance $5 000 for the effort, a third* attempt to close the break was made under the direction of Mr. C. N. Perry and the superintendent of Imperial Water Company No. 1, Mr. Thomas Beach. On my return from the East, on the 17th of June, I found them heroically attempting to stop the break, with the waters so high in the Colorado that all of the banks and surrounding lands were flooded, and I immediately stopped the work as we realized fully that nothing could be done until after the summer flood had passed.



"The Colorado on a Rampage."—At this time, the lower intake had been enlarged from a width of about 60 ft., as originally cut with the

* Really, the second serious attempt, Fig. 14.

dredger, to a width of possibly 150 ft., and it did not then seem probable that the Colorado River would turn its entire flow through the cut, but as the waters of the river began to fall, the banks of the intake began to cave and run into the canal, the banks of the canal below the intake fell in and, as known by most of the residents of the valley, the entire river began running through the canal and into the Salton Sea in the month of August of this year of 1905."

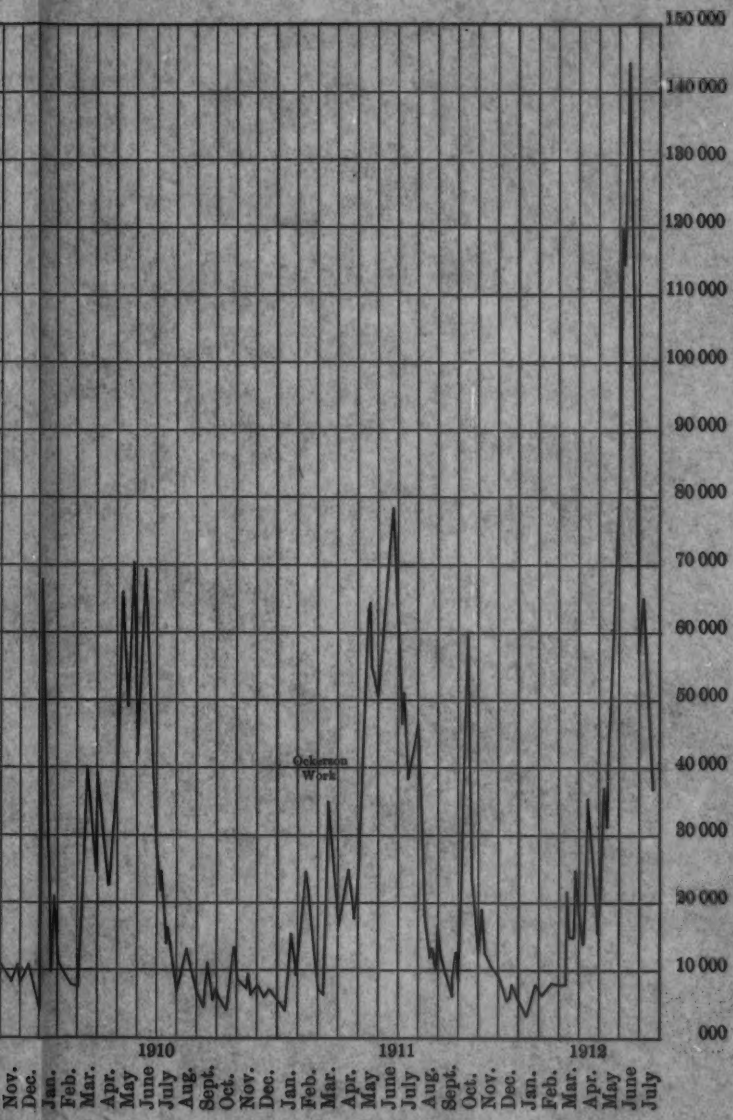


Plate XLVII shows the discharge at Yuma to have been an unprecedented sequence of floods from the Gila water-shed. Indeed, the precipitation throughout all that region traversed by the Southern Pacific line from Yuma to very near El Paso during this period was quite without precedent. Track ballasted with local material, which had always proved satisfactory, was during this year the despair of the entire Maintenance of Way Department, and for months trains were allowed to go over it only at half speed and with lurchings of the coaches and Pullman sleepers like ships at sea.

Mr. Rockwood's statement gives a very fair presentation of the matter as he viewed it. The writer is perhaps as well aware as any one that the river was diverted through this cut into the Salton Sea, and when he first inspected the situation in August, 1905, he felt, like practically all other engineers who gave the matter cursory consideration, that making this cut was a blunder so serious as to be "practically criminal." After 4 years of more or less bitter experience with the region, he is perfectly convinced that, matters having gotten into such condition, making the cut was absolutely imperative and by all means should have been done. The difficulty had not been any tendency whatever to divert the entire river, but—very much to the contrary—to induce enough water to go that way. Up to that time, a head-gate to prevent too great a quantity of water from entering the canals was of far less importance than some means of maintaining their carrying capacity. That a head-gate should have been provided is, of course, self-evident. It would have been utter folly, however, to have put a flash-board gate of any type directly in the diverting channel, because of the drift which would have accumulated against it. Nothing less than a structure containing immense openings could have been used without insuring that the cut would be choked up. This type of construction was practically unused in western irrigation works at the time, and would have cost a great deal of money, therefore, considering the financial condition of the C. D. Co., it is plain that the only

PLATE XLVII.
TRANS. AM. SOC. CIV. ENGRS.
VOL. LXXVI, No. 1270.
CORY ON
IRRIGATION AND RIVER CONTROL,
COLORADO RIVER DELTA.

practical thing would have been a gate, not in the cut itself, but in a by-pass, and built with the idea of closing the by-pass on the approach of the summer floods and using this gate as much as possible. It was not alone the straitened financial condition of the C. D. Co. and the situation generally in which it found itself which resulted in there being no permanent diversion works put in; two other important factors entered. The first was the practical change of management, from a construction point of view especially, to the Chaffeys in the summer of 1900; back to Mr. Rockwood in February, 1902, and internal difficulties in the C. D. Co. late in 1904. The second—indirectly connected with the first—was the hesitancy of the management to provide permanent head-works before the technical men in the corporation had agreed as to what the situation demanded. The real mistake was not in "putting all the eggs in one basket," but in not "then watching that basket." Obviously, no one could be responsible for doing such a thing without realizing the need for watching it most carefully and being fully prepared to take most aggressive action should occasion arise.

Southern Pacific Loan.

Early in January, 1905, it occurred to the management of the C. D. Co. that the phenomenal development of traffic furnished to the Southern Pacific Railroad by the Imperial Valley warranted the hope of financial assistance from that corporation. Mr. Julius Kruttschnitt, Director of Maintenance and Operation of the Harriman Lines, declined to consider the proposition, but Mr. Harriman, on being approached, was at once interested and ordered an investigation and report. As a final result, the Southern Pacific Company agreed to loan $200 000 on condition that 6 300 shares of the capital stock be placed in the hands of a trustee to be named by the Southern Pacific Company until the loan should be repaid, and taking over the management of the property until that time. Accepting a loan under such conditions was seriously objected to by a large part of the company's stockholders, but at the annual meeting in Jersey City, in May, a board was elected pledged to the arrangement. On June 20th, 1905, the Southern Pacific Company took over the management of the property, with Mr. Epes Randolph, President of the Associated Harriman Lines in Arizona and Mexico, as President, and

Mr. W. J. Doran, of Los Angeles, as the trustee mentioned in the contract. Both these gentlemen are still acting in these respective capacities. When the loan was arranged, and even when it was finally consummated, the railroad officials in San Francisco and the East did not consider the conditions along the river worthy of serious concern.

Mr. Rockwood was retained temporarily as Assistant General Manager and Chief Engineer, as members of the Southern Pacific management were entirely unfamiliar with the affairs of the C. D. Co.

Third Attempt to Close the Break.

As soon as the summer flood of 1905 began to recede, work was started. Immediately opposite the lower intake was an island, later dubbed Disaster Island, about $\frac{5}{8}$ mile long and $\frac{1}{4}$ mile wide, consisting really of a sand bar on which quite a growth of cottonwood and arrow weed had accumulated. A line of piling, 12 ft. from center to center, was driven from the upper end of this island to the Mexican shore, as shown in Fig. 15, and between this piling was woven barbed wire and brush. The theory behind this work was that, by spreading over a great width the water passing down the west channel and into the lower intake, a sand bar would be created, thus choking off the flow and gradually forcing all the water into the east channel. On July 15th about one-third of the river flow was going down the old channel and two-thirds toward the Salton Sea, and the result of this endeavor was still problematical. By August 1st a bar, approximately 2 800 ft. long, had been formed, but there was an opening, approximately 125 ft. long, through which the rush of water was too great to be controlled with the means at hand, and the work was abandoned. Up to this date, about $30 000 had been expended on the foregoing endeavors to close the break.

Various Suggestions for Handling the Situation.

At this time it was evident to all that the low-water flow of the Colorado would be entirely diverted into the old Alamo overflow channel and thence to the Salton Sea. The elevation of the water surface at the head of Disaster Island, with a flow in the river of 10 000 sec-ft., was approximately 100 ft., while the bottom of the Salton Sea is approximately — 287 ft., making the total fall in that direction 387 ft. The distance was about 95 miles by the watercourses, so that the average fall was 4.01 ft. per mile. Toward the Gulf the fall was 100 ft., and the distance to

tide-water was approximately 80 miles, or a fall of 1.25 ft. per mile. The continually diminishing quantity of silty water going down the old channel as the summer flood receded was constantly raising the bed along that direction, the action being rapid enough to be noticeable almost daily. In all probability there were about 6 months ahead during which the flow of the water would be low, and before this period should elapse the river must be re-diverted or the consequences would be most serious.

The plant and the salt deposits of the New Liverpool Salt Company in the bed of the Salton Sea were already entirely submerged, the water covering about 100 000 acres, with a maximum depth of about 16 ft. Except for the increase of depth and the consequent increase in the length of time this property would be shut down, no additional damage was really being done at this point. Indeed, 14 years earlier, this property was covered to a depth of 6 ft. by the great flood of February, 1891, and the summer flood following, and in all probability a similar and greater inundation would have resulted from the excessive floods during the spring and summer of 1905 had the C. D. Co. never constructed any works along the river. The rising waters of the Salton Sea were threatening the tracks of the Southern Pacific Railroad along the east side of the sink, and the officials of the Los Angeles Division were clamoring for aggressive action. The higher officials of the company, however, were not yet very much perturbed. On the other hand, the Alamo channel was being enlarged and deepened, to the very great benefit of the C. D. Co., and the irrigation system of Imperial Valley, because the insufficient carrying capacity of this channel and the heavy silt deposits therein constituted a serious menace to the entire project.

To close the lower intake entirely meant obtaining all the water required for the irrigation of Imperial Valley through the 4 miles of badly silted Main Canal lying between it and the upper intakes, and this was out of the question. Even with large sums of money, which might be obtainable from the Southern Pacific interests, machinery could not have been bought, assembled, and put into operation in time to have permitted the delivery of more than enough water to supply the inhabitants and live stock of the valley with drinking water if the river flow should be reduced to 6 000 or 7 000 sec-ft. Imperial Valley at that time consisted of at least 125 000 acres under cultivation, five

towns with an aggregate population of 2 500 people, and a rural population of approximately three times that number. There were, perhaps, 100 000 head of hogs, 50 000 head of cattle, and other live stock in proportion.

Many plans were suggested, from this time, August 1st, 1905, until the break was finally closed in 1907. Many of these, of course, were thoroughly absurd, and came from cranks and people who had not the faintest conception of the conditions. Indeed, almost the only people who appeared to be able to see that the problem was not merely one of shutting off the lower intake were the engineers of the C. D. Co. and a few of the well-informed men in Imperial Valley. Representatives of the New Liverpool Salt Company, the Southern Pacific Company, various departments of the United States and Mexican Governments, and the general public, all joined in demanding aggressive action to stop the menace of a new Salton Sea.

Such suggestions were addressed to Mr. Harriman and to nearly every other official of the Southern Pacific interests, and to Mr. Randolph and other authorities of the C. D. Co. Ultimately, most of these found their way to the writer; they constitute a most interesting collection. It is not profitable to mention more than four of these suggestions, which may be designated the Laguna Weir Plan, the Concrete Head-gate Plan, the Rockwood Head-gate Plan, and the Barrier Dam Plan. Edwin Duryea, Jr., M. Am. Soc. C. E., also offered to close the break according to a plan, which, however, he declined to outline.

The Laguna Weir Plan.—The Laguna Weir Plan consisted in abandoning operations for the time being at the scene of the break; concentrating all efforts on the completion, at the earliest possible date, of the Laguna Weir, which was being built by the U. S. Reclamation Service; building a canal thence passing Pilot Knob and intersecting the break from ½ to ¾ mile west of the Colorado River, this canal to have a capacity equal to the low-water flow of the river; then diverting all the river water through this canal; finally, to build a dam across the intake between the canal junction and the river bank in still water. The Laguna Weir was actually completed in the early spring of 1909, just before the annual record flood of that year. It is not clear just how its completion could have been essentially hurried. Had this plan been followed, the Colorado would have emptied into the Salton

Sea for 3 years longer than it actually did, and during this time 55 000 000 acre-ft. of water went by Yuma, only a very small portion of which would have gone down the old channel to the Gulf. This would have raised the water in the Salton Sea to the 180-ft. contour, with the effect of drowning out a large area of cultivated land in the Coachella Valley and forcing the abandonment of 60 miles of main line track by the Southern Pacific Railroad.

These effects, however, would have been of relatively minor importance. The irrigation system of Imperial Valley would have been strained far beyond the breaking point in several places, while the cutting back in New River would unquestionably have reached the Alamo channel and lowered the water therein far beyond the point where any could have been gotten into the Imperial Valley by gravity. This, of course, would have meant the depopulation of that region, an appalling result, without parallel in history.

The Laguna Weir Plan is thus seen to have been impracticable, and no one actually connected with the work gave it serious consideration. Nevertheless, Director Walcott, of the U. S. Geological Survey, who was a close personal friend of Mr. Harriman, strongly advised it, and Mr. Harriman almost insisted upon it for quite a time.

Concrete Head-gate Plan.—The Concrete Head-gate Plan was put forward by the late James D. Schuyler, M. Am. Soc. C. E., who acted as Consulting Engineer of the C. D. Co. from July, 1905, to June, 1906. It consisted essentially of building a reinforced concrete and steel head-gate on the Pilot Knob site, where solid rock foundation could be secured, such gate to be able to carry the low-water flow of the river; and then, from this head-gate down to its junction with the crevasse, to enlarge the canal to a similar capacity. This, it was considered, would permit the diversion of all the water through the head-gate and canal, leaving the river below, and consequently the break itself, dry. The underlying idea was somewhat similar to that of the Laguna Weir Plan, except that it contemplated only 4 miles of canal enlargement and a diversion structure which could be completed in 3 or 4 months, instead of 3 years.

This plan involved the construction of permanent head-gates on rock foundation at Pilot Knob, so long contemplated; and the construction and equipment of a dredge with which the requisite 4 miles of canal could be dug economically and quickly. The idea was adopted

in a tentative way in September, 1905, approximately 90 days after the Southern Pacific Company undertook the management of the C. D. Co., and Mr. Schuyler was instructed to proceed with the preparation of plans for the head-gate, while Mr. F. S. Edinger, under whose direction the Edinger Dam was built, arranged for the dredge. At the suggestion of the Golden State and Miners Iron Works, of San Francisco, the clam-shell type, with 150-ft. boom and 5-cu. yd. bucket, was selected. Work was begun on the concrete head-gate on December 15th, 1905, and contracts for the clam-shell dredge were arranged a few weeks later.

One of the chief recommendations of this plan was that the constructions, in large measure, would be permanent. It was assumed that, while perhaps the maximum quantity of water which would have to be diverted for the irrigation of Imperial Valley would never exceed 5 000 sec-ft., a gate twice as large would not have any particular disadvantages in its maintenance or operation. It was urged, further, that this arrangement of diverting structure and large canal would be available in case of future breaks, should any ever occur.

The difficulty about the plan was that, regardless of the size of the gate, enlarging the 4 miles of canal to carry 10 000 sec-ft. within sufficient time to afford reasonable relief was a very serious problem, while the capacity of this canal would be reduced so quickly by silt deposition that its use in case of future breaks would be out of the question. Furthermore, to insure the diversion of all the water in the river, required a canal cut considerably below the water-table in the ground through which it would have to pass, and large patches of quicksand occur so frequently in this region that it would be folly to hope to miss all of them. Such patches would cause the inflow of material from the sides and the bottom to a serious extent.

Mr. Rockwood's Plan.—Mr. Rockwood urged the necessity of a rapid re-diversion, not so much because of the effect on the Southern Pacific tracks along the Salton Basin as because he understood the critical condition at a number of points in the irrigation system of Imperial Valley, and that the severe strain could not be withstood successfully for very many months. His suggestion, made in August, 1905, was to put in, immediately beside the break, a wooden **A**-frame, flash-board head-gate, capable of passing the low-water flow of the river; with dredges to dig channels from the break to the gate both above

and below; divert the water through this by-pass and gate with a piling-brush-sandbag barrier dam; complete the dam as an earth fill across the break, and build levees both up and down stream as far as might be necessary; then close the gate to such an extent as would admit only enough water to supply the irrigation needs. This plan was approved, and work was started on September 20th. It was abandoned completely 3 weeks later; was again approved on December 15th, 1905; and was carried out until the gate construction failed, in October, 1906. It was daring only in its size and the foundation of so important a structure on alluvial soil, and it would have resulted in permanent diversion works on Mexican soil—where, by all means, they should have been, originally, and as contemplated in the Mexican concession, granted in 1904.

The Barrier Dam Plan.—The Barrier Dam Plan consisted in throwing a barrier dam of some sort across the crevasse and raising the water surface above it sufficiently high to throw all the discharge of the river down the old channel to the Gulf. The usual type of dam suggested was of piling and brush mattresses of fascines weighted down by sandbags. This method seemed to its proponents to afford opportunity for decreasing the quantity of water diverted in the minimum time, and neglected that side of the problem which required the furnishing of water for the Imperial Valley. The best plan for a structure of this type was that put forward by Mr. Edinger, and worked on under his direction from early in October until its destruction by the great flood of November 29th, 1905.

Fourth Attempt to Close the Crevasse.

Mr. Rockwood presented his plan to Mr. Randolph and Mr. Schuyler, and they, as well as several engineers of the Southern Pacific Company, approved of its trial. Plans were hurriedly worked out for a wooden A-frame, flash-board gate, 120 ft. long, with a concrete floor, and founded on piles. Rush orders for materials were placed, and the first shipments left Los Angeles on August 7th. It was fully expected to have the structure completed by November 15th.

The original intention was to construct the gate in a by-pass to be excavated by the dredge *Alpha* on the south side of the intake, but examination showed an unfavorable foundation, as the ground slid into the cut so rapidly that the dredge was almost caught and held by it. The plans, therefore, were changed, and it was decided to construct

a by-pass on the other side of the break; force all the water through this by-pass; and then build the structure where the intake had been, thus saving both time and money in the excavation. The break at this point was about 300 ft. wide—just about the length of excavation required for rapid and successful construction. The dredge was put to work on this by-pass, and no difficulty whatever was found in making the 700-ft. cut required. The plan worked very well, and a large part of the water began to go that way at once. Work was begun on the up-stream side of the coffer-dam, the idea being that, when all the water was diverted through the by-pass, another earthen dike would be thrown in, about 250 ft. below the first, and thus make the coffer-dam for the gate construction. In this way, the second dam would be built in still water and in very short order with the dredge.

At this time—about September 15th—it became evident to Mr. Rockwood that he could not attend to the business affairs of the company properly and remain in personal charge of the work along the river. It seemed easier to find some one capable of completing the gate in accordance with the plans outlined than to find any one qualified to handle the corporation's affairs. Mr. F. S. Edinger was selected, as he, until June, 1905, had been for many years Superintendent of Bridges of the Southern Pacific System, and had had very large experience in coffer-dam work. About 3 months previously he had left the Southern Pacific Company and entered the contracting firm of Shattuck and Desmond, of Los Angeles and San Francisco. About September 20th, Mr. Edinger and Mr. Rockwood went over the ground and the plans together, and Mr. Edinger commenced the work.

The records show that, about October 1st, the river usually rises 2 or 3 ft., principally due to rains on the water-shed of the Gila River and Bill Williams Fork. This year was no exception, and the slight rise about October 1st shook Mr. Edinger's confidence in the plan. He quickly outlined a barrier dam plan to Mr. Randolph, who approved of it, and work was shifted to it at once. This plan consisted of constructing a piling and brush dam across the west channel between the head of Disaster Island and the Mexican shore, a distance of about 600 ft., and it was expected that the river would all be turned down the east channel before a gate could even be put in. All material was at once removed from the gate site, and work was rushed on the construction of what is locally known as the Edinger Dam.

FIG. 20.—EDINGER DAM, NOVEMBER 8TH, 1905. BRUSH AND WIRE MAT IN FOREGROUND, READY TO BE PLACED.

FIG. 19.—ROCKBANK BEAR-CAVE, OCTOBER 6TH, 1903. PASSING 12,000 SEASONS THERE.

FIG. 20.—ROCKBANK BEAR, NOVEMBER 8TH, 1903. BROWN AND WHITE MAT IN PROCESSIONING, READY TO BE PLACING.

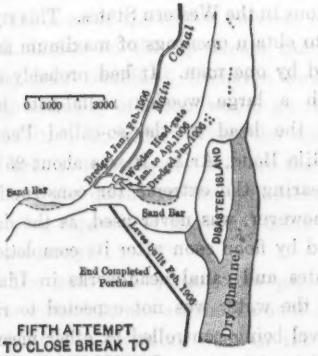
This plan of handling the situation, in addition to shutting off all water flowing into the Imperial Valley through the lower intake, was seriously defective in that even a short flood sufficiently great to send any water overbank in the immediate vicinity of the dam—and that would require much less water than usual on account of the silted-up condition of the whole river bed below the break—would in a few hours result in cutting a channel around the end of the structure and entirely shunting it. Indeed, such a re-diversion was exactly what took place a little more than a year later, when the waters broke under the levee, ½ mile south of the Hind Dam, in December, 1906. Had the Edinger Dam been entirely successful and completed on November 15th, such re-diversion would have been caused by the terrific flood of November 28th, and so on; the hydrograph, Plate XLVII, shows a number of floods sufficiently great to have done this. Indeed, at this time, no one seems to have realized that a large, deep, and efficient channel had been created from the Lower Heading westward for many miles, and that future safety demanded, not only closing the intake, but an elaborate system of levees reaching miles both up and down stream.

The plan of the Edinger Dam consisted in driving rows of piling and filling the interstices with brush mattresses and fascines. The idea behind it was essentially similar to that of the work abandoned about August 1st. To have been successful, the construction would have had to withstand a head of from 8 to 10 ft. However, on November 29th, when a head of 35 in. had been obtained, a terrific flood came down from the Gila, reaching a gauge height of 31.3 ft. at Yuma and a discharge of 115 000 sec-ft. Large quantities of drift were carried by the flood-waters. This drift collected against the Edinger Dam in great quantities, and a large volume of water went down the east side of the island and the old channel. Before the flood had reached its peak, the dam started to give way, and in an incredibly short time was practically destroyed. When the river had again fallen, the old channel was silted up higher than before, the new channel was scoured still deeper, and when the flow of the river had decreased to 17 500 sec-ft. all the water was again going toward the Salton Sea.

The flood not only wrecked the dam, but carried away practically all the material on the ground, and, after it receded, side-cutting along the west side of Disaster Island began to take it away rapidly. It was soon obvious that it would be folly to resume work at that location,

and it was decided that the piling-brush-sandbag barrier dam method was not to be given further consideration.

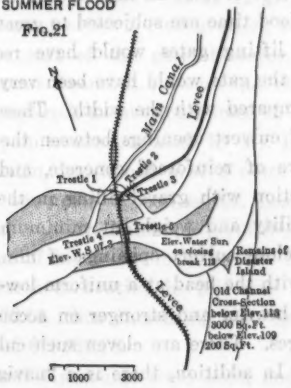
So much water went through the break to the valley, at the failure of this dam, that the *Alpha* was sent to the Quail River and put to work cutting a channel southward in the hope of diverting a large part of the flow into the Paredones and thence *via* Volcano Lake into the Gulf. It was an endeavor to divert a large part of the water from an old overflow channel on the north side of the delta cone into an overflow channel on the south side thereof. It had little result, however, and the Quail River cut soon closed itself.



On October 15th there were 20 white men and 25 Indians at work on the Edinger Dam; on November 1st, 42 white men and 50 Indians; on November 10th, 106 white men and 65 Indians, and on November 29th, 250 white men and 80 Indians. Two steamboats with barges attached, and the relatively large barge, *Silas J. Lewis*, with their crews, were also at work.

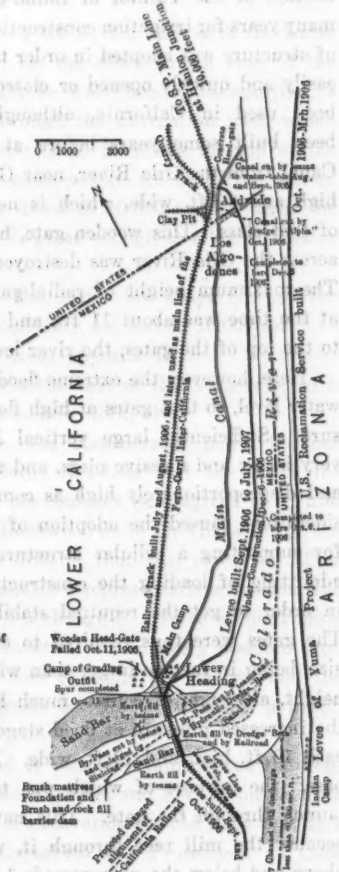
On the books of the company, the cost of the Edinger Dam is not thoroughly segregated from the expense incurred in the head-gate work up to the time of its abandonment for the barrier dam plan. The expenditures on it, however, were about $60 000, and the grand total to December 1st, 1905, was about $100 000.

Fifth Attempt to Close the Crevasse.



It was decided to work simultaneously on the Concrete Head-gate plan and the Rockwood plan, which was done.

Concrete Head-gate.—The location of this interesting structure is shown on Fig. 22, where the granite point of Pilot Knob is near the right bank of the river. The general design was outlined by Mr. Schuyler, and the principles used, dimensions, elevations of flow, etc., were submitted to Messrs. Rockwood and Randolph, and approved by them. George S. Binckley, M. Am. Soc. C. E., then worked out the details and prepared the working drawings. Contracts for the structural steel and ironwork were let to the Llewellyn Iron Works, of Los Angeles, and for the construction work to Mr. Carl Leonardt, also of Los Angeles, on November 25th, 1905. Time was made the essence of the contract, and Mr. Leonardt hurried the necessary equipment to the ground and began actual work 2 weeks later. Although it was expected to complete the gate ready for use within 90 days, the entire job was not finished until June 28th, 1906.



FIFTH ATTEMPT TO CLOSE BREAK TO APRIL 15, 1906-BEGINING OF SUMMER FLOOD

FIG. 22

Type and Size.—The intake gate is doubtless the largest and most expensive irrigation canal head-gate in America. The design is a modification of the Taintor or radial-gate type, which has been used for many years for irrigation constructions in the Western States. This style of structure was adopted in order to obtain openings of maximum area easily and quickly opened or closed by one man. It had probably not been used in California, although a large wooden radial-gate had been built some years before at the head of the so-called Peoria Canal from the Gila River, near Gila Bend, Ariz. It was about 25 ft. high and 30 ft. wide, which is nearing the extreme for construction of that class. This wooden gate, however, was never used, as the dam across the Gila River was destroyed by flood soon after its completion. The maximum height of radial-gates and canal head-works in Idaho at the time was about 11 ft., and the water was not expected to rise to the top of the gates, the river level being controlled by other means.

Here, however, the extreme flood level is 19 ft. higher than the low-water level, so that gates at high flood time are subjected to great pressure. Sufficiently large vertical lifting gates would have required very heavy and massive piers, and the gate would have been very large and disproportionately high as compared with the width. These considerations caused the adoption of culvert openings between the piers for supporting a cellular structure of reinforced concrete, and thus admitting of loading the construction with gravel filling in the cells in order to get the required stability and weight at minimum cost. The gates were thus required to close culvert openings of minimum size, being in fact no larger than with the head at a uniform low-water height, although, of course, much heavier and stronger on account of the increased pressure at flood stages. There are eleven such culverts, each 10 ft. high and 12 ft. wide. In addition, there is a "navigation pass," the purpose of which was to permit passing a small gasoline launch through the gate. This navigation pass is practically useless because the mill race through it, when the difference in water level above and below the gate exceeds 1 ft., precludes the idea of dragging a boat through it; indeed, no attempt has ever been made to use it. The floor of the gate is 98 ft. above sea level, according to the C. D. Co. datum, and 100.9 ft. according to the U. S. Reclamation Service datum. At the time, and until after the summer flood of 1909, the average low-water surface in the river was about 108 ft. The elevation

of the flow line at the gate, therefore, was fixed so that the culverts would run full at low-water stage. The present low-water surface is about 105 ft.

The area of the eleven culverts is 1 320 sq. ft., and, with the water 1 ft. higher on the up-stream than on the down-stream side of the gate, their combined discharge would be 8 500 sec-ft. In addition, a large quantity of water would go through the navigation pass, which is 10 ft. 3 in. wide. When the water is 10 ft. above the top of the culverts, it is necessary to close the gates within 3.8 ft. of the bottom to hold the discharge through them down to 10 000 sec-ft., when the carrying capacity of the canal below is great enough to allow the water to get away.

The gate was designed to pass the entire low-water flow of the river—which it was assumed would certainly not exceed 10 000 sec-ft.—without any diverting dam in the river opposite it.

Cost of Structure.—Table 12 gives the cost of this structure, with the contract prices for excavation, concrete work, etc.

The cost of the gate, however, was considerably more, because Contractor Leonardt presented a claim, insisting that the prices for earth and rock excavation named in his contract were agreed to by him on certain assurances made by Mr. Rockwood as to the character of the excavation, which had proved more difficult than was expected. This claim was made as soon as Mr. Leonardt's representatives reached the ground, and Mr. Randolph permitted a change to a force account basis because of his desire to hurry the construction in every possible way. The earth excavation in this way cost 64 cents per cu. yd. and the rock $2.06, thus increasing the figures by $10 813, making a grand total of $55 221.08.

Careful accounts were kept, and it was ascertained that the contractor made a profit of $2 700 on the concrete, and $741.50 on erecting the gates. What the earth and rock excavation should have cost is a matter of some, though slight, interest to the Profession, as these would necessarily vary according to local conditions. As a matter of fact, with a good pumping plant, a mining nozzle or giant, a hydraulic elevator, and some pipe, the earth excavation could probably have been handled for 20 cents per cu. yd., and possibly less. Much of the rock was fairly soft, and could have been worked easily and cheaply, so that, had the contractor put in power drills and one or two long-

boom derricks to handle the rock out of the cut, it is probable that the cost of such excavation would not have exceeded the contract price. The quantity of water entering the coffer-dam, or rather excavation pit, was surprisingly small.

TABLE 12.

Gate Structure.	
Earth excavation, 12 637.1 cu. yd. at $0.25	$3 159.28
Rock excavation, 5 700.81 cu. yd. at $1.00	5 700.81
Cement, furnished by company, 1 335 bbl. (Olsen, Gillingham, and Independence brands)	4 432.25
Concrete, labor, forms, sand, gravel, and rock, 1 204.83 cu. yd. at $9.00	10 843.47
Reinforcing steel bars, 25 722 lb. at 4 cents	1 965.16
Expanded metal for gate facings, 791 lb. at 4 cents	31.64
Allowance for 3 days' delay to contractor	102.50
Extras	807.07
	$27 042.18
Charges against contractor	271.70
Total cost of gate structure	$26 770.48
Iron and Steel Work for Gate.	
Llewellyn Iron Works' original contract for twelve radial gates and one slide-gate (in navigation pass) f. o. b. Los Angeles	$12 000.00
Freight to Yuma, on 212 184 lb. metal in aforesaid gates at $1.25 per ton	132.60
Regulating levers, shaft, and gear (subsequent contract)	580.00
Erection of gates (Leonardt's contract)	1 500.00
Total cost of iron and steel work	$14 812.60
Plans, engineering, and superintendence, 6.7%	2 825.00
Total cost of head-works	$44 408.08

Fig. 26 gives a plan and elevation of this gate, and Figs. 24 and 25 are views of the structure.

Purpose.—At the time this gate was designed, the money available for construction, through the Southern Pacific's connection and the loan of $200 000, justified the immediate construction of permanent head-works, indeed, building this and the Alamo Waste-gate were the chief items for which the loan was made. Furthermore, the entire diversion of the river at the lower intake had shown the folly of trying to get along without them. The gate, while intended as a permanent diverting structure, was, nevertheless, primarily designed for use in endeavoring to re-divert the river; otherwise, of course, it

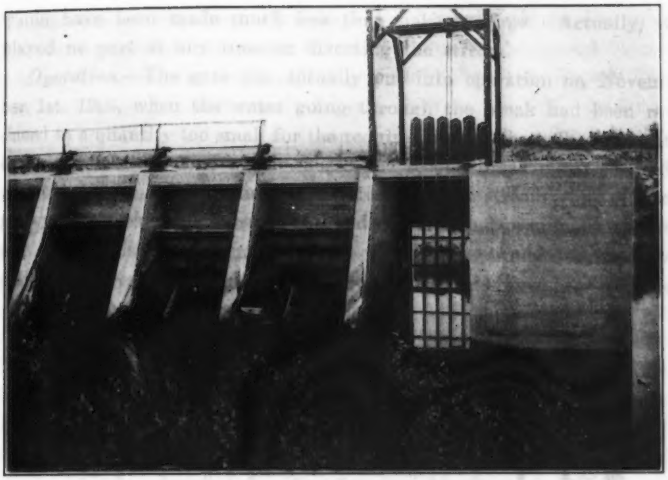

FIG. 24.—CONCRETE HEAD-GATE, JULY 10TH, 1906, SHOWING DETAILS OF GATES, NAVIGATION PASS, AND GATE AND ABUTMENT AT RIVER END.

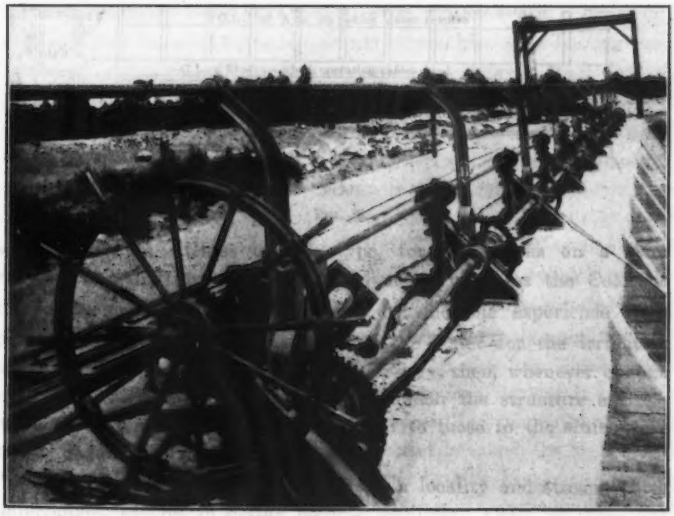

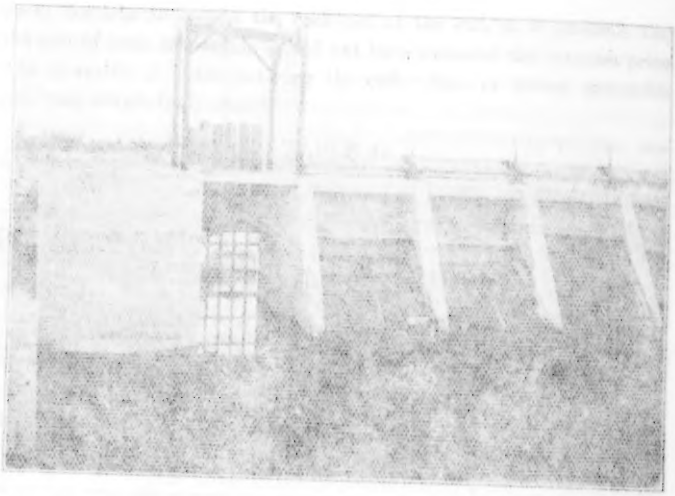

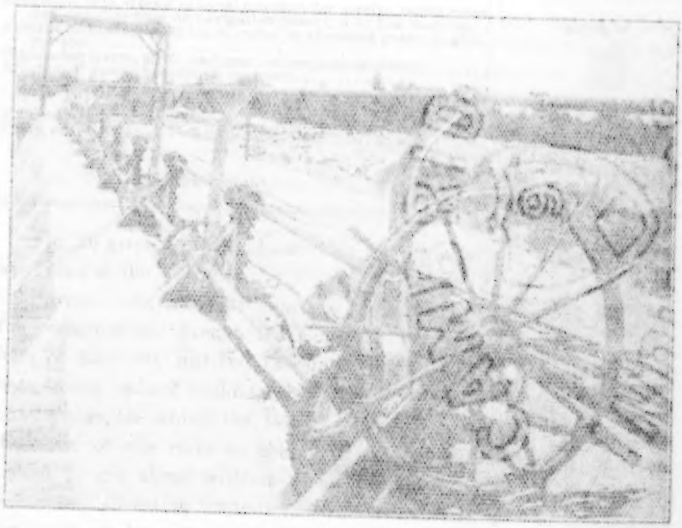

FIG. 25.—GATE RAISING MECHANISM OF CONCRETE HEAD-GATE.

would have been made much less than half as large. Actually, it played no part at any time in diverting the stream.

Operation.—The gate was actually put into operation on November 1st, 1906, when the water going through the break had been reduced to a quantity too small for the requirements of the valley. About 6 weeks later, the flood which caused the second break occurred, and resulted in an accumulation of drift on the up-stream side of the gate which choked up the underground culverts and practically put it out of commission. From that date to this the troubles caused by drift in the river, particularly at high-water periods, have been serious

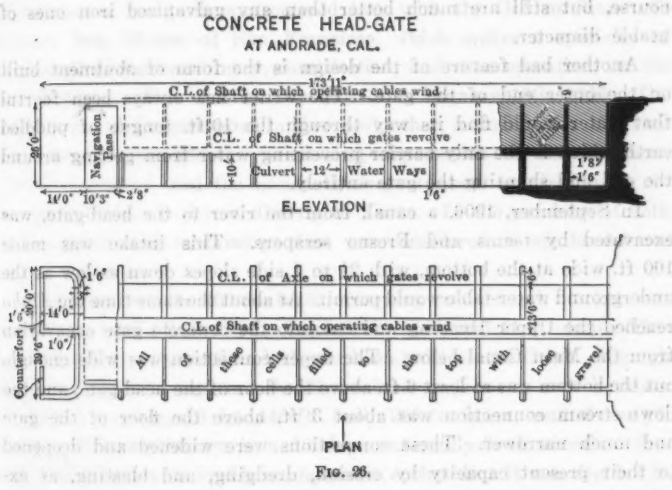

FIG. 26.

and often acute. Gates of this type, for head-works on a river carrying any drift to speak of, let alone as much as the Colorado often has, should be avoided. After considerable experience it is obvious that if permanent diversion of the water for the irrigation of the valley is not made on Mexican territory, then, whenever enough money is available, it will be best to abandon the structure entirely and make diversion through gates similar to those in the sluice-ways of the Laguna Weir.

Aside from the type of gate for such a locality and stream, three unfortunate features in design became manifest. Chief of these was the fault that the drums on which the wire cables for raising the

gates are wound are much too small. The gates themselves were designed for minimum weight with the necessary strength, and are not stiff enough, so that they tend to wedge unless exceedingly great care is taken. The net result is many broken cables. At one time only two of the eleven gates were in operation, some being clear down, some clear up, and some impossible to close entirely on account of driftwood under them. Fortunately, the *Delta* was near by and was used to raise the gates, so that new and strong plow-steel cables could be installed, replacing the original ones of Tobin bronze, ¾ in. in diameter, 19 wires to the strand. These plain steel cables corrode badly, of course, but still are much better than any galvanized iron ones of usable diameter.

Another bad feature of the design is the form of abutment built on the outer end of the gate. The writer has always been fearful that water would find its way through the 10-ft. tongue of puddled earth which is the only barrier preventing water from getting around the end and shunting the gate entirely.

In September, 1906, a canal, from the river to the head-gate, was excavated by teams and Fresno scrapers. This intake was made 100 ft. wide at the bottom, with 2½ to 1 side slopes down as low as the underground water-table would permit. At about the same time the *Alpha* reached the Upper Heading and cut into the concrete gate excavation from the Main Canal below. The upper connection was wide enough, but the bottom was at least 6 ft. above the floor of the head-gate, and the down-stream connection was about 3 ft. above the floor of the gate and much narrower. These connections were widened and deepened to their present capacity by erosion, dredging, and blasting, as explained later.

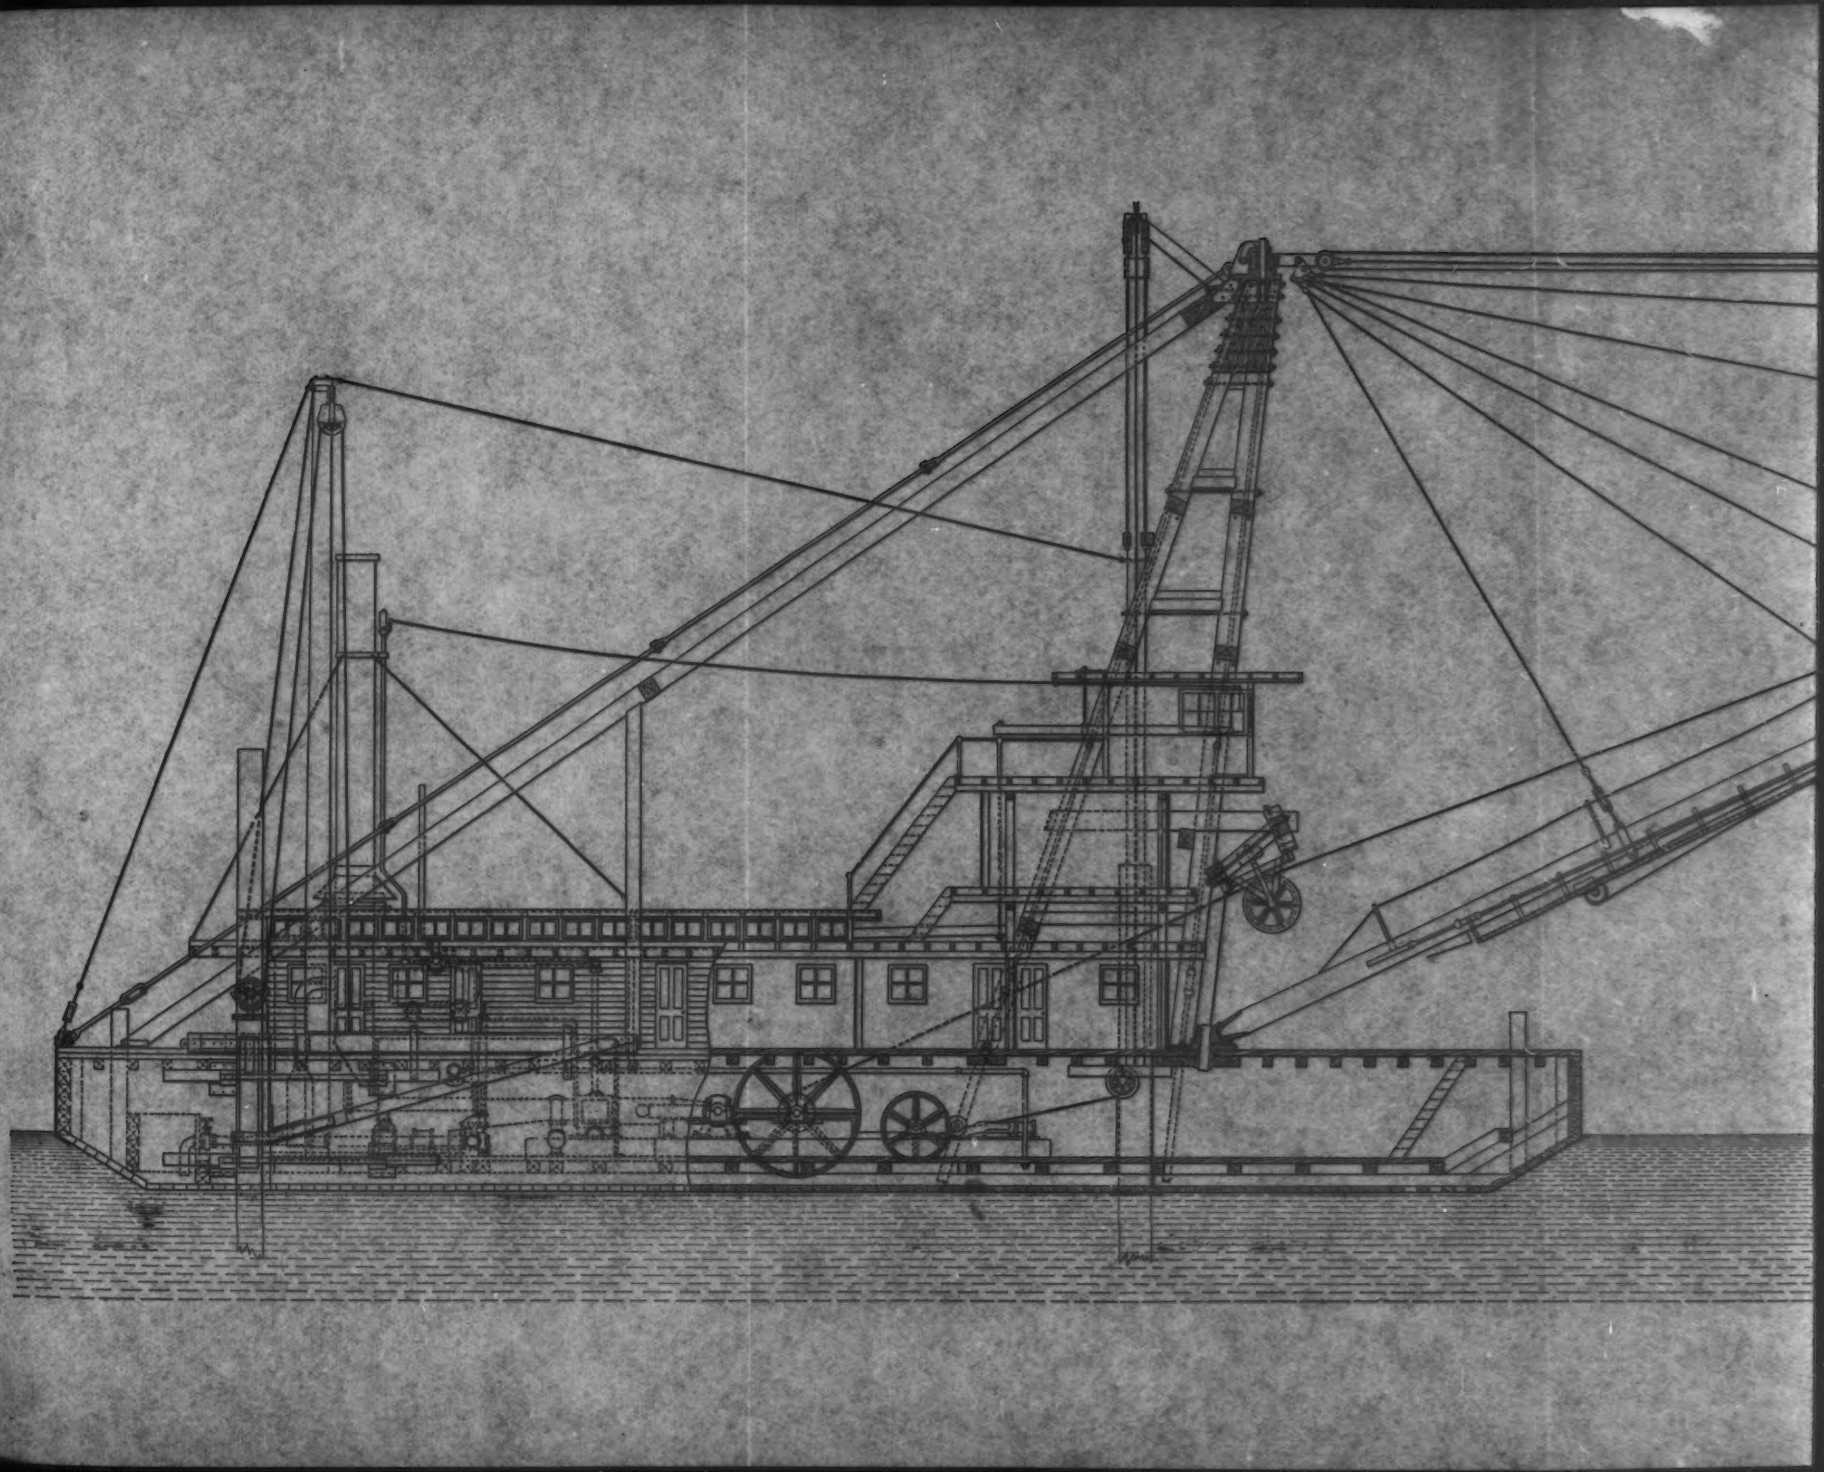
The Dredge, Delta.—The other element in the concrete head-gate plan of re-diversion was a canal from the head-gate to the break, a distance of approximately 4 miles. It was to be of sufficient size to carry the probable minimum flow of the river, 10 000 sec-ft. As it was obvious that this stretch of canal would have to be lower than the bed of the river all along the line, in order to permit of taking the entire low-water flow without a diversion dam in the river opposite the head-gate, a very large part of the cross-section to be excavated would be below the permanent water-table of the region. Therefore, some kind of excavating machinery which could handle large quantities of ma-

terial under water had to be provided. It was taken for granted that the cheapest and quickest method of providing this waterway was to enlarge the existing Main Canal, although the writer thinks this was erroneous. The dipper dredge, *Alpha*, by almost continuous operation in this part of the course, had built up levees on both banks so high as practically to limit its future operation without flattening down these levees with teams and scrapers. Largely on the advice of Mr. Edinger, it was decided to construct a clam-shell dredge of the type used almost exclusively for levee building along the Sacramento River. Accordingly, a contract for machinery, and for plans, bills of materials, etc., of the hull, was entered into with the Golden State and Miners Iron Works, of San Francisco, which makes a specialty of clam-shell dredge machinery, construction, and even operation, on the Pacific Coast. This contract was closed on January 10th, 1906. The 320 000 ft. of Oregon pine lumber and other materials for the hull were bought through the purchasing department of the Southern Pacific Company, and the unusually large timbers required were obtained in Oregon and sent directly to Yuma. In the purchase of both hull material and machinery, time was considered as of the essence of the contracts.

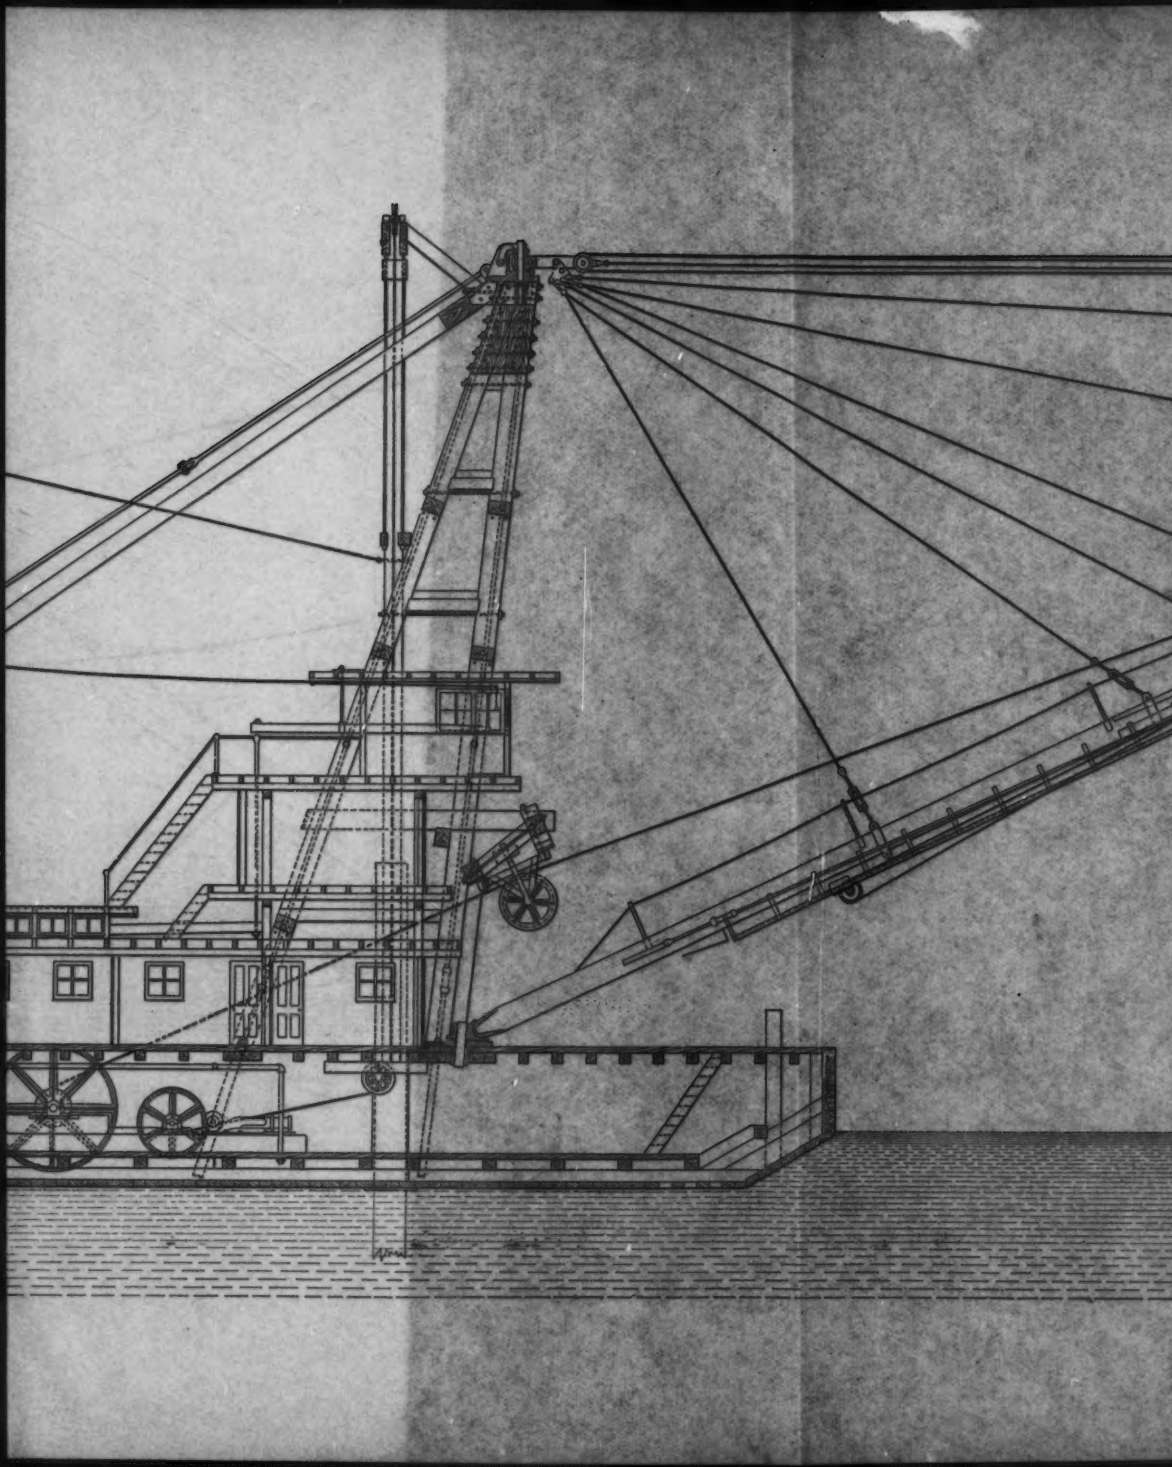
A dredge with a 150-ft. boom, carrying a 5-cu. yd. bucket was decided on, and a hull 120 ft. long, 54 ft. wide, and 11 ft. deep. This width was 2 ft. greater than had ever been built on the Coast, although the tendency is to increase the dimensions, and one is now building in San Francisco, 70 by 140-ft. hull, 205-ft. boom, and 6-cu. yd. bucket. The machinery is a 150-h.p., internally-fired, circular, fire-tube boiler, and a 20 by 24-in. engine on each side. It was decided to build the hull and erect the machinery at Yuma, and float the completed dredge down the river to the intake.

Lumber for the hull began arriving in Yuma late in January, and early in March the company was notified that all the machinery was ready at San Francisco for shipment. Mr. Edinger's connection with the company had ceased soon after the destruction of the Edinger Dam, and Mr. Rockwood had very little confidence in the feasibility of the concrete head-gate plan, or in the desirability or need for the clam-shell dredge, and felt that the great cost thereof would deplete seriously the $200 000 loaned by the Southern Pacific Company. Therefore, practically nothing was done in the matter, and so it came about

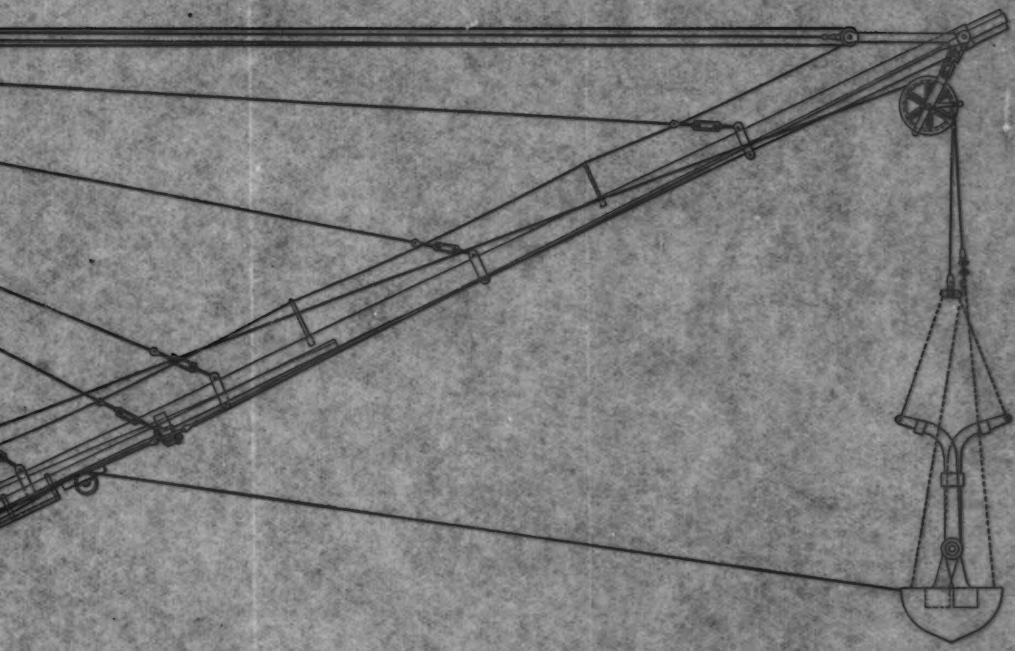
that the great conflagration in San Francisco, following the earthquake of April 18th, 1906, destroyed the plant of the Golden State and Miners Iron Works, in which all the machinery for this dredge was stored ready for shipment. Fortunately, the damage sustained by the apparatus was not extensive, and by May 15th, 1906, all the machinery had reached Yuma.



Mr. J. W. Brown, a member of the Golden State and Miners Iron Works Corporation, agreed to take charge of building the hull, and reached Yuma about May 1st, bringing with him a complete crew of mechanics and ship builders. Work was hurried, and with such success that the hull was launched about August 15th, the machinery was in place by the end of October, and the dredge weighed anchor and started down the river. At this time the river was getting low and some difficulty was encountered, but on November 26th, 1906, the clam-shell arrived at the mouth of the American intake. The total cost of the dredge, ready to start down the river, was almost $80 000, the cost of the machinery being $34 000, f. o. b. San Francisco. The weight of the craft is about 850 tons.



This dredge, Plate XLVIII, has been an invaluable piece of machinery to the C. D. Co. Had it been ready for use in August, 1905, the cost of doing the earthwork in the Hind Dam would have been wonderfully reduced. As it was, the dredge, after doing a little work in enlarging the intake above the concrete head-gate, was floated down and cut its way into the Main Canal following the upper Mexican intake. It was engaged on this work when the second break occurred, and continued thereon as though this latter event had not happened. Like the concrete head-gate, it played no part whatsoever in the rediversion of the river.



For the information of those who are not familiar with the results and cost of clam-shell dredge operation, the following data are given:

Operatives.

1	Captain	at $125 to $150	per	month,	and	board.
3	Levermen	" 85	"	"	"	"
2	Firemen	" 60	"	"	"	"
2	Deckhands	" 50	"	"	"	"

CLAM-SHELL DREDGE "DELTA"

FOR

CALIFORNIA DEVELOPMENT CO.

GOLDEN STATE AND MINERS IRON WORKS, BUILDERS.

SCALE OF FEET

0 5 10 15 20

Three shifts give a total of 22 hours actual work daily. The average time in operation, when proper repair work is done, is 28 days per month. When in good ground, and with side swings averaging 70° on each side, the time per bucketful is 40 sec. The quantity handled (varying according to the material) is from 3 to 8 cu. yd. as ordinary extremes. On the Sacramento River, under good conditions, 150 000 cu. yd. per month are handled.

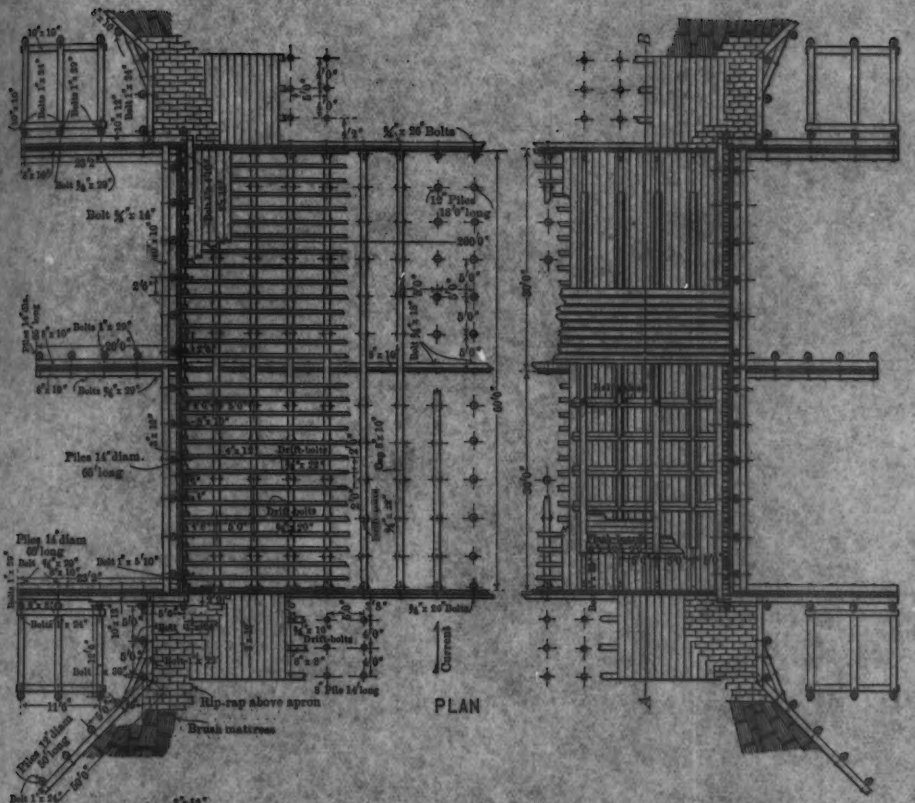
Monthly expense.

Maintenance and operation	$2 500
Interest on investment at 6%	400
Taxes and insurance	200
Deterioration	700
Sometimes as low as	$3 800

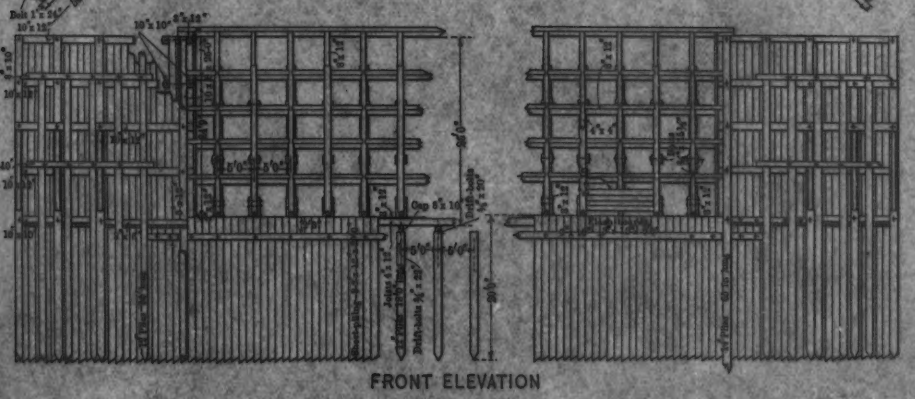
Ordinarily, the monthly expense in Mexico is $5 000. The average cost is 2¾ cents per cu. yd. The average cost of the work done by the *Delta* in Mexico is from 4 to 6 cents per cu. yd.

THE ROCKWOOD HEAD-GATE.

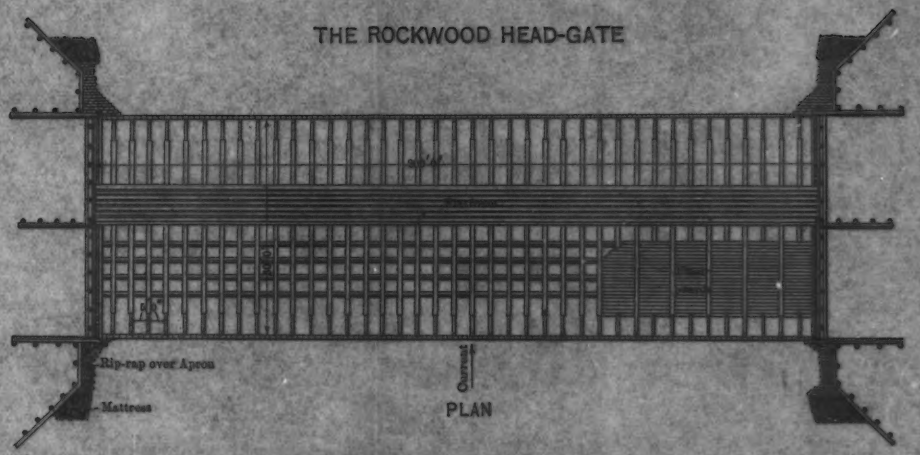
As already explained, it was decided to follow both Mr. Schuyler's and Mr. Rockwood's plans for diverting the river, and so, for the second time, on December 15th, 1905, Mr. Rockwood was authorized to proceed with the construction of a wooden head-gate beside the lower intake. The heavy flood of November 29th and its receding waters had widened the intake from 300 to approximately 600 ft., and, after considering the conditions, it was decided to build the gate directly in the old canal about 200 ft. north of the intake channel, in order to reduce the time and the quantity of excavation required, and to divert the relatively small quantity of water in the old canal around the gate with a by-pass to be dug by the *Alpha*. The gate, started and abandoned three months before, was originally planned for a width of 80 ft.; this was increased to 120 ft. in order to carry a maximum of 9 000 sec-ft. As the gate could not be completed until the spring of 1906, the length was extended to 200 ft. The over-all dimensions, including the wooden aprons, became 240 by 100 ft. The entire space, of course, had to be inclosed in a coffer-dam, and the excavation had to be made inside of it. The plans are shown on Plate XLIX.



As far as the writer has ever heard, this is the largest and most daring design ever made for a wooden A-frame, flash-board head-gate. Pile-driving was begun on January 7th, and the gate was completed on April 18th, 1906; the work was rushed day and night for the greater part of the time, and no real difficulties whatever were encountered. As in the case of the concrete head-gate, 4 miles above, the quantity of water seeping into the excavation was surprisingly small. The various items of the cost of this structure were not segregated, so that the details cannot be given, but the grand total expense of the gate proper, exclusive of the by-pass, was approximately $122 500.



The discharge of the river by April 10th, was 32 200 sec-ft., and showed that the annual flood had begun, therefore all idea of attempting to divert the water through the gate by damming the crevasse itself before the summer flood should have been passed, was abandoned.



Change in Engineering Staff.—On May 15th, 1905, the writer was transferred from the Southern Pacific Company in San Francisco to the Associated Harriman Lines in Arizona, with the title of Assistant to the President of those properties. About 5 weeks later Mr. Randolph's duties were increased, as he was put in charge of the C. D. Co. and the Mexican Co., and shortly thereafter the officials of the Southern District of the Southern Pacific Company urged on him the very serious fact that the track beside the Salton Sea would soon be under water, and insisted that aggressive action be taken to close the break on the river. About the middle of July Mr. Randolph sent the writer to the river to confer with Mr. Rockwood, and a day was spent together examining the situation. About August 1st a second trip was made, and after the disastrous flood of November 28th, 1905, a third visit. Toward the end of January Mr. Randolph again sent the writer to the Lower Heading to assist Mr. Rockwood in hurrying the construction of the wooden head-gate. As this work neared completion, Mr. Rockwood suggested that he had found it impossible to handle things in accordance with his own ideas; he believed that the best interests of all concerned pointed to his resignation, and urged that the writer take up the work. After considerable discussion it was agreed that, if Mr. Randolph also desired the arrangement, there would be no objection offered. Shortly afterward these gentlemen met in Los Angeles and agreed to the change, and on April 19th, Mr. Rockwood

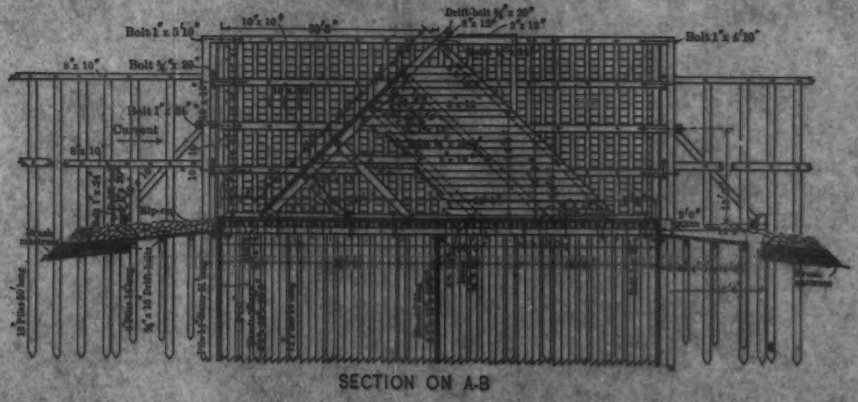
CORY ON
IRRIGATION AND RIVER CONTROL,
COLORADO RIVER DELTA.



THE ROCKWOOD HEAD-GATE

resigned as Assistant General Manager and Chief Engineer, and was appointed Consulting Engineer, and the writer was appointed General Manager and Chief Engineer. Mr. Rockwood continued to act as Consulting Engineer until October 1st, 1906, when he severed his official connection with the company.

The San Francisco Fire.—On April 18th had occurred the earthquake which resulted in the great San Francisco conflagration, and exaggerated rumors as to the extent of the disaster made it seem certain that the machinery for the *Delta* was utterly destroyed; but that was the least important result, as far as the C. D. Co. was concerned. It appeared that the key city to the Harriman Lines was practically in ruins, and the Southern Pacific Company, as a railroad organization, was very seriously hurt.

Mr. Randolph hurried to San Francisco to join with the other officials in the West in conferring with Mr. Harriman, who had at once started for the scene. There, in the bustle and confusion of temporary offices, with the ruins of San Francisco still smoking, with the facilities of the road to carry people away from the stricken city taxed to the very utmost, with the wonderful railway system which constituted Mr. Harriman's life work crippled to an unknown extent, and with the financial demands resulting from the disaster impossible to determine, Mr. Randolph succeeded in inducing Mr. Harriman to advance an additional $250 000 for controlling the Colorado River and protecting Imperial Valley. It has always seemed to the writer that this was really the most remarkable thing in the whole chain of extraordinary happenings.

The Situation.—The wooden head-gate was completed, and the upper and lower by-passes connecting it with the break had been fairly well started with the dredges, *Alpha* and *Beta;* the concrete head-gate was well under way; the material for the hull of the *Delta* was in Yuma, and the machinery seriously damaged in San Francisco; the tracks of the Southern Pacific Railroad along the Salton Basin were nearly awash for a considerable length; the annual summer flood of 1906 had begun, and, from the Weather Bureau reports from the drainage basin, would be a very large one; the irrigation system of Imperial Valley was already threatened at several vital points by the excessive quantity of water going down the Alamo channel or Main

Canal; and friction between the old C. D. Co. stockholders and the new management had commenced.

No very great degree of reliance could be placed on the wooden head-gate, considering the character of its foundations; and the failure or serious weakness of that structure meant the failure and abandonment of the Rockwood plan for re-diversion. The difficulties of the Concrete Gate Plan, under the most favorable circumstances, became more apparent with further investigation, and were very greatly accentuated by the delay in getting the *Delta* into commission. The probability of the withdrawal of financial support at any time through the discouragement of the Southern Pacific officials as to the ultimate success of the work was a serious factor. Transportation facilities from Yuma were very inadequate, consisting of the steamers, *Searchlight, St. Vallier, Cochan,* and the barge, *Silas J. Lewis,* all of sufficiently light draft to navigate through the shoals and sand bars of the Colorado. There were large quantities of willow brush suitable for fascines and mattress work near the break, but no timber suitable for piling. The nearest point where piles and heavy timber were obtainable was Los Angeles; from there they came by rail to Yuma, from which point they could be floated down the river only at considerable risk, so that it was cheaper to load them on barges and bring them down with steamboats.

Experience thus far had indicated the practical impossibility of closing the break with a piling-brush-sand bag barrier dam, and there were no quarries for many miles either west or east along the railroad, and none, of course, available except with railroad facilities for loading and transportation. Further, rock would require to be transferred to barges at Yuma and be brought thence by river to the scene of operations.

Practically every engineer—and they included many of established national and international reputation—who had visited the break considered a rock fill barrier dam as entirely unworthy of consideration, for two reasons:

First, it was believed that rock would sink into the soft alluvial silt bottom and keep on going down indefinitely, even if more and more slowly. Old river men quoted numerous instances of wrecked river craft. They cited a dredge, bought a few years before by the C. D. Co., which had sunk on its way from Yuma to the upper intake,

gradually settling entirely out of sight in a few months. The consensus of opinion, therefore, was that any rock fill would certainly settle out of sight unless built on a very strong brush mattress foundation, and the probabilities were great that such a mattress would break under the load and fail of its purpose.

The second vital objection urged against a rock fill barrier dam was that the water going over it while building would dislodge some portion of the fill or some one rock at the top, thereby increasing the overpour at this point, which would dislodge more rock and in this way quickly result in a breach which could not be closed.

It was thought that these considerations not only quite precluded the idea of a barrier dam, should the wooden gate fail, but rendered very doubtful the construction of a diversion dam or obstruction in the channel opposite the gate which would cause a difference in head, above and below it, great enough to throw all the water through the by-pass and gate. This head was variously estimated at from 3 to 6 ft. —the head on the finished dam would be about 15 ft. at low-water stage.

On one point there seemed to be accord, namely, that the situation was a desperate one and without engineering parallel, and that there seemed to be little more than a fighting chance of controlling the river. No two, of the nearly fifty eminent engineers who visited the scene and examined into the situation more or less carefully, agreed on any one plan as offering the greatest chances of success, but pointed out fundamental weaknesses in practically all other methods suggested. This feature was so marked that when the writer suggested to President Randolph that the immensity of the interests dependent for their safety on the re-diversion of the river seemed to render advisable a Board of Engineers, he answered that he would regard 100 ft. of good strong brush mattress in place on the river's bottom as more valuable than the report of any Board of Engineers which could be gotten together.

The immediate menace, however, was from the summer flood in passing through the Imperial Valley to the Salton Sea. The Weather Bureau's reports from the upper drainage basin then indicated a very great total discharge, and a peak perhaps as high as 100 000 sec-ft. The crevasse had now enlarged, and the old channel below had filled up, so that practically all this water—several times as much as had ever yet entered the valley—must go the new way.

Summer Flood of 1906.—Plate XLVII shows that, compared with recent floods, the summer flood of 1906 was very large, although it has been greatly exceeded since then, notably in 1907 and 1909. The increased fall down the Alamo River channel resulted by August 1st in lowering the river at the diversion point approximately 4 ft., but it silted up as the flood receded, leaving a net lowering of between 2 and 3 ft. (Fig. 3.)

It widened the break from 600 almost to 2 700 ft., and rendered far more expensive, in time, equipment, and money, the task of putting the wooden head-gate into commission. The most important effect, however, was the danger it caused in various ways in the Imperial Valley proper.

Such a vast quantity of water going down the Alamo channel was, of course, never contemplated in designing the new waste-gates near Sharp's Heading discharging down the Alamo River (built June to August, 1905), and at Station 134 on the Central Main, and they were taxed to their absolute limits. So much passed the Alamo Waste-gate that it caused a recession of the grade in that channel below, so that the structure was, figuratively speaking, on stilts. Twice the chute below the structure had been extended, the last time in February and March, 1906, when the equipment was removed just as the water began to go over the top of the gates.

By a peculiar and most fortunate coincidence, when the Alamo Waste-gate was discharging approximately 3 500 sec-ft. and Sharp's and the Encina Head-gates were being utilized to the capacity of the canals below them, the water in the Alamo above this point spread overbank for miles, going to the west and south sufficiently deep to save the situation. Thus it happened that when the peak of the flood was reached, and approximately 75 000 sec-ft. were going down the Alamo channel toward the Salton Sea, all but about 5 000 sec-ft. were going overbank to the south and west. Had not this most fortunate condition existed, the Imperial Valley irrigation system would early have been broken into the deep channel of the Alamo below the waste-gate, and at once cut the water out of every canal.

Most of this overbank flow to the south and west collected in the various sloughs and low lands, particularly Beltran's and Garza's Sloughs, and flowed into the New River. The small channel of this watercourse was overtopped, of course, and the water spread out, just

south of the Boundary Line near Calexico, for a maximum width of about 10 miles. Some of the water overtopped the divide of the delta cone, gained the Paredones channel, and thence ultimately reached the Gulf.

The most critical points were where the New River channel crossed the Boundary Line, and a little farther down along the Central Main. At Calexico and Mexicali this broad sheet of water rose until it covered the ground about 4 ft. in depth. (Fig. 28.) The danger was not appreciated in time to throw levees to the west of the railroad track and thus protect that property. The disposition of the towns and the railroads was to wait for the C. D. Co. to build protective levees, in spite of that company's announced intention of doing nothing of the sort.* When the situation was finally realized, about 5 miles of levee—maximum height 5 ft.—encircling the two towns and connecting at the north and east with higher ground, was hurriedly built. Strong winds blew in the spring for two and three days at a time, and when such storms swept over a wide stretch, even though the ground had a considerable quantity of brush, waves were caused which made the maintenance of these levees at times very critical. They were held successfully, however, until the recession of the New River grade made them no longer necessary.

Along the Central Main, from near the branch railroad crossing west to beyond the "Five Gates" (where the canal turns to the north), the water rose so high during the last days of February that it overtopped the south bank of the canal (Fig. 29), and only by the most desperate work was it prevented from overtopping the north bank and sending water northeastward across the country to the Mesquite Lake Basin and the Alamo channel. Had this occurred, the Town of Imperial would have been most seriously threatened, perhaps destroyed, and the New River and Alamo chasms would have been joined by a third one, about 25 miles long, diagonally across the valley northeast and southwest. The C. D. Co. then greatly strengthened this north bank and raised it 4 ft. for a distance of nearly 3 miles. When the situation was most threatening the citizens of Calexico and Mexicali were called out to help hold the levees, while the people of Imperial rushed down to aid in the fight along the Central Main.

* This was because the company's attorney advised that it was not responsible legally for damages caused in the United States by operations of the Mexican Company in Mexico, and to avoid carefully any action which might be considered as an admission of responsibility by the company.

Both the Alamo and New River channels cut back, owing to the large quantity of water flowing in them, and the Salton Sea began to rise at the rate of approximately 7 in. per day. The Southern Pacific main line there was being shifted from time to time, by means of "shooflies." Along the branch line from Imperial Junction to Calexico the trouble at the crossing of the Alamo channel was far greater than should have been permitted. At no time was more than 3 500 sec-ft. going down the Alamo, yet this small quantity was permitted to eat away approximately 300 acres of land, in a semi-circular form, from the right bank of the channel where it is crossed by the branch railroad into the valley, and caused the railroad to "shoofly" its tracks five times. The alluvial soil of the Imperial Valley is very easily eroded, especially on the concave side of river bends, but it should have been possible to control at reasonable cost a stream of 3 500 sec-ft., with a velocity never exceeding 7 ft. per sec.

The Inter-California Railroad from Calexico toward Yuma had been constructed as far as Cocopah and practically all of this was under water. The Holtville Interurban Railroad, crossing the Alamo River, was cut out from time to time, the channel at that point being lowered more than 30 ft. This caused serious trouble with the discharge pipe of the Holton Power Company, the plant being left rather high, and considerable work was required to keep it from being undermined by side cutting. The head available, however, was increased by 30 ft.

When the grade of New River had receded to a point about 3 miles above the International Boundary Line, a large area of adobe formation was encountered, and the fingers of the stream began to eat away in various directions and threatened to tear up the country throughout that region in a frightful way. The rate of recession was also greatly slackened. Long before the peak of the flood had been reached, it was evident that the situation along the Central Main and at Calexico was very serious and must become much more so, until grade recession might give relief. It was decided, therefore, to use dynamite liberally in an endeavor to localize the New River's grade recession and to facilitate its progress.

From observations and soil and other data at the time available the probability seemed slight of such recession extending more than 6 or 7 miles beyond Calexico, or far enough to endanger lowering

FIG. 27.—ALAMO WASTE-GATE, NOVEMBER 17TH, 1906. ABOUT 30 FEET HEAD AGAINST GATE.

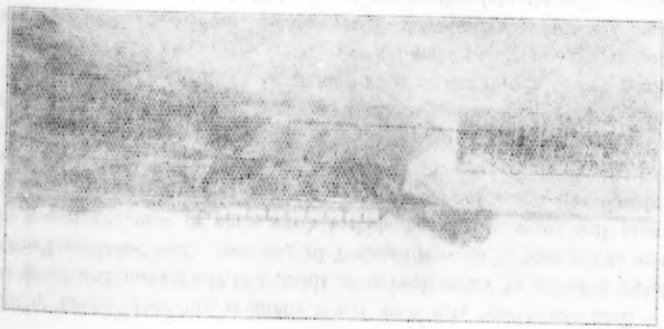


FIG. 28.—PORTION OF 4-MILE LEVEE PROTECTING CALEXICO AND MEXICALI, IN FLOOD OF JUNE, 1906.

FIG. 29.—OVERFLOW AGAINST WEST AND SOUTH BANKS OF MAIN CANAL NEAR FIVE GATES, 2½ MILES NORTHWEST OF CALEXICO.

the water surface in the Alamo above the controlling works and so menacing the water supply of the valley before the summer flood of 1908. It was known that very large areas of adobe soil existed in the Garza's and Beltran's Slough country, so that the cutting there would be very much slower. There thus seemed to be considerable leeway, while the strain on the irrigation system of the valley was so severe at several critical points that it was utter nonsense to think it could be held through another flood season.

In this dynamiting, from eight to sixteen ½-lb. sticks of dynamite were tied in a bundle about a fulminating cap connected with from 8 to 12 in. of water-proof fuse. The fuse was then lit and the bundle tossed into the water. A little practice and careful observation enabled one to become quite proficient in estimating how far the bundle of dynamite would be washed down stream by the current before the cap exploded the charge, and in placing the charge to get maximum results. Undoubtedly, the course of the grade recession was considerably checked and bad erosion somewhat mitigated by this work, but it is very doubtful whether the time of the grade recession's passing Calexico and Mexicali was markedly accelerated.

When this occurred the results were spectacular in the extreme, the rate of cutting back at this point being fairly uniform at 1 ft. per min. The side cutting of the east bank of the wide, deep barranca for several days threatened Calexico, and carried away a considerable part of Mexicali, including the railroad station, brick hotel, and a number of smaller buildings. The actual damage sustained was about $15 000 in Calexico and $75 000 in Mexicali.

For a short distance past Mexicali the cutting back followed the borrow-pits of the Inter-California Railroad, utterly destroying it and carrying away much of the track and trestle material. About a mile out of town, the grade rose slightly above the flood-waters, but farther on, for several miles again, the roadbed was practically destroyed, although no more track material was lost.

These flood-waters covered about 6 000 acres of cultivated farms, of course, utterly ruining the crops. Greater damage, however, occurred as the grade receded and the water rushed from each side toward the newly-made channel, resulting in cutting back fingers or side cañons from the main stream to distances and depths depending on the length of time required to drain off the contributory water.

Some of these side cañons extended back from 2 000 to 2 500 ft. It thus happened that about 3 000 acres of improved and 10 000 acres of unimproved land were eroded to such an extent as to be practically ruined for agricultural or any other purposes. Of this area, about 7 000 acres were public land. The area occupied by the New and Alamo channels themselves was increased by about 7 000 acres.

The greatest damage in the Imperial Valley proper, however, was caused by the destruction of the flumes in the West Side Main over New River in Mexico and the Central Main over New River northwest of Imperial, leaving Mutual Water Companies 6 and 8 without water until January, 1908. These two districts contained about 30 000 acres in actual cultivation, and were rendered practically uninhabitable and absolutely waterless for about 1½ years.

Except as noted, agricultural operations in the valley were facilitated by the flood, there being at all times plenty of water in the canals. Prospective settlers, of course, were kept away almost entirely, but the inhabitants of the valley displayed a remarkable confidence that the trouble would be overcome, and business was not affected very seriously. Indeed, during these very times, the new and independent town site of El Centro was the scene of really wonderful building activity, and the Holton Power Company, directly and indirectly, practically doubled its plant and holdings in the valley.

The effect of this flood, in a geological way, was of extraordinary interest and very spectacular. In 9 months the runaway waters of the Colorado had eroded from the New and Alamo River channels and carried down into the Salton Sea a yardage almost four times as great as that of the entire Panama Canal. The combined length of the channels cut out was almost 43 miles, the average width being 1 000 ft., and the depth 50 ft. To this total of from 400 000 000 to 450 000 000 cu. yd. must be added almost 10% more for side cañons, surface land erosions, etc. Very rarely, if ever before, has it been possible to see a geological agency effect in a few months a change which usually requires centuries.

Preparation for Diversion Work.

All measures to prevent avoidable damage to the irrigation system in the valley from the flood-waters having been arranged, operations were resumed on the river. The break opposite the wooden head-gate

had been widened during the flood from 600 ft. to more than ½ mile, and necessitated work on a far larger scale than had ever been suggested. The opinions to the contrary notwithstanding, the ability to get rock in large quantities and rapidly seemed to the writer to be so essential, and it was so obvious that much better transportation facilities were required, that it was decided to build a branch railroad from the Southern Pacific main line at a point 7 miles west of Yuma (now known as Hanlon's Junction) to the break.

The located line of the Inter-California Railroad, construction of which had been stopped by the overflow waters at Cocopah, ran only a few hundred yards west of the wooden head-gate and 150 ft. west of the concrete head-gate. This Inter-California Railroad is a Mexican subsidiary of the Southern Pacific Company, and it was not difficult to arrange a change in its alignment to cross the Alamo where the best location for the diversion dam could be found and to build at once that portion from the break north to the concrete head-gate. Thence northward the permanent alignment was expensive and would require considerable time to construct, therefore it was decided to make a temporary connection of about 6 000 ft. from Hanlon's Junction to the concrete head-gate. It was arranged that the Southern Pacific should build the entire branch line and charge the total cost, on a force account basis, to the C. D. Co., and when later, if ever, the Inter-California Railroad should be completed, all that portion of the branch which could be incorporated with the permanent alignment of the road would be taken over by it at such a figure as it would cost at that time. The stretch from Hanlon's Junction to the western line of the lands of the C. D. Co. is in the Yuma Indian Reservation, and, according to the rules and regulations of the Interior Department, it would have taken some time to acquire a right of way for this portion. As it was feared that special permission might not be quickly obtainable, nothing whatever was said, but the line was simply built. Such a course was deemed justifiable, considering the gravity of the situation, the necessity for haste, and the very small discretionary powers given to Government officials in such cases. As soon as the existence of this track was no longer absolutely vital, permission was requested in the usual way and in due course was obtained. Construction of this branch line was begun on July 1st, and

on August 15th the first train load of materials passed over it to the Lower Heading.

Quarry.—The granite point of rock on which the concrete head-gate was founded seemed favorable for quickly developing a quarry where a large quantity of rock might be obtained, and instructions were given to do the best possible with it. The rock is a second-class granite, and, before the first closing was completed, a quarry had been developed with a 600-ft. face averaging 40 ft. in height. The development of this quarry and track room for outfit cars, locomotives, etc., called for the building of a large yard of sidings and spurs. This quarry was entirely on C. D. Co. land—that bought from Hall Hanlon at the very beginning.

Clay Pit.—Between the quarry and the Boundary Line, and about ½ mile west of the branch railroad, there was an opportunity to develop rapidly a clay pit. Advantage was taken of this, and by the time the first closing was completed, there was a steam shovel face 600 ft. long and averaging 60 ft. in height. The clay in this bed is rather hard and requires some blasting, but it melts down in water, and when mixed in about equal proportions with the cement gravel from the Mammoth gravel pit makes a very impervious material for dam construction.

The Mammoth Gravel Pit.—This pit is on the Southern Pacific Railroad 41.08 miles west of Hanlon's Junction. It had been thoroughly developed at that time and had been used for ballasting the main line for more than 100 miles in each direction. It is the property of the railroad, and the material obtained there is fairly high in clay, the result being essentially a cementing gravel, which makes the surface of the track almost impervious.

Other Quarries Available.—At Declez, a point on the Southern Pacific Railroad 195 miles west of Hanlon's Junction and 49 miles east of Los Angeles, there is a large, well-equipped quarry of very good granite, from which material for the construction of the breakwater at San Pedro Harbor, 19 miles southwest of Los Angeles, is obtained. The output of this quarry is very large, the rock running up to 12 tons.

Near Ogilby, 7 miles west, a large area is covered with lava "nigger-head" rock, essentially one- or two-man size, which had been in part denuded to furnish rip-rap around the railroad bridge over the Colorado

at Yuma. The tracks, however, had been torn up, and no stone had been obtained therefrom in years.

At Tacna, 52 miles east of Hanlon's Junction, there was a quarry formerly used by the railroad but abandoned because the rock therefrom was small and of poor quality.

At Patagonia, on the branch line south from Benson toward Nogales, and 370 miles east of Hanlon's Junction, there was a well-equipped quarry controlled by the Southern Pacific. Its output was a reddish limestone, considerably smaller than that at Declez, but yet frequently turning out 10-ton rock.

These four sources of supply constituted the utmost possibilities, aside from the quarry which might be developed at Andrade.*

Brush.—By no means all the area contiguous to the Colorado is covered with willow brush, but it occurs in spots, often of very large extent. Such areas on the west bank of the river near the Edinger Dam had been cleared away, and west of the old Main Canal there was an old shallow lake which, though now drained, was practically barren. All brush, therefore, had to be obtained from the south side of the break, and with an average wagon haul of about 1 mile. The growths, ranging from 6 to 18 ft. in height, were ideal for fascines and mattress work. Main and branch roads were cut by Indian labor in order to get this material to the front rapidly.

Dredges.—The dipper dredge, *Alpha*, and the suction dredge, *Beta*, were in reasonably good condition, but the former could not be used in the sand bar left exposed in the bottom of the break when the waters receded, because the material slipped down to such a flat slope that it would have imprisoned the craft. After doing all it could in the by-pass and more solid ground, it was started to deepening the old Main Canal toward Algodones. Dams were built behind it from time to time, and water was pumped into the canal at the upper intake to keep the machine afloat. The quantity of water required indicated a surprisingly small seepage loss from this old canal into the surrounding country, and this is in accord with the unexpected experience with the coffer-dams of the wooden and concrete head-gates.

Steamers and Barges.—During the latter part of 1905 the Mexican Co. purchased the steamer, *Searchlight*, 91 ft. long, 18 ft. wide, and

* Andrade is the name of the Inter-California railroad station on the American side of the Boundary Line, Algodones being on the Mexican side.

drawing, without load, 18 in. of water. It had a barge, about 55 ft. long and 25 ft. wide, on which most of its load was carried. The steamer, *Cochan*, 135 ft. long and 31 ft. wide, the largest on the river, belonged to Yuma parties, and as it had been leased by J. G. White and Company for hauling materials and supplies to the Laguna Weir, it was not available. There was another steamer on the river, the *St. Valliers*, 75 ft. long, which was a little smaller than the *Searchlight* and in very poor condition. In addition to these there was the barge *Silas J. Lewis*, 115 ft. long and 35 ft. wide, which was fitted with a donkey engine with which it pulled itself up stream. This barge was rented for $15 per day, and its deck was cleared for mattress weaving.

Grading Outfits.—The Southern District of the Southern Pacific Company—from Santa Barbara and Fresno, Cal., to El Paso, Tex.—has enough reconstruction and betterment work to keep two or three grading contractors' outfits at work except during the very hot season. An arrangement was made with one of these, Shattuck and Desmond, to supply an outfit on the force account schedule paid by the railroad, with provisions for the payment of all duties and for all stock dying from heat. This firm secured, fed, and housed its own laborers. Inasmuch as there was no very definite plan as to the work which would be required, no contracts were feasible, hence the force account arrangement. At one time about 800 head of this firm's stock, with complete camp equipment, Fresno scrapers, plows, etc., were on the work.

Materials and Stores.—Arrangements were made with the Southern Pacific for equipment, materials, and stores, on the basis of cost plus 10%, and for freight charges of 0.5 cent per ton-mile, until the provisions of the Interstate Commerce Commission prohibiting such freight arrangement went into effect. Two steam shovels were brought in for quarry work and one for the clay pit. Complete work trains were requisitioned from time to time until a maximum of ten was reached. A roundhouse foreman and an assistant master car repairer were sent by the railroad company, and temporary, but effective, plants were installed at Andrade. Three carloads of repair parts and stores for engine, car and air-brake repairs were sent out, used from, and returned when the work ended. All requisition blanks, rules, and other organization methods of the railroad were continued.

When the Southern Pacific built the Lucin Cut-off, consisting of a long trestle bridge and an immense fill across Great Salt Lake, in Utah, there were bought a large number of steel side-dump cars, of 45 cu. yd. capacity, locally known as "battleships," weighing approximately 20 tons, and having a capacity of 100 000 lb. with a permissible 10% overload. These cars were frequently loaded to 125 000 lb. on this work, as the trip between the Andrade quarry and the break did not exceed 4 miles. At first 80 of these cars were secured, and more and more were sent until about 300 were finally in service. Such a quantity of railroad equipment necessitated rather extensive terminal facilities, and these were provided on the American side of the line because of the customs regulations of the Mexican Government.

The railroad from Hanlon's Junction to the Lower Heading, the quarry, clay pit, steam shovels, etc., were under Mr. Eulogio Carrillo, Assistant Engineer of the Southern Pacific Construction Department, from June 1st, 1906, to July 21st, 1907, as a superintendent of the C. D. Co., from which he received his salary, the railroad giving him leave of absence for that period. All the men under his direction, however, were carried on the Southern Pacific payrolls, and bills were rendered later by that corporation to cover this expenditure.

There were two reasons for having the railroad company supply so great a quantity of labor, equipment, materials, and supplies. First, it afforded an opportunity to assemble quickly a thoroughly organized and efficient force of men; the advantage of obtaining materials and supplies at low prices by the purchasing department of the Harriman systems; immediate shipment of repair parts not kept on hand, thus reducing delays to the minimum; and the ability to increase or decrease rapidly the force and equipment without confusion. The second reason was that no immediate cash was required, and as bills of all kinds were not usually presented and approved in less than about 6 months, approximately 3% in interest was saved. All bills were rendered at actual cost plus 10%, which thus meant really cost plus 7%—a very low figure for superintendence, etc.

Whenever any train, equipment, or men left the main line and came on the branch line they reported to and were under the jurisdiction of Mr. Carrillo, who in turn reported to and was under the sole jurisdiction of the writer. In this way no misunderstanding arose, and the entire force obeyed instructions as quickly and fully as though

there were absolutely no connection between them and the Southern Pacific.

Storehouse at Lower Heading.—Duty had to be paid on everything taken into Mexico, but, nevertheless, a very complete storehouse of repair parts, small tools, etc., was established at the Lower Heading. No requisition system was put in, however, because it was felt that the losses which would thus occur would amount to much less than the delay due to any form of red tape, whatsoever. Everything received was charged to the work, and at its closing down an inventory was made and the work was credited with the value of the material left.

Climatic Conditions.—From about June 1st to the middle of September or October 1st, the temperature of this region is so high that until 10 years ago it was not considered advisable to continue large construction work during that season. There can be no doubt that ordinary labor is only from one-third to two-thirds as efficient in such heat, and during this particular year the general average seemed to be about one-half. There is little wind during this period, and the humidity is ordinarily very low, though occasionally it is quite high for periods of two or three days.

Mosquitoes are frequently a terrible pest, very often driving even cattle out of regions near stagnant water. There is relatively little vegetation about Andrade, and at the Lower Heading a large camp compound was entirely cleared and the stagnant pools in the vicinity drained at a slight cost, so that the mosquitoes, while annoying, were by no means serious.

Brush and arrow weed growths are so dense that white men, no matter how well acclimated, cannot work very hard in cutting them down. Men from the central part of Mexico were imported, but they could stand it little better. Indian labor is the only kind for that sort of work.

Labor Conditions.—The work of rehabilitating San Francisco after its disastrous conflagration drew there an immense amount of shifting labor. To the south Los Angeles was growing in every direction. The Harriman Lines, under President Randolph, was employing large numbers of men constructing the West Coast Railroad from Guaymas toward Mazatlan and Guadalajara. Much betterment work was in progress on the lines from Los Angeles to El Paso, and large forces were required for building "shooflies" and shifting track along the

Salton Sea. J. G. White and Company was rushing work on the Laguna Weir, and the Reclamation Service was building the Roosevelt Dam near Phœnix. Thus the labor situation in California as a whole, and in this part of California in particular, was acute. The immigration laws of the United States prevented the importation of Mexicans, except in a very small way, but here the work was in Mexico. It was decided, therefore, to obtain laborers from Central Mexico, ship them from El Paso to Yuma in bond, and back into Mexico at the Lower Heading. Arrangements were made with the Labor Agent for the Southern Pacific, Southern District, Mr. Ben Heney, of Tucson, to ship 500 men. This plan was an utter failure, for two reasons. The Mexican officials did their best to prevent Mr. Heney's agents from getting men started, and the 75 men who arrived were unable to stand the climate.

Attention was then turned toward getting Indians in large numbers, and arrangements were made with Mr. C. E. Dagenette, United States Indian Outing Agent, with the result that, by the time work was in full swing, practically all the men, women, and children of six Indian tribes were on the work—the Pimas, Papagoes, Maricopas, and Yumas, from Arizona; and the Cocopahs and Diegueños, from Mexico. These six tribes fraternized and got along together without any difficulties whatever, and constituted a separate camp of about 2 000 people. About 400 workmen could be depended on from this collection. They were paid 20 cents an hour, and every 9 men received in addition one man's pay to go to a squaw for cooking their food. The Indians bought their own supplies, and to avoid duty built their camps on the Arizona bank, crossing the dry channel below the break to and from work.

Indian labor was very satisfactory, and, indeed, just what other arrangement could have been made is very problematical. Under intelligent foremen who understand their peculiarities, chief of which is lack of assurance and consequent timidity in going ahead with work, they are quite satisfactory. They must be paid weekly, and very few can ever be induced to work on Sunday or to put in overtime, regardless of how critical the stage of work may be when the whistle blows.

Very fortunately, indeed, an unexpectedly large amount of floating labor came in from every part of the United States, men who are attracted to any work which has achieved notoriety for any reason.

Once on the ground these men did not work any great length of time. A work train ran into Yuma every night for provisions and supplies, returning early in the morning, and it always carried a considerable number of cheerful capitalists out and sadder and wiser men in. Yuma at that time was "wide open," with all sorts of lures which few of these floaters could resist. To what extent the work would have suffered had Yuma then been a closed town, as it is now, is a question.

The general wages paid were:

Pile-driver foreman.....50 cents per hour.
Pile-driver donkey runner.....43¾ " " "
Good pile-driver helpers.....31¼ to 37½ " " "
Ordinary labor.....27½ to 30 " " "
Work from 8 to 10 hours per day.
Board deduction, $22.50 per month.

Commissary and Camp Plans.—The usual outfit cars were provided for all men carried on the rolls of the railroad, and many were boarded in the dining cars, which were a part of Mr. Carrillo's permanent construction outfit. The remainder of the men were boarded by Mr. M. C. Threlkeld, of San Francisco, who had and still has a contract with the railroad to board all gangs engaged in maintenance of way and betterment work on its lines. Mr. Threlkeld took an essentially similar contract for feeding the white laborers of the C. D. Co., the first contract being for 25 cents per meal in the United States and 40 cents in Mexico, the contractor to pay all customs duties on material and supplies. After the second break, and when the work was continued at President Roosevelt's request, it was deemed probable that the Mexican Government would refund duties on provisions thereafter, so that the contract was changed on January 1st, 1907, to 25 cents per meal, the Mexican Co. to pay the duties. This contract covered meals for all white laborers, including men on dredges, on the steamer *Searchlight*, etc., and gave Mr. Threlkeld the exclusive selling of clothing, tobacco, notions, etc., to the laborers. The Indians bought relatively little from him, however, preferring to deal with Yuma merchants with whom the local Indians were very well acquainted.

Excellent board for the men was insisted on and furnished. It was believed that good board, especially with lots of fresh vegetables, would be a large factor in keeping men on the work, and this was found to

be the case. Large numbers of mosquitoes were feared, in spite of precautions taken, so bunk houses were built, with brush ramada roofs, and carefully and effectively screened all round. These precautions were not exactly necessary, but were nevertheless well worth their cost.

Policing of Camps.—The many different classes of laborers on the same job and under Mexican laws made it essential to have effective police arrangements, and bar liquor from the camp absolutely. The Yuma Indian Reservation extends to the line, and, in addition was then and until 1908, a part of San Diego County, and a "dry" region. Across the river in Arizona is "wet," but the United States laws against selling liquor to Indians are rigorously enforced. In Lower California, however, the idea of liquor control has not even germinated, and it was necessary to promise to prevent American Indians from getting liquor in Mexico before permission could be obtained to take them out of the United States—and this was quite proper. Accordingly, arrangements were made with the Mexican authorities to put the entire region under martial law, and send a force of rurales with a military commandant at their head to police the camps. This proved extremely efficient and satisfactory, and there was absolutely no disorder at any time.

Customs and Duties.—Except for the operations of the C. D. Co., there was no development in Mexico along the river; therefore, until 1908, the nearest custom house in Lower California was at Mexicali. A garrita was maintained at Algodones, however, where material going down the river to land in Mexico was passed. During the construction of the Edinger Dam, all camps and supplies were kept on Disaster Island in the middle of the river, so that there were no customs charges. When the construction of the wooden head-gate was begun, endeavors were made to get the Mexican Government to establish a customs office at Algodones temporarily, but without success. Accordingly, all bills of material to be passed had to be sent to the custom house in Mexicali; there the charges were assessed, and the manifest was returned to Algodones before the goods could be taken over, which was very cumbersome and slow.

Another method of getting goods across the line was taken advantage of, namely, by boletas. The Mexican Government permits each individual, on payment of duties, daily to take across $20 (Mexican) worth of dutiable stuff without manifest, and the authorities agreed to

permit goods to be passed at the Algodones garrita by this boleta method, having individual employees of the company sign the boletas. In this way emergency stuff was passed.

Under the concession of the Mexican Co., machinery and materials for permanent construction was to be admitted without duty, but the intention of this provision was plainly for the company to make out a list of what would be required once for all, and that such freedom from duties would apply to the original entry of the machinery and material, and not to subsequent repair parts, etc. Obviously, it did not contemplate the refund of customs charges in such a case as closing the crevasse. Nevertheless, it seemed probable that the customs charges for material and supplies other than provisions would be refunded, because the Mexican Government itself was vitally interested in stopping the break. Tentative negotiations toward this end were started, but the procedure for securing such permission is a long one, and it was advised that the work be prosecuted and the request for refund made after its completion. It was also made plain that no refund would be given for duties on provisions, as it was impossible to determine that the provisions passed were all actually used on the work. When the work was completed a request for a refund was made, and, on President Diaz's recommendation, the National Congress, by vote, refunded approximately 75% of all duties paid, amounting to more than $40 000.

The chief objection, therefore, was the red tape involved in passing goods, and the delays which followed any slight technical mistake in classification. As an illustration: an inspector investigated the customs transactions of the period about a year later, and assessed a fine against the company for $3 000 for utilizing the boleta method of passing emergency materials and supplies. On proper presentation of the facts, however, this fine was remitted. Stock with harness and grading equipment was permitted to be passed into Mexico under bond for a period of 6 months, as also was machinery, which provision assisted very greatly in the work.

All payrolls, time checks, receipts, and legal papers require stamps to be affixed and cancelled, inspectors from time to time visiting all corporations and checking the books. If any irregularities are found in the books or papers for the 6 months immediately preceding, such inspector is then permitted to go back to the period of 6 months imme-

diately preceding that, etc. If, however, everything is regular for the first 6 months preceding, that operates to prohibit inspection prior to that time. These inspectors get a considerable percentage of fines assessed and collected, and are consequently quite zealous, so that it is profitable to obey the stamp law scrupulously.

Necessity for Mexican Corporation Doing Work.—On taking charge of the affairs of the Mexican Co., the writer found that up to that time work done in Mexico had been paid for on the American side of the line through the C. D. Co., and in this way no Mexican stamps were required for payrolls, time checks, etc. In other words, the C. D. Co. had its forces go over into Mexico and do work on the canals of the Mexican Co. directly. As this was obviously contrary to the spirit of the Mexican laws on the subject, arrangements were made at once whereby the Mexican Co. did all work in Mexico and billed the C. D. Co. therefor at actual cost, the C. D. Co. turning over all materials and supplies required on the Mexican side of the Line at its expense.

Mr. A. F. Andrade, now Depositario for the Mexican Co., and Assistant General Manager of the Inter-California, was made General Agent of the Mexican Co., and was in charge of all negotiations between that corporation and the Mexican Government, and to his tact, energy, and ability is attributed the relatively small amount of irritation and delay encountered.

Occasionally, rules and regulations had to be disregarded, and this was done when it was deemed quite necessary, knowing that the local officers would report such infractions of the laws, but that the higher officials would view such infractions very sensibly when sooner or later brought to their notice with full explanations. For example, before permission was given to run trains into and out of Mexico after dark, a serious situation developed just at sundown, immediately requiring rock at the Lower Heading, and the Mexican officials at the Boundary Line would not permit trains to pass. Their protests were disregarded, for while the officials under the circumstances could not act otherwise, it would have been folly not to have disregarded their orders, considering the urgency of the matter. Proper explanations were at once made, and the company was not criticized in any way for the action.

Difficulties in doing work in Mexico are largely due to ignorance of Mexican conditions, customs laws, and personal characteristics, and doubtless are no greater than a Mexican would encounter in doing work in the United States. It is very desirable for the highest officer in charge of work to speak Spanish well, as minor Mexican officials are far more impressed with a statement coming from him than from any subordinate officer.

METHODS OF DIVERSION OF RIVER THROUGH ROCKWOOD HEAD-GATE.

The triangular space between the two faces of the **A**-frame and the horizontal cross-bracing of the wooden head-gate was made into a long pyramid, by flooring the bottom and sides, which was filled with sand taken in by wheel-barrows, in order to give additional weight to the gate in resisting the buoyant effect of the water.

By August 5th the discharge of the river had fallen to 24 500 sec-ft., and directly beside the Rockwood Head-gate the receding waters had exposed sand bars on each side of the main channel—the situation being as represented by Fig. 23. When these sand bars had dried sufficiently, teams were used in throwing up an embankment on the line of the diversion dam. Brush jetties were also used to narrow the channel, the *Beta* assisting. In a little more than a week the stream was narrowed to 600 ft., the river gradually falling. Work was then begun on weaving a brush mattress, 100 ft. wide up and down stream, and sinking it on the bottom of the river. The decks of the barge, *Silas J. Lewis,* were cleared and skids were rigged thereon; ½-in. steel cables, 8 ft. apart, were anchored to "dead men" in the north bank and unwound from spools beneath the skids, such cables constituting the longitudinal strength of the mattress; and to these were fastened brush fascines averaging 18 in. in diameter and 100 ft. in length. These fascines were built up between vertical pins at the upper end of the skids and bound with baling wire, and as they were completed they were pushed down to the last one in the mattress and sewed to it and to the supporting cables with ⅜-in., 9-strand, galvanized-iron cable and cable clamps. Fig. 30 shows the method of sewing and fastening. When a length of mattress equal to the width of the barge was completed, the barge was slowly pulled from under it, and it caught the silt and at once settled heavily to the bottom. No kind of weighting whatsoever was required. Another

FIG. 30.—WEAVING BRUSH MATTRESS.

FIG. 31.—DOWN-STREAM END OF BRUSH MATTRESS ABOVE WATER BECAUSE OF SILTING ACTION.

barge width of mattress was then woven and sunk, and so on. Figs. 30 and 31 show the method of constructing the mattress and the number of men employed.

It required 20 working days, with two shifts, to weave and sink two mattresses, one on top of the other, across the bed of the stream, or a total of 1 300 ft.; thus the average rate was 65 lin. ft. or 6 500 sq. ft. daily. The work went ahead without interruption or difficulty except that once the anchor lines controlling the barge were not handled with sufficient care and the first layer of mattress was not sunk across in a straight line, but curved down stream in the middle perhaps 20 ft. at the maximum point. This, however, was not important.

The prevailing idea as to the necessity for such bottom protection in the river may be better realized from the fact that several engineers with the longest experience on the river joined in urging that a solid canvas back be sewed on the under side of the mattress. It was feared that the water might start a wash through a break in the mattress, that such a stream would carry the sand from below, cause a depression for the mattress to span, and result in breaking it when weight should be put on above. This, however, was deemed unnecessary.

While the mattress work was being completed, a 4-pile railroad trestle with 10-ft. bents was started across the center line of this foundation, decked, and a railroad track built thereon. This trestle was driven from both ends, and was ready for the passage of trains on September 14th, 6 days after the completion of the mattress. In the mean time, the earthwork across the north sand bar had progressed sufficiently to connect the rails, so that trains could run out on the trestle. On the south side, the jetty work and the *Beta* had built up a sand bar on which a frame trestle on mud-sills was erected, connecting the earth embankment on the south sand bar to the trestle, thus affording tail room for trains. This frame trestle was filled in with material from the clay pit at Andrade.

At this stage, brush fascines were put in between the bents of the trestle over the channel, laid longitudinally with the stream, and sunk by rock from the quarry at Andrade. The rock was loaded into "battleships" with a steam shovel, hauled down, and dumped from the trestle. In this way a difference of 6 ft. in water elevation above and below this diversion dam was attained with no difficulty whatsoever.

Meanwhile the by-pass in which the Rockwood head-gate stood was being enlarged in several ways. The *Alpha* had cut a small channel from the crevasse to the gate from above and from below, through the solid ground, and the *Beta* had enlarged these cuts until it was taken over to assist in the jetty work on the south side of the river. A small ditch was cut with teams and scrapers across the sand bar, as an extension of the down-stream end of the by-pass. This channel was excavated to the water-table with Fresno scrapers, and made as narrow as possible, reliance being placed on enlarging it by the erosion of the water. In two or three places adobe deposits of considerable extent were found, and in these dynamite was used, as already explained.

The steamer, *Searchlight,* was anchored in the upper by-pass for two or three days with its rear end against the bank and the stern wheel kept going as fast as possible. This greatly hurried the erosion. The increasing head on the diversion dam aided these methods of enlarging the capacity of the by-pass until on October 10th only about 1 450 sec-ft. of the river's total discharge of 14 300 sec-ft. was not going through the gate.

The alignment of the by-pass was unfortunate, as it had quite a sharp curve, and the upper end left the river at a sharp angle. At this point cutting began, and to prevent it a small brush mattress was woven and weighted down with rock.

It was soon seen that, with the 4-ft. openings between them, the A-frames of the gate caught the drift in the water very badly. Anticipating this, cables had been stretched across the entrance of the by-pass and fitted with grab-hooks, like fish hooks on a trout line. These grab-hooks were of $\frac{3}{8}$-in. wrought iron fastened with from 6- to 8-ft. lengths of sewing cable to the cable spans at intervals of about 8 ft. It was hoped that these would catch drift where it could easily be removed, and prevent trouble at the gate. However, they did very little good.

When the current through the gate increased to 6 or 8 ft. per sec., a scour developed both above and below. Soundings showed that the scour below the gate was not at all serious, but was really far less than had been anticipated. The eddies at the ends of the gate caused side-cutting, as is always the case, but really nothing alarming. The scour above the gate, however, was surprisingly great; some was expected, but not nearly as much as occurred. Brush and

rock extension of the apron, as shown on the plans, had not been put in as it had been the intention to use rock from Andrade in lieu thereof. When soundings, which were taken frequently, showed that the by-pass bed was eroded to the level of the floor of the gate, approximately 1 000 cu. yd. of rock were loaded on a barge which was swung in front of the gate and held by cables until unloaded.

Failure of Wooden Head-Gate.

On October 3d a serious settlement of the earth filling in the north abutment suddenly occurred. Excavation was at once made to ascertain the cause, and some small leaks in the end wall on the up-stream side of the **A**-frame were found. These were stopped up, and the earth was leveled to only a few feet above the water surface on the outside. Two days later the lower wing-wall in this same abutment spread out at the bottom on the west side. The gate itself buckled up about 0.3 ft., about one-third of its length from the abutment, such buckling apparently occurring very slowly within 24 hours, ending on October 5th. These signs of weakness were accompanied by the tearing up of the up-stream apron in relatively small sections, which were at once thrown against the **A**-frames by the current. With great difficulty these were taken out piecemeal, and then only in part. These, together with the drift which accumulated, caused a head of 4.4 ft. on the gate on October 11th. At this time the discharge through the gate was about 12 000 sec-ft.; the maximum discharge through it was about 13 000 sec-ft. on October 8th.

These indications of weakness showed that it would not be safe to use the gate after closing the break, and that it would be very fortunate if it held until this could be accomplished. Furthermore, the drift made it very difficult, if not impossible, to set the flash-boards. Accordingly, on October 5th, a pile bridge was begun just above the gate and connected with the track to the south by a frame bent trestle supported on mud-sills—the same construction as had been utilized on the south side of the channel. This trestle was finished in the morning of October 11th, and it was intended to dump rock from it and fill up the gate in this way and not attempt to use the flash-boards.

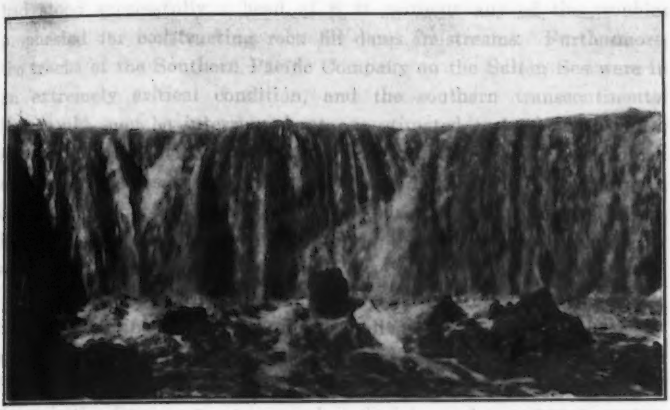
When the first rock train was slowly pushed over the trestle, at 11 A. M., three bents of the frame trestle settled and wrecked the train,

fortunately injuring no one seriously. Just why construction, which on apparently the worst ground on the south side of the main channel was entirely satisfactory, should have failed here, is not known—things happened thereafter too rapidly to find out. At any rate, had the trestle stood and had the large number of loaded "battleships" held ready been dumped, the writer has always believed that the head-gate would not have failed utterly. Be that as it may, at 2:30 P. M., without any warning, the gate suddenly buckled up at a point about one-third of the way from the south abutment (Fig. 46), and the larger portion—from there to the other abutment—floated down stream about 200 ft., where it lodged. The remainder of the gate stayed in place, although it settled in the central end. When the gate went out, the 4.4-ft. head above it caused a destructive wave of water, carrying large quantities of drift and débris from the wrecked gate against the railroad trestle crossing the by-pass about 300 ft. below. In about 5 min. this damaged the trestle seriously, and would have marooned a locomotive and train standing on the south side of the by-pass had not the engineer taken chances and pulled across before the piling began to go out.

The pond above the diversion dam extended some distance up stream and contained a large quantity of water which had to run out before the flow through the by-pass was reduced to the discharge of the river. By the time this occurred, considerable inroad had been made at the point where the upper by-pass left the river—which had been protected by a small brush mattress—and for a time it threatened to work down to and through the earth portion of the dam. Aggressive work was centered there, and such action was finally arrested.

Closing the Break with Rock Fill Barrier Dams in Series.

The lowering of the water above the diversion dam left it dry, except for a surprisingly small quantity of leakage, and enabled examination of the rock fill which had been produced by an ever-increasing proportion of rock with respect to brush. This condition of affairs seemed to indicate that the reasons urged why a rock fill dam of considerable height could not be built in a running stream were not altogether strong, and suggested the possibility of very quickly controlling the situation with a series of rock fill dams, each of which should sustain a head of not more than 4 ft. This particular dam



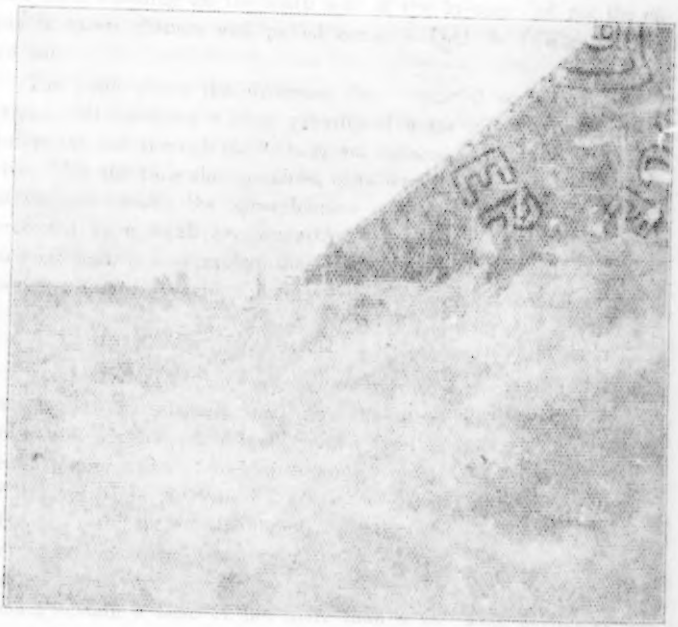


FIG. 32.—GRADE RECESSION IN NEW RIVER NEAR CALEXICO. MAXIMUM RATE OF RECESSION, 1 FOOT PER MINUTE. DROP, 28 FEET. JUNE, 1906.

FIG. 33.—THE HIND DAM, PASSING 7 000 SECOND-FEET. HEAD, 10 FEET.

had stood successfully a head of 6 ft. without any of the troubles prophesied for constructing rock fill dams in streams. Furthermore, the tracks of the Southern Pacific Company on the Salton Sea were in an extremely critical condition, and the southern transcontinental line would soon be interrupted, at an estimated cost of $1 000 000 a month. It was obvious that, if this were to be prevented, very quick action was necessary, and if hope should be abandoned, withdrawal of financial support in controlling the river was almost a certainty. Furthermore, other plans of controlling the situation possessed most serious difficulties, as already explained.

As a matter of insurance, however, a rush order was wired for additional sewing cable for building a diversion dam across the Colorado directly opposite the concrete head-gate, exactly as had been done successfully opposite the wooden head-gate to divert the river through the former structure, and as had been done with the other, trusting to dynamiting, dredging, erosion, etc., for enlarging the 4 miles of Main Canal thence to the break. This done, the trestles across the by-pass, above and below where the wooden head-gate had been, were repaired, and a third trestle, 30 ft. above the lower one, was hurriedly thrown across this stream, which was carrying the entire flow of the river, the waterway through the opening of the gate being only 120 ft. wide.

Such method of closing the break and forcing the river down the old channel by three rock fill barrier dams in series was therefore considered problematical only because there was no mattress under any of them, and the brush mattress idea had always been regarded as essential. The branch railroad from Hanlon's Junction to the Lower Heading was now in excellent condition, and the Andrade quarry was sufficiently developed to permit the use of the two steam shovels, producing about 5 000 cu. yd. of rock daily, by working night and day. It was felt that with these facilities, together with the rock which could be obtained from quarries within a distance of 400 miles to the east and west, rock could be put into the stream faster than the water could carry it away.

As a matter of fact, these three dams were built up so rapidly and successfully that only 10% of the water was going through the by-pass by October 29th, most of the remainder—8 600 sec-ft.—going over the diversion dam with the mattress foundation. Here, a sec-

ondary trestle, with 4-pile bents, 15 ft. apart, parallel to and 30 ft. up stream from the first, had been rushed, and from the two a rock fill dam was completed, turning all the water—9 270 sec-ft.—down the old channel and actually closing the break on November 4th. That is, after working on other lines continuously for 15 months, the stream was controlled by a rock fill dam in 24 days. In other words, the rock fill barrier dam plan, which had not been advocated, or indeed seriously considered, by a single man, proved to be a very simple and efficient, though expensive, method of re-diverting the river. The fact that there was a very substantial brush mattress foundation, however, was deemed by many as of vital importance.

Leakage through the structure was stopped by dumping "battleship" trainloads of gravel from the Mammoth gravel pit and clay from the clay pit, the whole being puddled with fire streams. The *Beta*, which was kept above the diversion dam in order to be taken up the river and used in the intake above the concrete gate, was used in widening the up-stream toe of the dams.

A week and a half after the failure of the wooden head-gate, the success of the series rock fill dam plan seemed assured. The *Alpha* had finished its trip up the Main Canal and cut into the excavation in which the concrete head-gate had been built. The intake from the river to the concrete head-gate was completed, and by October 29th the river at this point had been raised approximately 4 ft. by operations at the break. The dam holding out the river here, and those which had been left by the *Alpha* on its way up, were blown out, and water commenced to flow through the concrete head-gate and Main Canal into the Alamo channel below the diversion operations. The initial discharge was about 150 sec-ft., and had increased but little when the river re-diversion was complete. At that time (November 4th) the water height at various points was as follows (C. D. Co. datum):

Above the dam	113.0 ft.
Below the dam	97.3 "
Opposite concrete head-gate	114.5 "
Floor of concrete gate	98.0 "

By November 15th only 300 sec-ft. were flowing in the Main Canal, the fall of 17 ft. in these 4 miles not having resulted in much erosion, because of several stretches of adobe deposits, though the current was

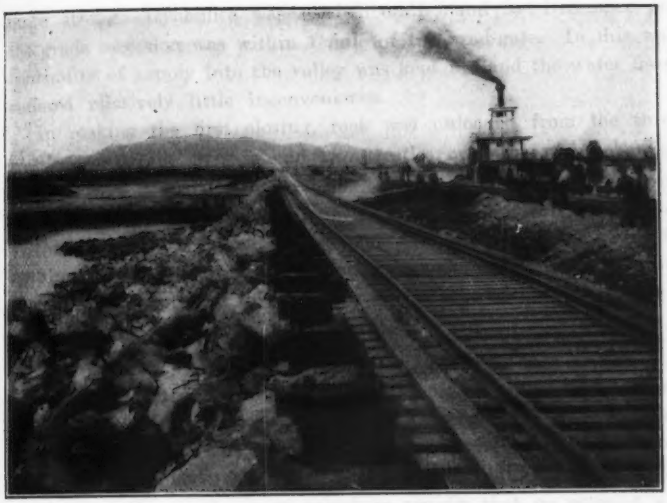

FIG. 34.—SEALING THE HIND DAM WITH GRAVEL AND CLAY BY HYDRAULIC JETS, NOVEMBER, 1906. NOTE SLOPE OF DOWN-STREAM SIDE OF ROCK FILL DAM.

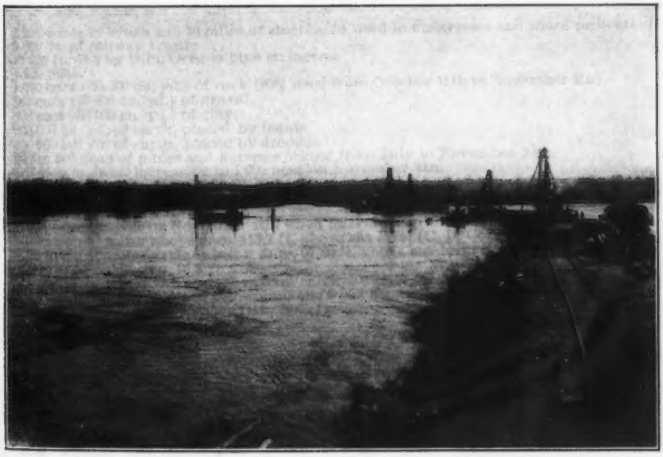

FIG. 35.—GENERAL VIEW OF THE SECOND BREAK, JANUARY 20TH, 1907.

quite strong. Dynamite was used liberally, and by December 5th the grade recession was within 1 mile of the head-gate. In this way continuity of supply into the valley was kept up, and the water users suffered relatively little inconvenience.

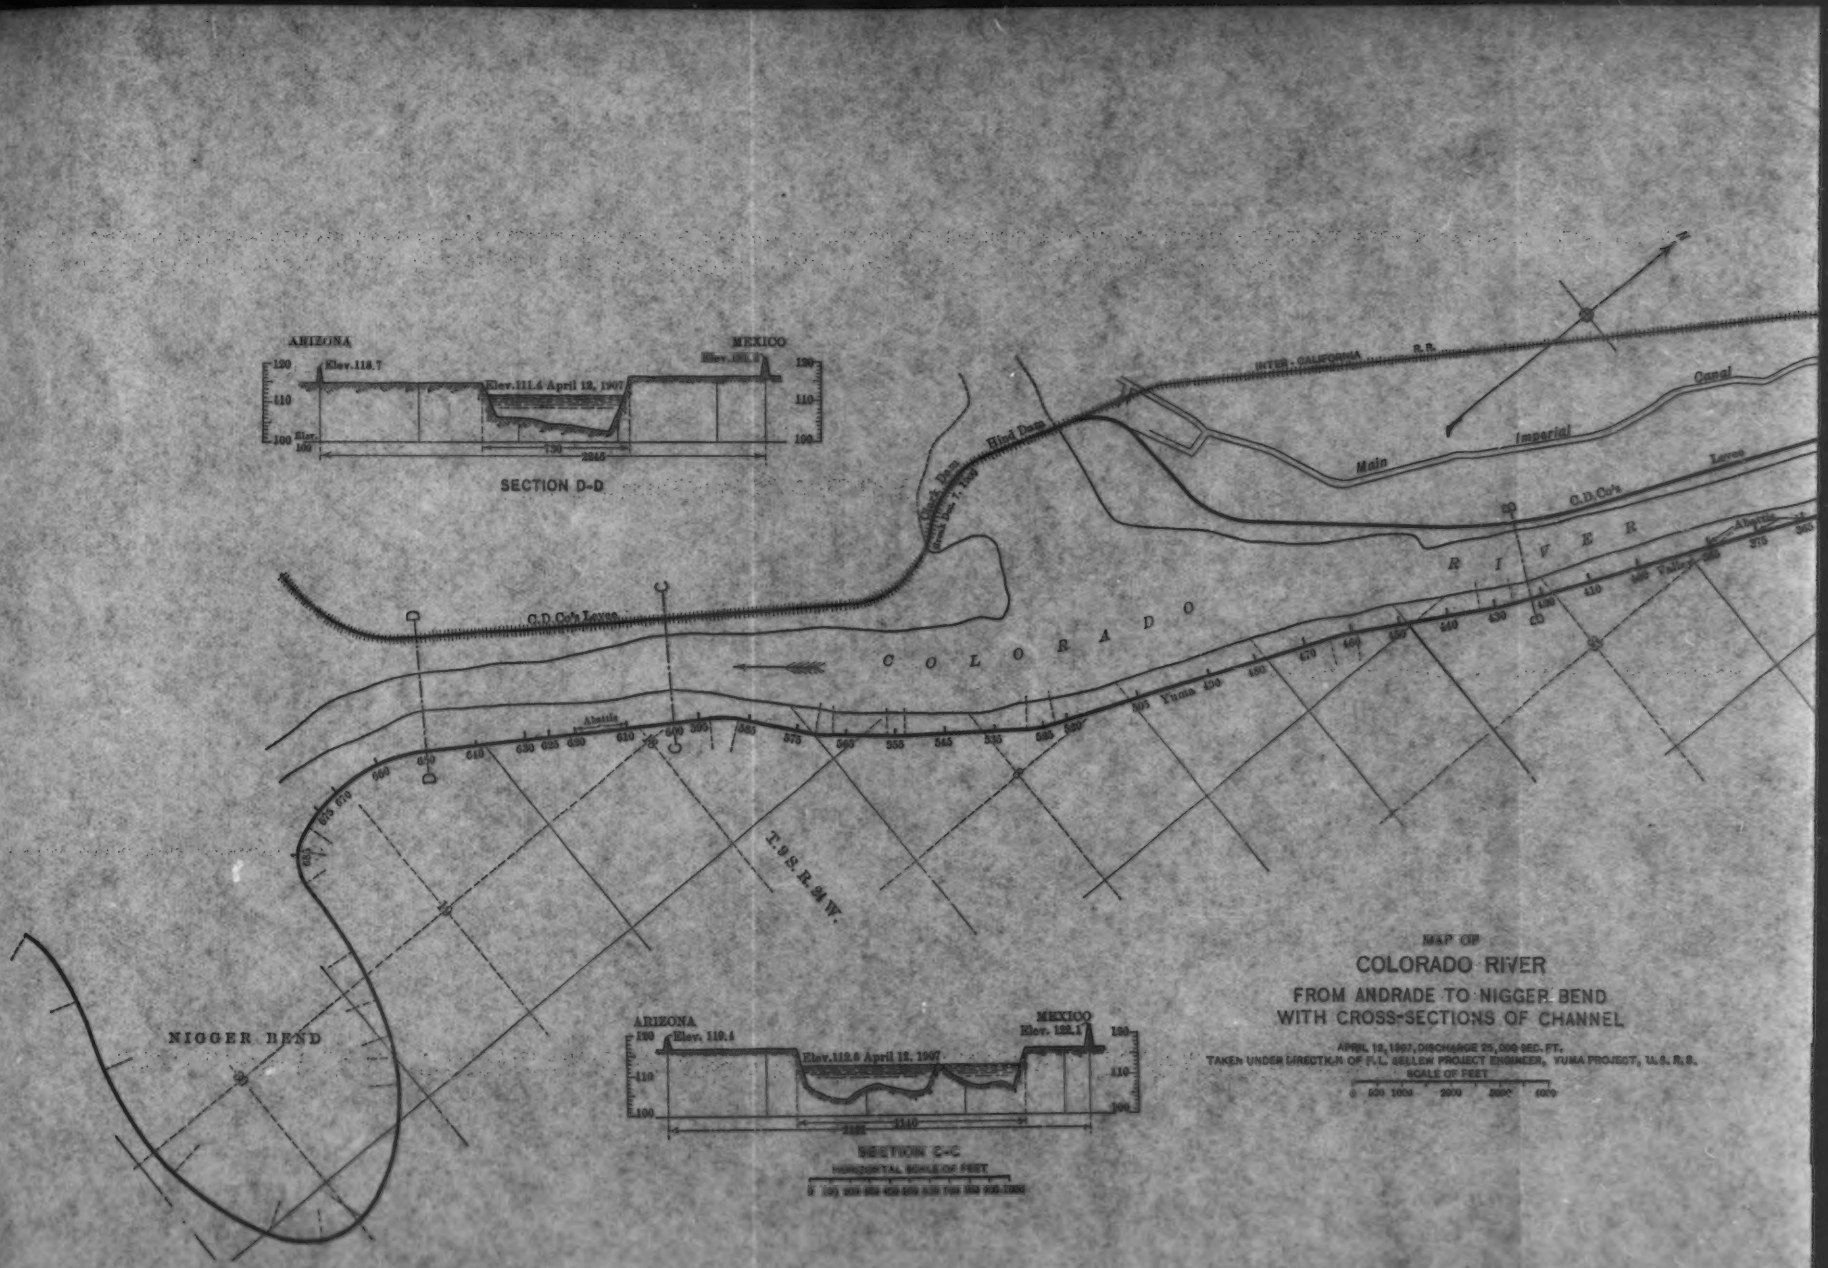
In making the first closing, rock was unloaded from the three trestles across the by-pass and two trestles over the main channel. Records were kept daily of car loads of rock from Andrade and from the distant quarries unloaded from each trestle, but this record, unfortunately, has been misplaced, and the totals obviously signify nothing. As the quantities of various materials used during the entire period from August 1st to November 4th may be of interest, they are given in Table 13.

Completing the Hind Dam.

The dams across the break and the by-pass were hurried to completion with material from the Mammoth gravel pit and the clay pit at Andrade. It was decided that the structure should have a top elevation of 124, and that meant increasing its height fully 8 ft. The tracks over the trestles were raised so rapidly that no attempt was made to recover the stringers or caps.

TABLE 13.—Approximate Data of Constructing Diversion Work on Colorado River.

2 200 cords of brush and 40 miles of steel cable used in mattresses and shore protection.
3 800 ft. of railway trestle.
15 200 ft. of 8 by 17-in. Oregon pine stringers.
1 100 piles.
1 690 cars (50 000 cu. yd.) of rock (90% used from October 11th to November 4th).
841 cars (32 000 cu. yd.) of gravel.
808 cars (33 000 cu. yd.) of clay.
200 000 cu. yd. of earth, placed by teams.
200 000 cu. yd. of earth, placed by dredges.
200 to 500 head of mules and horses working from July to November 20th.
200 men in June, increasing to 1 000 men on November 4th.
Discharge of river, June 27th, 99 200 sec-ft.
Discharge of river when actual work of constructing channel was begun, August 6th, 24 400 sec-ft.
Discharge of river on November 4th, when final closing was made, 9 275 sec-ft.
Elevation of water above dam, 113.1 ft. above sea level (C. D. Co. datum).
Elevation of water surface below dam, 97.30 ft. above sea level (C. D. Co. datum).
Total head on closing, 15.8 ft.
Elevation of water surface above dam one week after closing, 112.60 ft. above sea level.
Elevation of water surface below dam one week after closing, 95.85 ft. above sea level.
Total head on dam, November 11th, 16.75 ft.



The tracks were gradually pulled together to a final 13 ft. between center lines, which helped somewhat, but the proper side slopes were chiefly obtained with fire streams, five 1¼-in. nozzles, each throwing about 225 gal. per min., being used. The mixed materials as dumped assumed a slope of about 1¼ to 1, as a rough average, and

these were very quickly and cheaply flattened down hydraulically to about 2¾ to 1 on the river side and 2 to 1 on the land side. Furthermore, the slopes were really well finished with very slight additional care and expense.

In its final form the dam has about 400 ft. of 15° curve at the north end, and 2 275 ft. of tangent; the dam is connected at each end with the levees extending along the river. At the north end there are 200 ft. of high dam with a rock fill core to within 8 ft. of the top —where it crossed the by-pass. A little more than half way toward the other end there is 600 ft. of another high stretch with a rock core on brush mattress foundation; the remainder is from 16 to 20 ft. high. This is known as the Hind Dam, so called after Mr. T. J. Hind, Superintendent of the work at the Lower Heading after June 1st, 1906, to distinguish it from the Clarke Dam, closing the second break, so called after Mr. C. K. Clarke, Superintendent of the second closing, December 20th, 1906, to February 20th, 1907. About 80% of this dam was complete on December 7th, 1906.

Levee Construction.

The original plans had been to connect the north abutment of the wooden head-gate with the embankment along the river side of the Main Canal, and to build a short section of levee to the south to prevent a flank movement of the river around the diverting dam. The enormous channel which the summer flood of 1906 created in the old Alamo made it obvious that, not only must the break be closed, but that, by a rather elaborate levee system, all overflow water must be kept from getting around into the Alamo. Surveys and examinations showed the necessity of an additional levee from the wooden head-gate to the concrete head-gate, and a levee from the diversion dam south for from 5 to 6 miles. J. C. Allison, Assoc. M. Am. Soc. C. E., Assistant Engineer of the Mexican Co., was assigned to make surveys for these levees on August 1st, and their location was completed early in September. The elevation of the top of the concrete head-gate was 124, and it was decided to put a track over this structure and extend it down the levees, so that the grade was made 126 at Andrade, 124 at the Lower Heading and over the Hind Dam, and thence for 4 miles south, generally 6 ft. above the old high-water marks. At all points the grade was kept approximately 2½ ft. higher than that

IRRIGATION AND RIVER CONTROL.
COLORADO RIVER DELTA.

of the levee opposite the Yuma Project, because, should the latter break, the damage would be far less than if the levees on the west side were to fail, with re-diversion of the river to the Salton Sea. Between the head-gate and the Lower Heading it was necessary to locate the levee very close to the river, because it must obviously be between the river and the Main Canal, and some large areas of bad adobe, damp, and impossible to work with teams, lay close to the canal and extended well toward the river. Below the break, the levee was also close to the river, because of the similar soil conditions for about 4 miles.

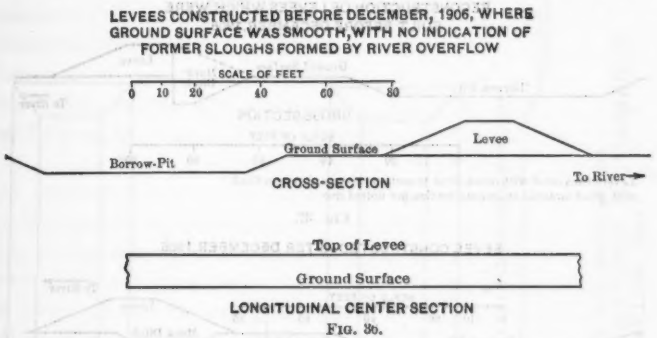

FIG. 36.

The levee was designed with a top width of 8 ft. and slopes of 2½ to 1 on the river side and 2 to 1 on the land side. The ground for the base of the levee was cleared and grubbed, but no "muck-ditching" was done. The desirability of muck-ditching was fully realized, and it was a part of the levee design. Experience in the valley had always shown that, not only ditch and canal banks, but low borders of irrigated fields, etc., leaked badly when water was first applied. Indeed, interesting cases were cited of water in considerable volume disappearing into the ground for several days, doubtless flowing away under the surface through partly opened cracks of buried layers of cracked adobe.

On the other hand, the money supplied by the Southern Pacific Company was for closing the break, and only for that purpose, until the re-diversion of the river was assured. No narrow construction was placed on this, to prevent building levees at all, but it was not considered proper to incur any avoidable expense in this direction until it should have been clearly demonstrated that it was physically

possible to close the break. No muck-ditching had been done in levee building on the Yuma Project up to that time, and, besides, experience in the valley had always been that cracked adobe layers when thoroughly saturated and under the weight of a few feet of earth soon soften and the underground interstices automatically close. It was thought that the levees could probably be maintained until their bases would thus soak up tight, although it was certain that they would leak like sieves when water first came against them. For these reasons the muck-ditch work in the levee plans was ordered to be omitted.

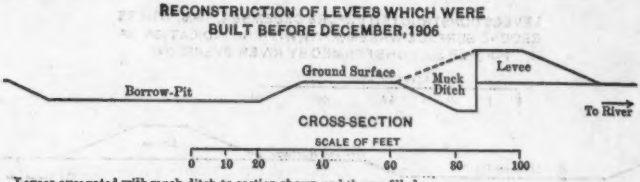

FIG. 37.

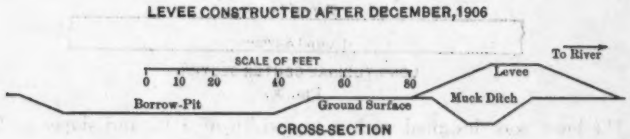

FIG. 38.

Material for the levees was taken from borrow-pits on the land side. It was fully realized that this was not in accordance with the usual practice, but it was decided on after careful consideration of the advantages and disadvantages. The location of the levee was forced very close to the river for a great portion of the way, and the levees of the Yuma Project on the opposite side were also so close to the stream that the distance between was in many places only 1 400 ft.—an exceptionally narrow waterway for such an unruly stream as the Colorado. As it was certain that the current at flood stages would be very great in such sections, it was extremely desirable not to disturb in any way the rank vegetation between the river and the levee, as it could not help but greatly break up and retard currents and thus protect the levee from erosion.

Experience with the levees of the Yuma Project showed that the hope that borrow-pits would be silted up was vain, and instead, that

they would be cut together to form a continuous canal having eddying currents below the traverses during high floods, unless extensive brush abatis work was used. This sort of protection was deemed very unsatisfactory, because, though the Mexican Co. actually owns the land on which the levees were located in Mexico, it is practically impossible to exercise very much control over the Indians, owing to the indifference of local Mexican authorities. The Indians have always utilized any overflowed areas along the river as they wished, for their little garden patches, and these levees must absolutely cut off such water. For a long time it was utterly impossible to keep these nomads from planting seed in the borrow-pits, where the ground remains wet the longest, and from destroying all brush growths that start therein. It was considered impracticable to maintain brush abatis work, which, when dry, would only make it easier to burn off the area in front of the levee for a garden clearing.

On the other hand, the land spoiled in making borrow-pits was of little value, being non-irrigable under existing conditions. There are no quicksand pockets above the water-table in that region, and, the soil being alluvial silt with more or less sand intermixed, there was consequently no fear of water-soaked material running, such as occasionally causes levee trouble elsewhere. There is also along the river no surface soil crust, which it is undesirable to disturb in levee building.

The only pertinent objection to land-side borrow-pits in this case, therefore, seemed to be the matter of increased total head, which it was decided did not outweigh the advantages of an undisturbed rank vegetation as a protection against the erosion of the water slope by swift currents.

These levees were built by the Shattuck and Desmond grading outfit on force account, with the intention of changing to a yardage basis as soon as possible. On December 6th, 1906, about 1½ miles above and below the dam, respectively, had been completed, 5 miles more were under construction, and the ground was cleared for another 2 miles.

Situation of the California Development Company and the Mexican Company.

About November 15th, 1906, the various operations along the river were making satisfactory progress, and the writer for the

first time since June 1st left the river, hurriedly investigated the condition of the C. D. Co. and the Mexican Co. and reported his findings toward the end of that month. As a result of this, when the second break occurred a few days later, he advised against further advances by the Southern Pacific Company, and President Randolph concurred and so reported to Mr. Harriman. The fact that such a decision was made by the Harriman interests unqualifiedly has not been generally accepted without some mental reservations. It may be interesting, therefore, to make some excerpts from this report. The balance sheet for the combined C. D. Co. and Mexican Co. was approximately as follows:

ASSETS.

Real estate (chiefly in Mexico)		$545 037.26
Stocks (chiefly unsold water stock)		175 600.00
Plant:		
Machinery and equipment	$179 621.82	
Branch railroad track	63 000.00	
Canals in Mexico	375 000.00	
Canals in United States	308 616.37	
		926 238.19
Accounts receivable (chiefly notes secured by water stock)		235 137.02
Total		$1 882 012.47

LIABILITIES.

S. P. Co.—Audited bills and interest		$1 532 595.73
General audited bills and interest		73 786.72
Bonds and accrued interest		515 200.00
		$2 121 582.45
Damage claims (probable):		
New Liverpool Salt Co	$50 000.00	
Land owners	200 000.00	
Water Companies Nos. 6 and 8	500 000.00	
S. P. Co	1 000 000.00	
Inter-California R. R.—S. P	250 000.00	
		2 000 000.00
Total		$4 121 582.45
Net liabilities		2 239 569.98

The possibility of extending the canal system and selling additional water rights was discussed, and the opinion was offered that such possible returns would probably just about suffice for building a canal from the river into the valley, to take the place of the Alamo channel, which might be necessary in 5 or perhaps not for 20 years; and for building new controlling works on it in the valley.

The conclusions were that maintenance and operation expenses, properly estimated, would take up the returns from the sale of 600 000 acre-ft. per annum. The cost of protecting the region from the Colorado flood-waters was set down as problematic, probably averaging $100 000 per year, and fluctuating enormously, and it was advised that the task of controlling the river was too serious a tax on the enterprise under any possible circumstances, while international complications would probably mean considerable delay in arranging for such work equitably and satisfactorily.

The Second Break.

On December 5th, 1906, a severe flood came down from the Gila, as shown by Plate XLVII. Superintendent Hind and the writer, who were in Imperial Valley at the time, received telegraphic notice from the water-shed, and went at once to the river. For reasons already explained, trouble was expected from water getting under the levees, because no muck-ditch protection had been provided, and a large force of men was detailed to watch the sections for a mile on either side of the Hind Dam day and night as soon as water came even near the river toe of the levee. Information from the upper stations throughout the Gila water-shed frequently indicate floods which never materialize, and this was another case of the "truth itself" being not believed. There was so much accumulated work in the valley that there was no time to watch a discharge of 30 000 sec-ft., although a river stage which would test out and soak up the levees was obviously of great importance. Mr. Hind and the writer were in Yuma, returning to the valley, when the flood reached the Lower Heading, where the river began rising at midnight and rose at the rate of 1 ft. per hour until the peak was reached early in the morning. At 3:30 A. M. Mr. Hind and the writer left Yuma on the work train, reaching the Lower Heading about 5:15 A. M., and found three serious and distinct breaks within 100 yd., the first one being about 2 400 ft. from the south end of Hind Dam. In addition water was finding its way under the levee in

about ninety other places, within the stretch where the water reached the toe of the levee, or about ¾ mile above and an equal distance below the dam. Mr. J. Calvert, General Foreman, had fully obeyed instructions, and when the water began to reach the toe of the levees at the lowest point, had commenced work with his force of about 75 men, doing all that seemed possible. The trouble was not that any one break could not have been easily handled, but that so many points of weakness were developed practically at the same time. Indeed, it is really remarkable that the situation got beyond control in only these three places.

A part of the general arrangements with the Inter-California Railroad was its use of the Hind Dam. On the south end of this dam the proposed alignment turned a small angle to the right, and it was planned to have the fill for the next 2 miles without any openings—constituting thus a spur levee to prevent any water which passed through the main levees from reaching the old channel of the break beyond the dam. Had this fill been ready, or had the first serious break been 500 ft. farther along, sand bag diking across the traverses and out into the brush to force the water to spread out and follow an old and well-defined swale which entered the Alamo 2 miles beyond, would have been easily possible. In either case, the damage would have been limited to losing less than 1 000 cu. yd. of levee section.

As it was, however, the water coming through the breaks filled the borrow-pits on the land side, overflowed the intervening traverses, and, as the land in general sloped westward, over-topped the last traverse by the channel of the break below the dam, and caused a rapid grade recession from there, following the borrow-pits through the nearest break. When Mr. Hind and the writer reached the scene, the first of the three breaks was beyond control, and the situation was hopeless.

By the time the grade recession had reached and passed through the break, the flood had crested, and the water had risen against the levee to a depth of about 4 ft. The water rushing through rapidly increased, and cut into the far side of the bank, and was deflected and began cutting into the land side of the levee. This soon breached the dike about 1 000 ft. from the end of the Hind Dam. This breach became the main break, and was rapidly widened and deepened until, within 24 hours, the old channel was again entirely dry and the river had been re-diverted into the Salton Sea.

The men of the grading outfit engaged on levee extension work 3 miles down the river were flooded out, and the steamer *Searchlight* was sent to relieve them. The re-diversion into the Salton Sink occurred so rapidly that the steamer was left grounded there in the old channel, and inasmuch as it was the only craft on the river not controlled by the contractors on the Laguna Weir, this was a serious matter.

The Southern Pacific Quits.

This disaster brought to the higher authorities of the Harriman Lines a thorough realization of the size of the great task of controlling the Colorado. The imperative need of invulnerable levee construction for at least 10 miles along the river was made evident, and the difficulty and cost of building and maintaining such a system was emphasized. Entirely aside from the very great cost of bank protection work to prevent the breaching of levees through the side cutting of the banks, was the difficulty of building in such bad soil a line of defence which would be absolutely dependable.

The financial condition of the C. D. Co. and the Mexican Co., as just explained, was very bad, and, under the most favorable circumstances possible, the chances of the Harriman interests ever being able to get back very much of the moneys already advanced were extremely remote. In addition, however, it was apparent that an unusually efficient and expensive levee system would be required, the first and maintenance cost of which was too large a burden to undertake.

The stockholders of the irrigation properties notified the Southern Pacific management controlling them that the properties could not be expected to do such overflow protection work, and indeed should not pay more than a proportional part based on the total value of the property interests in jeopardy, especially in view of the immense amount of work which had already been done at its expense. Urging that the irrigation company had caused the menace (which may or may not be entirely the case) had not the slightest significance to the Southern Pacific interests, which were really the only ones with any funds, collateral, or equipment, and were in no possible sense responsible for any changes in physical conditions along the Colorado River, except to make them very much better than they otherwise would have been.

FIG. 40.—LEVEE FAILURES RESULTING IN SECOND BREAK, DECEMBER 7TH, 1906. NOTE THE SHORT LENGTH OF THE TWO GAPS.

FIG. 41.—EFFECT OF FLOOD OF DECEMBER 7TH, 1906, ON LEVEE OF U. S. RECLAMATION SERVICE, OPPOSITE LOWER HEADING.

On the other hand, it was recognized that something would have to be done very quickly because the summer flood of 1907 would in all probability cause such grade recessions as to force a hurried exodus from Imperial Valley which would be without a parallel in history. The chances of such grade recession extending far enough to render the control of the river after that flood very much more difficult, were remote. The matter was made complex by the fact that all work had to be done in Mexico and practically all property interests in jeopardy were in America; and there were no provisions, State or National, to handle such a curious situation. Unless the river was turned and kept going to the Gulf, the Southern Pacific would suffer the loss of its traffic from the Imperial Valley and would have to change its line and build 100 miles of track, but, to obviate these losses would certainly not justify it in undertaking to control the river single-handed.

Accordingly, the people of Imperial Valley were notified that, while the Southern Pacific would be very glad to place such equipment and organization as it had along the river at the disposal of any party who wanted to proceed with the work, and would be willing to contribute toward the expenses thereof in proportion to the value of its interests as compared to all others in jeopardy, it would not advance additional funds without a definite arrangement for being reimbursed. Work on a roadbed following the —100-ft. contour was ordered and rushed to completion. The cost of grading was very small, and such a line would preclude the possibility of the interruption of transcontinental traffic by the Salton Sea for at least 4 or 5 years, during which time a line lying entirely above sea level could be economically constructed.

On December 13th a mass meeting of the people of Imperial Valley was held in Imperial, and subscriptions for river control work, totaling $950 000 were made by various interests. These were the Imperial Valley Improvement Company (the practical successor of the Imperial Land Company) $100 000; the Holton Power Company, $100 000; the C. M. Co., $250 000, and the directors of the mutual water companies together a bond issue of $500 000. All these were made promising payment 90 days after the break should have been closed successfully, the railroad to assume all risk of the work.

While considering these subscriptions, it was urged in opposition that the mutual water companies might not be able legally to issue

bonds or expend money for river protection work at all, or indeed that the people of the valley could raise money, except by individual subscription, for work to be done in Mexico. Requests were sent out in all directions, resulting in numerous civic and political bodies and authorities of the State wiring to President Roosevelt asking to have the United States Government act in the emergency. The President acted promptly, and as the result of telegraphic correspondence with Mr. Harriman, instructions to start work on the river were received on December 20th.

In the meantime the organization at Andrade and at the Lower Heading had been kept intact. The quarry was developed, sidings just across the border in Mexico were lengthened to 7 000 ft., and material and equipment of all possible kinds which might be needed were gathered in readiness to proceed whenever orders might be received.

Senator Flint's Bill.

Immediately after the holidays, Senator Frank C. Flint, of California, introduced a bill in the Senate providing for the appropriation of $2 000 000 to handle the situation. Under the provisions of this bill, whatever sum might be found just should be paid to the Southern Pacific Company for work then under way, and the remainder should be utilized to establish an irrigation project for Imperial Valley by the U. S. Reclamation Service. The idea was that the irrigation of American land in the Salton Basin and the regulation of the Colorado River were inseparably connected, and that as soon as the situation should be under control by the Southern Pacific Company, the entire matter should be turned over to the Reclamation Service for future handling. Director Walcott sent Professor A. E. Chandler, of the University of California, then with the Reclamation Service, to the scene to make a special report, and President Roosevelt, on January 12th, 1907, sent a special message to Congress severely criticizing the promoters of the C. D. Co. and the management of the properties, and urging the passage of the Flint bill in order to relieve the settlers of Imperial Valley from the "injustice" they were enduring.

When the bill reached the House, Hon. S. C. Smith, Representative from the Eighth California Congressional District—in which Imperial Valley is located—opposed it, advising that he did so because of re-

quests from his constituents in the valley. There can be no doubt that, with very few exceptions, the farmers in the valley objected to the bill, preferring the existing irrigation arrangements to those which would follow under the Reclamation Service,* and desiring governmental assistance in river protection work, and in that only. Largely due to Mr. Smith's efforts, the bill failed to pass.

Change in Organization.

In spite of the opinions of visiting engineers, experience during the first closing left little doubt that there would be any particular difficulty in making the second closing without any brush mattress foundation. Even had such been deemed desirable and worth the delay in time, very little brush was available nearby because of the large quantity used for the first closing. It was felt that the work was standardized and consisted in throwing ordinary railroad trestles across the break and from them making rock fill dams in series. The levee construction work to be done, however, was very much of a problem in every way. Superintendent Hind was transferred to the levee reconstruction and extension, and Mr. Clarke, formerly Resident Engineer of the Tucson Division, Southern Pacific Company, came to the work as Superintendent of the second closing on December 20th, 1906.

At the same time, an entire change in the accounting system was ordered, effective December 7th, the date of the break. Prior to that time the work had been done by the Mexican Co., with material and funds supplied by the C. D. Co., and the latter corporation from time to time borrowed money from the Southern Pacific Company. This was changed so that the Mexican Co. was furnished money by Epes Randolph, Agent of the Southern Pacific Company, and the C. D. Co. had nothing to do with the matter whatsoever. On the American side of the line, the operations were exclusively under the name of "Epes Randolph, Agent, S. P. Co." The railroad furnished supplies and material to him under the same arrangements and conditions as it had furnished them to the C. D. Co., namely, at cost plus 10 per cent. One marked difference, however, occurred in making these charges, namely, that after January 1st all freight bills were rendered at traffic

* Among the objections, the two most important were the probable increase in cost of water and the necessity for reducing individual holdings probably to 40 acres or less.

rates instead of at ½ cent per ton-mile, this being made necessary by the provision of the Interstate Commerce Commission which took effect at that time.

Closing the Second Break.

The work of closing the second break was in several ways interesting. To begin with, the current struck where the south end of the Hind Dam had been, and was there deflected sharply, resulting in very serious erosion. Few people who saw the break at this stage believed it possible to hold this erosion from going entirely through the structure, but by unloading immense quantities of rip-rap, the fill was held, the water in front cutting to a depth of about 42 ft.

Two trestles were decided on and started, five pile-drivers being used, one at each end of each trestle and a floating machine in the middle of the stream. These trestles had to be thrown in a curve concave up stream to connect with the levee on the south side, therefore the piles had to be driven in a very strong quartering current. The channel was narrowed and the bottom cut down to a maximum depth of 38 ft. In driving 90-ft. piles under these conditions, there was constant danger of overturning the driver and losing the machinery, therefore two complete pile-driving outfits were kept in reserve and two boats waited below the trestle to pick up any men who might be thrown overboard.

On December 28th one line of trestle was practically completed, when a flood, shown on Plate XLVII (which, by the way, let the stranded steamer *Searchlight* get back up the river to the work), carrying unusual drift, tore out about one-third of it. Three times this occurred, resulting in the loss of a large quantity of bridge material. All this was obtained through Mr. R. H. Ingram, General Superintendent, Southern District, Southern Pacific Company, and the following telegram from him is interesting:

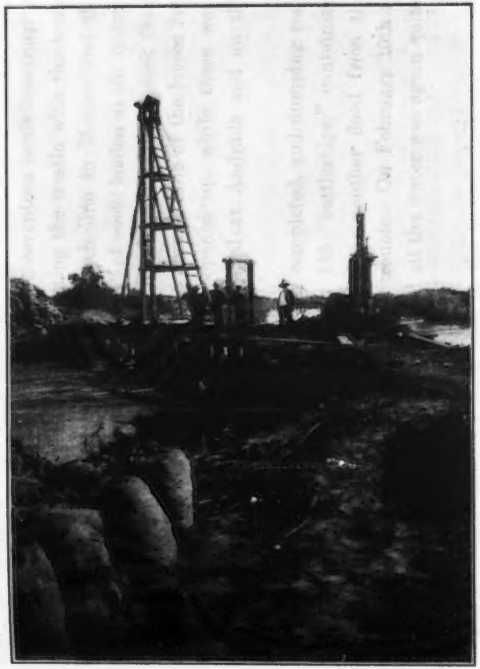
"Los Angeles, 1/14/07.

"H. T. C.—

"We have exhausted all available supply of piles in San Diego and Southern California. There is very little hope of getting any in Northern California. If you feel that you will need any more please let me know at once as we must make arrangements with the Atlantic System.*

"R. H. Ingram."

*The lines from New Orleans to El Paso.



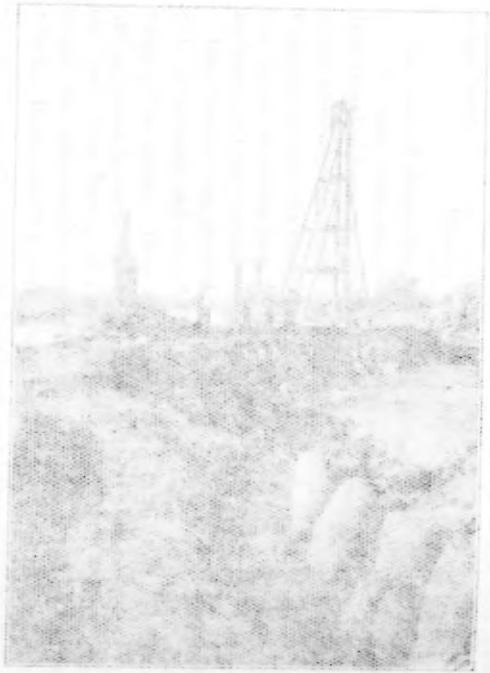


FIG. 42.—CLOSING THE BY-PASS AROUND ALAMO WASTE-GATE. DISCHARGE, 2 500 SECOND-FEET. FINAL HEAD, 10 FEET.

FIG. 43.—RECONSTRUCTION OF LEVEES, SHOWING MUCK-DITCH.

On January 26th, 1907, the first trestle was finished for the fourth time, all stringers were in place, and the track was two-thirds laid. In the second trestle, 50 ft. above the first, seventeen bents remained to be driven. The fill on the south, connecting the trestle with the levee, was 60% completed. Stored on the branch line in Mexico and the United States there were 175 "battleships" of rock, loaded at the quarry of the C. D. Co. by steam shovels, and 100 flatcars of large rock from the distant quarries. At each end of the dam, ½ mile of the levees had been reconstructed, and 1½ miles more opened up, while there were 1 100 men and 1 000 head of stock engaged at Andrade and on the river.

On January 27th, the first trestle was completed, and dumping rock from it began at 5 P. M. By daylight 145 "battleships," containing 6 600 cu. yd. of rock had been unloaded as another flood from the Gila began arriving, but it caused little trouble. On February 10th at 11 P. M. the second break was closed, and all the water was again going down the old channel.

The following materials were used in the second closing:

4 000 ft. of railroad trestle—of this, 1 800 ft. were carried away by floods before either trestle could be completed or any rock could be dumped. When rock dumping began, no more trestle was lost; the final result was two trestles, 50 ft. apart, and each 1 100 ft. long, or 2 200 ft. of trestle.

16 000 ft. of 8 by 17-in. Oregon pine stringers—8 000 ft. of these were removed.

1 200 piles.

45 000 cu. yd. of earth placed by teams—making 960 ft. of earth dam to connect with the levee, 31 000 cu. yd. being placed by February 2d.

2 157 car loads, or 55 000 cu. yd., of rock used prior to actually closing off the water.

221 car loads, or 7 735 cu. yd., of gravel.

203 " " " 8 840 " " " clay.

The discharge of the river when work began on December 20th, 1906, was 12 500 sec-ft.

Dec 31st	48 900 sec-ft.
Jan. 7th	15 200 "
Jan. 12th	44 300 "
Jan. 18th	16 300 "
Jan. 20th	33 400 "
Jan. 27th (when first rock dumping began)	13 800 "
Feb. 3d	31 300* "
Feb. 7th	17 700 "
Feb. 11th	20 800 "

After the break was closed, 956 car loads, or 38 240 cu. yd., of clay and 873 car loads, or 33 555 cu. yd., of gravel were used to complete the Hind-Clarke Dam. The rate of dumping rock, etc., is shown by Table 14.

TABLE 14.—CAR LOADS OF MATERIAL.

	"Battleship."	Flatcar.	Clay.	Gravel.
January 27th to February 2d	606	501	8	15
February 3d to 9th	489	386	58	140
February 10th to 10th midnight	85	91	38	28
	1 180	977	104	173
February 11th to 15th	323	77	99	48
	1 503	1 054	203	221

The water was shut off on February 10th at 11 P. M. and the flatcar rock then on hand and *en route* was unloaded in order to release the cars, the rock from Andrade being used until the 18th in raising the dam hurriedly to protect it against possible floods. The total car loads of material used in the closing and in the finishing up of the Clarke Dam were:

"Battleship."	Flatcar.	Clay.	Gravel.
1 490	1 182	784	873

During the entire operations subsequent to the second break, including finishing up the Hind-Clarke Dam complete, but exclusive of the rip-rap to hold the grade before the completion of the trestle over the break on January 27th, the following car loads of material were used:

"Battleship."	Flatcar.	Clay.	Gravel.
1 517	1 240	956	2 052

*4 300 sec-ft. down the old channel.

The clay pit was closed on March 3d, and the Hind-Clarke Dam was finished, except for the final surfacing with the spreaders, on March 15th.

Two steam shovels, and part of the time three (not including the one in the Mammoth gravel pit) were engaged from September, 1906, to May, 1907, at $7.50 per day, prior to January 1st, 1907, and at $12.50 thereafter. During the period, there were from 1 to 12 locomotives, at the following rates:

American, light	$ 8.00 per day.
Moguls	10.00 "
Consolidation	12.00 "
Car pile-drivers, working 40 days at	10.00 "
Donkey engines	1.50 "
Skid-drivers, complete	2.50 "

The Clarke Dam extends from the south end of the Hind Dam across the second break to the levees on the south. These two dams, consequently, constitute one continuous structure, which is known as the Hind-Clarke Dam.

RESULTS OF EXPERIENCE IN CONSTRUCTING THE HIND-CLARKE DAM.

The experience obtained in making these two closings, according to the methods used, afforded some information regarding work of this class which is believed to be entirely unique and in some respects

unexpected. In the first place, it was shown that the brush mattress bottom protection is not only unnecessary, but adds to the cost, both in time and money, provided rock is thrown in at a reasonably rapid rate. In discussing the possibility of handling the situation along the lines decided on, the opinion was freely expressed that the rapid current would carry smaller rocks indefinite distances down stream, and that the larger ones would quickly settle into the soft, water-soaked, alluvial soil to indeterminate but very great depths. As a matter of fact, a relatively small quantity of "battleship" rock sufficed to blanket the bottom of the stream with a mattress of rock which fulfilled essentially the same function as a mattress of brush.

In this type of construction it is desirable to have rock of various sizes, such as obtained by blasting large quantities in the quarry and loading with a steam shovel. Large stones (from 1 to 7 or 8 tons), which can be loaded on flatcars only with derricks, are effective, but not absolutely necessary in raising short sections where, through carelessness or a little unexpected settling, an unusual quantity of water is going over a low place in the dam with consequent menacing velocity. Such large rocks were unloaded by a great number of men using pinch-bars, and, to prevent upsetting, the cars were chained to the stringers when unloading especially heavy rocks. One man was killed during each closing by going overboard with a large rock, and these were the only serious accidents. No equipment was lost during either closing.

Two trestles were used in both cases. These were 30 ft. apart in the Hind Dam, and 50 ft. apart in the Clarke Dam, the idea being that the current would prevent building a rock mattress extending far enough up stream by merely dumping rock from the trestle on which the closing was made. Careful examination of the resulting cross-section, when the water was shut off the first time, seemed to indicate pretty clearly that it was a needless precaution to have two trestles for final heads of 14 ft. or less. As there was to be no mattress in the second closing, it was decided to use two trestles, in order to take no avoidable chances. Everything worked so well that it seemed safe to do a little experimenting, and, practically speaking, the second break was closed from the lower trestle alone.

In both cases the fills at both ends were kept well above the possibility of being overtopped, and of uniform heights across the re-

FIG. 44.—RAIL IN LOWER TRESTLE CAUSED BY DRIFT BREACHING AND TAKING OUT FOUR BENTS OF UPPER TRESTLE.

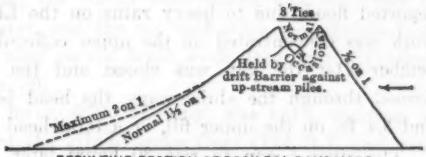
FIG. 47.—MUCK-DITCH CONSTRUCTION IN LEVEE EXTENSION WORK, 1907.



maining length. Train loads extending entirely over the trestles were unloaded most of the time; but short sections of the fill which were low were promptly filled in, and great care was exercised to distribute the overpour evenly. Once, in the building of each of these structures, a local settlement occurred, resulting of course, in large quantities of water going over the relatively short lowered section. The same experience was had in making the upper coffer-dam wall for completing the gap in the Laguna Weir. The construction of a rock fill barrier dam was regarded as impracticable by engineers, because of just such occurrences surely breaching the barrier hopelessly. In point of fact, continued dumping of even small rock soon stops such so-called breaks, although that results in the waste of much material.

The chief difficulty is caused by drift in the stream being caught by the trestle. Theoretically, such drift should be very easily broken up and carried to the bottom by dumping rock. In practice, however, there is difficulty in keeping drift accumulations from seriously threatening the trestle. In Fig. 44 a very sharp kink will be observed which is due to drift accumulations throwing the entire trestle out of line. Two or three bents were taken out of the upper trestle from this cause.

It was found that a cross-section of the dam under the trestle is about as shown in Fig. 48, so that it is the inevitable little breaks and slides, rather than actual settling, which occurs in such cases. Local readjustments or settlings were easily handled with an estimated quantity of 100 sec-ft. per lin. ft. of dam going over the rock fill. How much more could be handled safely with the rock available is not known. The writer would say that experience along the Colorado River would not justify using the rock fill barrier dam method for quantities in excess of half that flow, on an average, although possibly much greater rates of discharge over such a structure might be safe. The quantity which went over the 680-ft. crest was 27 000 sec-ft.

RESULTING SECTION OF ROCK FILL DAMS MADE DURING FIRST AND SECOND CLOSINGS

FIG. 48.

The total length of rock fill dam used in the trestle was 1 125 ft., and the water was allowed to pour over 680 ft. of it; the trestle consisted of 4-pile bents, all piling vertical, 15-ft. spacing

between bents, average penetration of piling about 18 ft. The total head, or the difference in water surface above and below the dam, was 12.45 ft., all developed in place in 13 days and 5 hours.

By way of comparison, the building of the upper and lower sides of the coffer-dam within which the central or channel portion of the Laguna Weir was completed is most interesting. One line of trestles, 740 ft. long, was thrown across the stream just above the upper edge of the weir, and another trestle, 728 ft. long, below the lower edge, the trestles being about 400 ft. apart. From these trestles rock fills were built up, and all the water in the river was forced through the sluice-gates at the ends of the weir, the Arizona sluice-way being 2 700 ft. distant and the California sluice-way 1 500 ft. There were well-developed quarries at each end of the weir, and the haul was from 1 500 to 3 500 ft. The following equipment was used:

One 2½-cu. yd. Atlantic type steam shovel (in California quarries).
One 2½-cu. yd. Marion steam shovel (also in California quarries).
Seven 12½-in. American steam hoists, mostly in the Arizona quarries.
Six 18-ton standard gauge Davenport locomotives.
Fifty 6-cu. yd. dump cars.
Eighteen 5-cu. yd. steel dump cars.
Fifty flatcars.

By December 10th, openings to and from the sluice-ways were completed, and the rock fills were advanced until the head was 2.8 ft. On December 19th, the head had been increased to 6.9 ft., of which about 3.5 ft. were on the lower rock fill, while 8 500 sec-ft. were going over these and 3 200 sec-ft. through the sluice-ways. On account of a reported flood, due to heavy rains on the Little Colorado water-shed, work was concentrated on the upper coffer-dam, and by noon of December 21st the gap was closed and the river—9 950 sec-ft.—was turned through the sluice-ways, the head being 3.5 ft. on the lower and 5.4 ft. on the upper fill, or a total head of 8.9 ft.

The river began to rise 30 hours later, and crested at daybreak on the 23d, the discharge being 35 250 sec-ft. Water passed over the entire length—4 200 ft.—of the completed dam, 3.2 ft. deep, but lacked 10 in. of reaching the general level of the upper rock fill. The lower coffer-dam was injured considerably by water running length-

wise of the dam on the down-stream side, so that the upper rock fill stood all the head, which reached a maximum of 10.1 ft. Two weeks later the damage sustained by the railroad tracks on top of the finished parts of the structure had been repaired, the lower coffer-dam had been completed above the danger line, and work had commenced on the 650-ft. gap in the main structure within the coffer-dam.

About 600 men were engaged on the closing, working in two 10-hour shifts. The total cost of turning the river through the end sluice-gates and constructing the coffer-dam is given as $86 072; the total rock used was 59 750 cu. yd. of excavation, making 82 800 cu. yd. in the rock fill. No lives and no equipment were lost, and the time required after beginning to dump rock was about 2 weeks.

The total cost of the rock work in the fills, including trestles, quarrying, train service, superintendence, depreciation, and all overhead charges of the project, was $1.04 per cu. yd., of which 45%, or $38 720, was for excavation, Class 1 (quarrying solid rock).

Completing the Clarke Dam.

The Clarke Dam was rendered impervious by dumping Mammoth pit gravel and clay from both trestles. No attempt was made to puddle or settle the material by hydraulicking, as was done with the Hind Dam. Small local settlements occurred from time to time for a year after the dam was completed, but nothing disquieting in any way. Imperviousness was very quickly obtained, indeed, long before the structure was raised to grade and widened to its proper dimensions.

In constructing the Hind Dam, every effort was made to hurry the work, and the stringers were not taken out. With the Clarke Dam, all stringers were removed, the tracks were raised and narrowed to 13 ft. from center to center, and the top and sides were finished off with the gravel spreader used on the levee work, leaving the finished structure as shown by Fig. 50.

Spur Levee.—A spur levee, 8 700 ft. long, was built, starting at the elevation of the top of the Hind-Clarke Dam (124 ft.), and with an initial descending grade of 0.5 per cent. The purpose of this levee is to prevent water from any break in the main levee south of the Hind-Clarke Dam from getting into the old dry channel below, as happened when the second break occurred. It is intended to hold such water back and make it spread over the low country in a sheet.

This levee, which was decided on, but not started, before the second break, is located along an old overflow channel slightly higher than the country on either side, and where test-pits showed need for little muck-ditching. Arrangements were made later with the Inter-California Railroad to change its alignment to use this spur levee and the Hind-Clarke Dam, and it was thus extended by this railroad grade for 4 miles without any opening.

Changes in Staff.

The success of the Hind-Clarke Dam being assured, arrangements were concluded whereby F. C. Herrmann, M. Am. Soc. C. E., on February 1st, 1907, became Assistant Chief Engineer of both the C. D. and Mexican Cos., particularly for the purpose of making surveys and estimates for reconstructing and extending the canal system in Imperial Valley. About March 1st, the Clarke Dam being then well advanced, Mr. Clarke was transferred to the valley and appointed Superintendent of Construction of both companies, Superintendent Hind remaining in charge of all operations along the river until they were finished, when he was transferred to the Harriman Lines in Mexico, on August 1st, 1907. On May 1st, Mr. Clarke returned to the railroad as Resident Engineer of the Coast Division. Nearly two years later he came back to the valley as Superintendent of Imperial Water Company No. 1, and early in January, 1910, was appointed by the Receiver of the C. D. Co. as Assistant General Manager and Chief Engineer, which position he resigned in April, 1911. The writer remained as General Manager of the properties, but relinquished the title of Chief Engineer in both companies in July, 1908, and issued circulars advancing Mr. Herrmann to the positions which he held until he left the companies, in March, 1910, after the appointment of a receiver. His successor in the Mexican Co., and its present Chief Engineer, is Mr. C. N. Perry, who first came to the valley with Mr. Rockwood in 1892, and was Resident Engineer of both companies from October, 1901, to August, 1906, and so was in immediate charge of most of the existing canal construction in Imperial Valley. Since April, 1911, Mr. J. C. Allison has been Chief Engineer of the C. D. Co.

Levee Reconstruction.

On December 20th, 1906, reconstruction on the existing levees was begun by tearing away the land side of the levee and excavating a

continuous muck-ditch as deep as the test-pits indicated to be necessary. The usual location of a muck-ditch is under the center of the levee section, but, in reconstruction work, this was not practicable, and besides, there were several reasons for location nearer the land toe, which will be mentioned later. The excavation was made as narrow as possible with the use of 4-horse Fresno scrapers, and it was found that the walls, not only of the natural soil, but of the recently constructed levee section, stood practically vertical without any caving. (Fig. 43.) The muck-ditch was excavated 1 ft. lower than the lowest layer of cracked adobe soil lying above the permanent water-table, and was refilled with the material removed, care being taken to keep out roots and clods of adobe exceeding 3 or 4 in. in greatest dimension. When the muck-ditch was completed, the land side of the levee was replaced to the slope of 3 to 1, instead of 2 to 1, as originally built. This work was started on force account, but was soon changed to a yardage basis, on the following schedule:

Levee section removed and replaced in embankment, 12 cents per cu. yd.

Muck-ditch excavation and refill, 17½ cents per cu. yd.

Reinforcing levee section, 19 cents per cu. yd.

The total earth handled was 199 000 cu. yd.

Levee Extension.—At the same time, surveys were commenced for extensions of the levee to the south. From Mile 7 the original alignment continued closely paralleling the river, and here all clearing had been done for 2 miles, and about 20% of the fill had been made. At the south end the flood caused three breaks, close together, through almost completed levee section. These breaks were due to bad material, that is, adobe which in working had broken up into small, hard clods. Directly across the river, similar breaks had occurred in the levee of the Yuma Project. In addition, the river during this flood showed a marked tendency to cut into the west bank immediately opposite.

The surveying party found that the most suitable soil and the highest ground, west of the river bank itself, lay along the Paredones overflow channel, which turned away more than a safe distance from the river. This channel was followed beyond the undergrowth to open country, and a hurried reconnaissance showed that at some future time, by building approximately 20 miles of levee, most of it relatively low,

connection could be made with the mountain chain on the west side of the delta at Cerro Prieto.

It was felt that the work now in progress was not merely to prevent flood-waters from quickly getting around the end of the Hind-Clarke Dam, but that very soon a system of dikes constituting a continuous line of defence for the Imperial Valley must be provided. President Roosevelt had not requested or authorized Mr. Harriman to construct anything so elaborate, but only what would form a protection for a few years at most, or until suitable permanent arrangements could be made to control the river properly. Such levees as were to be built, however, obviously should be constructed with a view to being incorporated in their entirety in the final scheme.

Two plans for keeping the overflow waters of the Colorado from getting into the Salton Sea are at once seen to be better than any others. One is a levee line along the Paredones ridge and north of Volcano Lake to Cerro Prieto, and the other is a line of levees parallel to the river practically to tide-water. These two plans are shown in Fig. 4. The first would protect all American interests and all that territory in Mexico lying to the north and west; the second would also protect the very large area lying between. This additional area is the property of the C. M. Co., and is in an extremely good location for irrigation from the Colorado. The C. M. Co., on being approached regarding the matter, thought that its present interests would be best served by the northern line of defence, which thus precluded the possibility of financial assistance from that company in giving additional protection, and the matter resolved itself into a decision as to which of the two lines could be built and maintained at least cost. The instrumental data regarding the region were insufficient to decide between the two possibilities, and, incidentally, the same condition of affairs unfortunately exists to-day. However, something had to be done, and at once. Based solely on careful reconnaissance, the northern line of levees was decided on, and the portion to be immediately built was located to a point about 10 miles below the Hind-Clarke Dam, this being enough to prevent water from getting around into the Alamo channel during flood stages. Aside from the desire to do only what was absolutely required and could certainly be finished before the summer flood, it was felt that the officials of the Mexican and American

Governments should have the greatest freedom in determining on future work for controlling the river.

The grade was determined from existing high-water marks along the line of the levee, checked by high-water marks along the line of the river; and several miles at the lower end has a grade of 3 ft. per mile. The cross-section decided on was a top width of 10 ft. and slopes of 3 to 1 on each side.

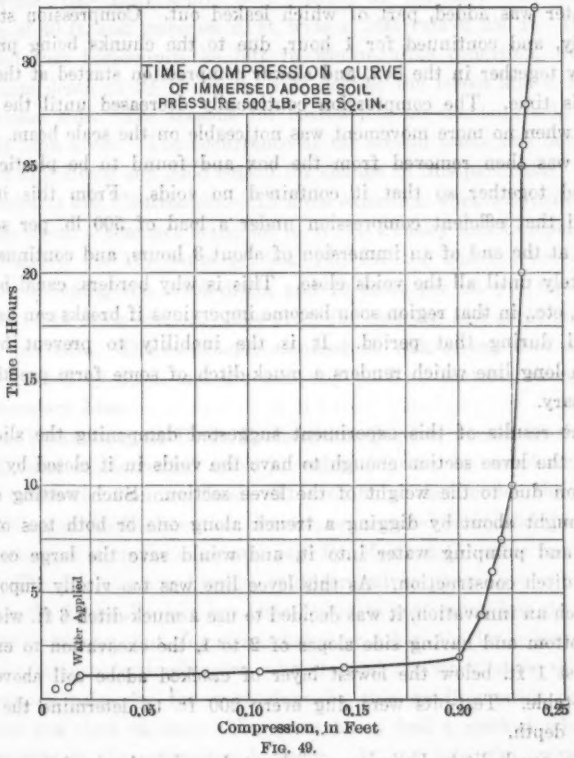


FIG. 49.

Muck-Ditches.—The Yuma Project, U. S. Reclamation Service, loaned one of its engineering corps, the method being to grant leave of absence to the members and have them carried on the payrolls of the Mexican Co. This corps was in charge of Mr. C. W. Ozias, Assistant Engineer, and was assigned to levee location work. Mr. Ozias was

instructed to make tests for determining the time at which efficient compression of adobe soil would take place with distributed loads, as under a levee when immersed in water. For these tests some hard chunks of adobe were taken from the muck-ditch excavation, 2 ft. below the surface at Station 178, and placed in a box 1 ft. in each dimension, in as nearly natural condition as possible, and kept under a continuous pressure of 500 lb. per sq. ft. At the end of 1 hour ½ cu. ft. of water was added, part of which leaked out. Compression started rapidly, and continued for 1 hour, due to the chunks being pressed closely together in the box, and slower compression started at the end of this time. The compression continually decreased until the 40th hour, when no more movement was noticeable on the scale beam. The mass was then removed from the box and found to be plastic and pressed together so that it contained no voids. From this it appeared that efficient compression under a load of 500 lb. per sq. ft. starts at the end of an immersion of about 3 hours, and continues indefinitely until all the voids close. This is why borders, canal banks, levees, etc., in that region soon become impervious if breaks can be prevented during that period. It is the inability to prevent breaks over a long line which renders a muck-ditch of some form practically necessary.

The results of this experiment suggested dampening the slickens under the levee section enough to have the voids in it closed by compression due to the weight of the levee section. Such wetting could be brought about by digging a trench along one or both toes of the levee and pumping water into it, and would save the large cost of muck-ditch construction. As this levee line was too vitally important for such an innovation, it was decided to use a muck-ditch 6 ft. wide on the bottom and having side slopes of 2 to 1, the excavation to extend at least 1 ft. below the lowest layer of cracked adobe soil above the water-table. Test-pits were dug every 200 ft. to determine the necessary depth.

The muck-ditch, however, was located under the land toe of the levee, as shown in Fig. 38, because it was not deemed desirable to prevent water from getting under the levee, but, on the other hand, to allow water to go under it as far as possible and still certainly hold it back with the muck-ditch. In this way the cracked adobe layers under the

levee section would become impervious as a whole in the minimum time after the water came as high as the toe of the levee.

The muck-ditch, except for two short stretches, was filled with the soil taken from it, only a few places being found in the 17 miles constructed where bad material occurred in such masses as to render it at all difficult to mix the adobe clods with satisfactory material taken out of the excavation.

Borrow-Pits.—Borrow-pits were located on the land side, leaving a berm of 40 ft. and traverses 20 ft. wide at intervals of 250 ft. It was specified that borrow-pits be left in workmanlike condition, with a maximum depth of 2½ ft. on the side nearest the levees and 4 ft. on the farther side. The reasons for borrow-pits on the land side have already been given. The occurrence of the second break was not considered to indicate any good reason for change in this particular.

Contracts and Contractors.—All levee extension work was done on a yardage basis, a contract being let to W. K. Peasley and Company, of Los Angeles, for 18½ cents per cu. yd., for the entire levee cross-section, including the muck-ditch, and 10 cents per cu. yd. for refilling the muck-ditch section. The price for clearing and grubbing was $2 000 per mile. The contractor assumed all risk of expenses due to delays caused by flood, and the company paid all customs charges at the Boundary Line.

The Yuma Project, U. S. Reclamation Service, permitted the use of 120 head of its rented stock in order to assist in completing the work before the summer flood. This outfit worked under the usual regulations of the Reclamation Service, on a rental basis, and the levee contractor put it on the work and paid the Mexican Co. what the latter paid. The Reclamation Service engineers advise that levee construction on the Yuma Project has been found to cost much less than Mr. Peasley's contract, but, for some reason or other, the levee contractor and the company's timekeepers, who checked the work, show that the contractor's price for the work done by this grading outfit on this job was less than its cost. The great hurry had a marked effect on the expense to the contractor, however. At any rate, the writer had an opportunity to examine the contractor's books later, and found that his profit on this job, with proper overhead and equipment deterioration charges, was 17.3%, and none of the possible delays due to floods, etc., occurred.

All work was very carefully inspected by an unusually large corps of men, and every precaution was taken to prevent any roots or rubbish from getting into muck-ditches or fills, and to see that all muck-ditch construction was carried to the depths ordered.

Railroad Track.—When completed, all levees, both as reconstructed and extended, were laid with a railroad track consisting of new 6 by 8-in. Oregon pine ties 8 ft. long and good old 56-lb. relaying steel obtained from the Southern Pacific Company. This was done partly because of the great advantage in maintenance work in future and partly to distribute a blanketing of Mammoth pit gravel.

On the completed work 15 miles of track were laid on the main levee, 1½ miles on the spur levee, 5¾ miles from Hanlon's Junction to the Lower Heading, 2.6 miles of sidings, quarry tracks, etc., in California, and 2.7 miles of sidings and double track over the Hind-Clarke Dam in Mexico. No part of this track has been taken up, but the main line and sidings between Hanlon's Junction and the end of the spur levee have been sold to the Inter-California Railroad.

Gravel Blanketing.—Vegetation, springing up like mushrooms on fills in the region, very soon precludes any possibility of inspection. The roots also attract burrowing animals. Furthermore, the danger of erosion on the water face by swift currents due to the fall of 3 ft. per mile made it exceedingly desirable to provide a better surface for the eddy currents. For these reasons all levees were blanketed on the top and both sides with a 15-in. layer of gravel from the Mammoth gravel pit, which, as has been said, supplies a cementing material which packs into an almost impermeable surface. It was practically impossible—and would have cost more money—to have blanketed the water face only, or to have put a greater depth on it than on the land side, because all the gravel was hauled in "battleships" which dumped equal quantities of material on each side. Ordinarily, two cuts of cars were unloaded, a considerable portion of the first being used on the top and to surface the track. The remainder was spread evenly over the two slopes of the levee with a home-made spreader devised and constructed with an ordinary flatcar temporarily taken for the purpose by Superintendent Hind at a total cost of $300. Its construction is shown by Figs. 45 and 52. With this the gravel was spread in an extraordinarily workmanlike manner at a cost of 0.1 cent per cu. yd. It worked in either direction, and the ordinary process was to have one cut of gravel

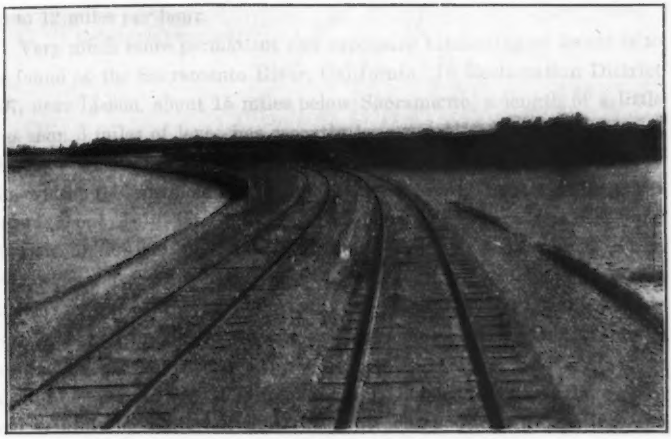

FIG. 50.—SOUTH END OF HIND-CLARKE DAM, SHOWING LOCATION OF SECOND CLOSING.

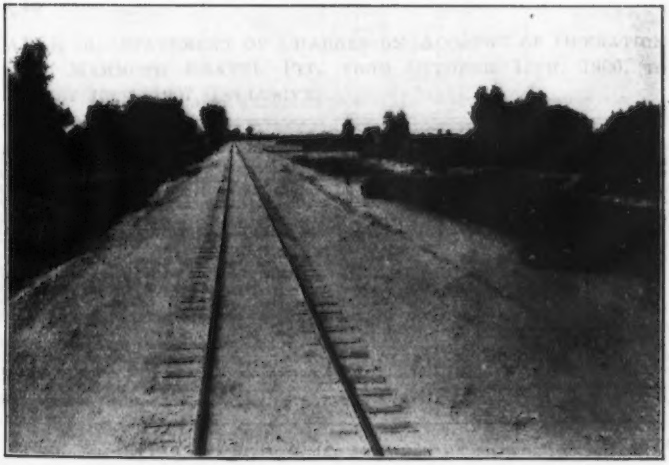

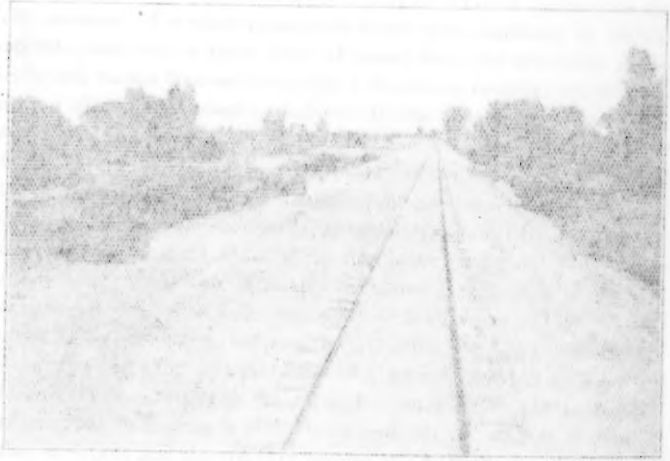

FIG. 51.—TYPICAL SECTION OF COMPLETED LEVEE WITH LAND-SIDE BORROW-PITS.

dumped along from 3 000 to 6 000 ft. of levee, and have a locomotive take the spreader on two round trips, the usual speed being from 10 to 12 miles per hour.

Very much more permanent and expensive blanketing of levees is to be found on the Sacramento River, California. In Reclamation District 307, near Lisbon, about 15 miles below Sacramento, a length of a little less than 3 miles of levee has recently been completed. This keeps out the back waters, in which there is little current, but, on account of the width, the wave action is relatively severe. The blanketing was begun about July 1st, and finished about December 1st, 1911, and consists of 700 000 sq. ft. of reinforced concrete 4 in. thick. (Fig. 56.) The reinforcement was a No. 10 gauge wire, 6 by 6-in. mesh, known as the Clinton Electrically Welded Fabric. The concrete was a 1:2:5 mixture, with rock brought by train from Oroville to Sacramento and thence by barge to the work, and cost there about $1.50 per cu. yd. The Reclamation District furnished the cement and reinforcing material, and the contractors, Richard Keating and Sons, of San Francisco, did all the other work. Mr. P. N. Ashley, County Surveyor of Yolo County, Woodland, was engineer. This covering cost 13 cents per sq. ft., or a total of about $94 000, or approximately $32 000 per mile. The average height of the levee was 22 ft.

TABLE 16.—STATEMENT OF CHARGES ON ACCOUNT OF OPERATION OF MAMMOTH GRAVEL PIT, FROM OCTOBER 15TH, 1906, TO JULY 15TH, 1907, INCLUSIVE.

Labor of gangs in pit getting out gravel		$23 312.46
Use of tools, 2% on above labor		466.25
Wages of trainmen in pit		3 108.91
Wages of enginemen in pit		2 111.65
Wages of operators, etc., at pit		897.19
Rental of engine in pit		2 302.50
Rental of steam shovel in pit		2 457.50
Fuel furnished for pit engine		4 495.14
Fuel furnished for steam shovel		1 594.41
Material purchased for pit engine repair	$184.63	
Material purchased for steam shovel	548.90	
Miscellaneous supplies	6 890.88	
Miscellaneous pit engine supplies	237.98	
		7 862.39
On store department expense, 5%		393.10
Shop repairs to steam shovel		727.19
On shop expense, 10%		72.72
Freight on material shipped to pit		6 345.86
Miscellaneous credit		119.74
Total		$55 927.53

July	.....	239	59	298
Total	1 528	9 206	3 339	14 073

The following is a detail of charges for royalty to Epes Randolph, Agent, S. P. Co.:

Value of tracks in Mammoth gravel pit, property of S. P. Co.		$16 832.00
Interest on $16 832.00 for 1 month at 6% per annum	$75.74	
Depreciation on $16 832.00 for 1 month at 5% per annum	70.13	
	$145.87	
Interest from December 1st, 1906, to July 15th, 1907, 7½ months		1 094.03
Total number of cars removed by Epes Randolph, Agent, S. P. Co., 9 206, or	$0.11883	interest per car.
Charge for gravel, 1 cent per cu. yd., 30 cu. yd. per car, or	0.30	royalty per car.
Total royalty charged per car	$0.41883	

Average cost per car, $55 927.53 divided by 14 073 = $3.9741014 per car.

In blanketing the levees, 5 285 carloads, or 185 000 cu. yd., were used. Of this, 4 803 carloads, or 168 000 cu. yd., were used on the 15 miles of main levees, or 16 800 cu. yd. per mile, and 482 carloads, or

17 000 cu. yd., on the 1.6 miles of spur levee, or 10 633 cu. yd. per mile.

Wing Levees.—In addition to blanketing the levees with cementing gravel, wing levees of gravel were built out into the brush, at intervals of about 400 ft. Their purpose is to check the flow of water in the V-shaped section between the trees along the near toe and the water face of the levee. Brush abatis work was not considered sufficiently permanent.

Telephone Line.—A two-wire, metallic-circuit, telephone line was constructed along the land toe of the levee after the gravel blanketing was finished. The location was unfortunate, as the rapid growth of willows and other bulb vegetation just behind the levee caused considerable annoyance and expense. It would have been much better to have put the line on the land slope, about 9 ft. from the center of the levee.

At each mile post a 6 by 8-ft. wooden tool and telephone house was put up, and white boards were nailed to telephone poles at points half way between, to mark the ends of the patrol beats. When floods are expected, sacks, tools, etc., can be distributed and kept in these houses, but between times it was found impracticable to leave anything but the telephones on account of malicious and thieving passers-by. It was also found that the heat in these houses during the summer was sufficient to melt down and spoil many of the rubber receivers, so that only metallic ones are now used.

General Data.—The total length when complete was 15 miles of main levee, having an average height of 8 ft. and an average muck-ditch yardage of from one-third to one-fourth of the main section, and 1.6 miles of spur levee, with a height of from 20 to 4 ft. and a muck-ditch yardage of about 15% of the main section. The quantities and costs of the extension work after the second break were as follows:

154 500 cu. yd. muck-ditch excavation at 18½ cents.
49 700 " " " " refilling, which was twice handled, at 10 cents.
443 000 " " embankment at from 18½ to 25¾ cents.
166 700 " " original specification at 18½ cents.
100 800 " " wide check at 19 cents.
154 545 " " checkerboard system at 25¾ cents.
9.66 miles of clearing and grubbing, $2 000.

FIG. 53.—TYPICAL SECTION OF COMPLETED LEVEE, WITH INTERRUPTED BORROW-PITS ON THE RIVER SIDE.

FIG. 54.—CONNECTING CHANNEL ERODED BETWEEN INTERRUPTED BORROW-PITS DURING SUMMER FLOOD, 1907.

Enlarging Main Canal and Building Secondary Levee on Canal Bank.—On November 26th, 1906, the *Delta* cut its way into the Main Canal just below the Boundary Line and commenced deepening it and building a secondary levee on its river side beginning at the concrete head-gate and working down stream. It reached the Lower Heading and connected the levee bank with the north end of the Hind Dam in May, 1907, and started back, improving the work at various places and continuing this until July 21st, 1907. This levee was built in exactly the same way as those around the Reclamation Districts of the Sacramento River, and was made with a minimum height of 3 ft. greater than the main levee opposite along the river bank. Though not a very efficient construction, it, nevertheless, will serve to prevent water from getting into the Main Canal from breaks in the main levee until they can be repaired.

Criticism of Levee Work Done.—All parties interested assumed that the Harriman interests were doing work in the capacity of a contractor for the United States Government, and not in any sense in its own behalf, and that the engineers of the Reclamation Service were "available for consultation." Certain of these engineers, individually, criticized the excavation of the borrow-pits on the land side of the levee, and so a request was addressed to the U. S. Reclamation Service for a Consulting Board to consider the situation and make recommendations. Such a Board was appointed, all being members of the Service, consisting of A. P. Davis, W. H. Sanders, D. C. Henny, and Francis L. Sellew, Members, Am. Soc. C. E. This Board inspected the works then under way, and on January 10th reported, recommending among other things that:

"4. Borrow-pits should be on the water side, berms between them of greater width than the pits, and care should be taken not to disturb the vegetation on the berms, which should also be protected at frequent intervals with barbed-wire fences of 4 to 5 wires, the bottom of which is at the surface of the ground * * *.

"7. The levees now built should be provided with cut-off trenches under the water slope and later provided with sheet-piling reaching below borrow-pits * * *.

"8. All levees should be blanketed with gravel on water slope and railroad track maintained on the levee."

The clearing for half of the extension work was done at this time, and the work already started was continued as theretofore. Fear of

erosion trouble, because of borrow-pits on the river side, and correspondence with the New York office of the Harriman Lines, resulted in the appointment of another Consulting Board consisting of Messrs. L. C. Hill, W. H. Sanders, and F. L. Sellew, Members, Am. Soc. C. E., of the U. S. Reclamation Service, and William Hood, M. Am. Soc. C. E., Chief Engineer of the Southern Pacific Company, which met at Yuma, thoroughly examined the work, and reported on February 14th, among other things, as follows:

"Existing Levee Between Cement Head-Gate and Dam Across Lower Intake.

"Spur dikes (traverses between borrow-pits) to be increased in width to at least 50 ft. on top and to be at least 4 ft. in height above the general level of the original surface of the ground, and to extend at least 300 ft. northerly from the northerly edge of the borrow-pits, and in this 300 ft. no borrow to be made on either side of this levee and no brush to be cut outside of the limits of the slope stakes.

"The end of the levee and for some distance on the sides on each side near the end to be thoroughly brushed.

"These cross-dikes to be not to exceed 600 ft. apart, and where now located essentially farther than this, an intermediate cross-dike to be put in * * *.

"An abatis work, being in effect a wire and brush wing dam, shall be built from a point on the slope of the levee nearest the river, situated well above high water, and such wing dam pointing down stream, approximately, per local conditions, at an angle of 45 degrees to the levee.

"This to be made with suitable posts or stakes driven into the levee and between the levee and existing trees and thence by assistance of trees acting as posts or stakes and suitable barbed wire fencing in two lines not less than 2 ft. apart, and the whole filled with brush thoroughly wired down.

"These wing dams to occur at no greater distance apart than 500 ft. * * *.

"Levee Below Dam Across the Lower Intake, This Being Partly Completed and Under Construction.

"The same remarks as to spur dikes and abatis work apply as stated above with reference to existing levee between the cement head-gate and the dam across the lower intake * * *.

"For the levees as constructed, material has been taken from the land side instead of the river side, as recommended by the previous Consulting Board of the Reclamation Service.

"As these conditions now exist, the present recommendations are with a view to make the levees as secure as practicable under present conditions * * *. As to the still unconstructed portion of the 10¼ miles of levee now intended to be constructed southwesterly from the dam across the lower or Mexican intake, this unconstructed portion being several miles, we recommend and expect that the recommendations of the Consulting Board of the Reclamation Service as to the position of the borrow-pits, position, depth and character of muck-ditches, and all other matters, be strictly complied with."

Accordingly, the additional levees, constituting 4.11 miles at the south end, were built with muck-ditch under the river slope and with borrow-pits on the water side of the levee. These pits are 100 ft. lengthwise of the levee, with spaces between them 100 ft. in width, on which every care was taken not to disturb the vegetation to the water toe of the levee. This method of borrow-pits is known locally as the "checkerboard" system. (Fig. 39.)

It is obvious that the checkerboard system requires an average haul of excavated material of about 175 ft. in excess of that required by the ordinary plan.

According to comparative tests, this increase in length of haul and inconvenience in handling teams resulted in increasing the cost of work about 6¾ cents per cu. yd. for embankment only, or approximately 30% of the cost of team work.

It was deemed advisable to complete the main levee high enough to be beyond danger of overtopping by floods before doing anything on the spur levees between the land side borrow-pits recommended by the Consulting Board on February 14th. About the middle of May bids were asked for constructing them (described in the first item of the report of the second Consulting Board), and the lowest bid was $40 per acre for clearing, $80 per acre for grubbing, and 31 cents per cu. yd. for embankment, making their estimated cost between $12 000 and $12 500 per mile of main levee. Accordingly, a third Consulting Board was requested, and was appointed by Mr. A. P. Davis, Chief Engineer of the Reclamation Service, consisting of C. E. Grunsky, Consulting Engineer to the Secretary of the Interior; L. C. Hill, and F. L. Sellew, which Board met on June 19th and recommended as follows:

"1. That in lieu of the general system of cross-dikes recommended by the second Consulting Board:

"(a) To complete at once the cross-dikes now being constructed

about 500 ft. southerly from the south end of the Clarke dam, making it 10 ft. wide on the top and giving it the same height as the crest of the spur levee with which it connects;

"(b) To construct a second cross-dike about 500 or 600 ft. southerly from the first, also 10 ft. wide on top and with a height the same as the crest of the spur levee with which it connects;

"(c) To construct cross-levees, with crest at least 4 ft. above made ground (tops 10 ft. wide) between the main levee and the secondary levee [along the east bank of the main canal from the concrete head-gate to the north end of the Hind Dam. H. T. C.], near or on the southerly bank of the old upper Mexican intake, and a second within about 1 000 ft. of the southern end of the secondary levee."

This recommendation was carried out.

Summer Flood of 1907.

The levees, including the secondary one along the Main Canal and the cross-levees mentioned in the recommendations of the last Consulting Board of the Reclamation Service, were completed on July 21st, 1907, and the Epes Randolph, Agent, fund was closed. The *Delta* continued deepening the Main Canal and at the same time raising and strengthening the secondary levee on its river side for 3 months longer, but it was estimated that the cost of such work balanced the deepening of the Main Canal done while strengthening the same secondary levee, prior to that date. After that time all charges for maintenance and operation of the head-gates and levee system were made by the Mexican Co. against the C. D. Co.

The flood of 1907 was a record one in total discharge, and probably would have been in gauge height reached at Yuma had it not been for the unusual conditions lower on the river. The old channel of the Colorado was considerably higher than usual, from the point of diversion to the Gulf, the erosion since the diversion and until the coming of the summer flood being of not much importance. It had been silted by the very small quantity of water carried as the re-diversion became more and more a reality, and, in addition, it was appreciably raised by the flood of December 5th which stranded quantities of heavy silt.

The vegetation of the lower delta lands depends on the annual overbank flows, and these lands had not been covered for two seasons, due to the river diversion north of the delta's dividing ridge, much of the light vegetation had perished, and large tracts of the region had been burned over. In designing the levee system it was deemed conservative

practice not to take into account any such increased overbank flow, and to consider that the whole channel would be much less efficient and would deepen much more slowly than usual under the coming summer flood, on account of the fact that the bed had been undisturbed for 2 years, and hence was compacted and dry. Cross-sections are shown on Plate L. However, the flood of 1907 came up very gradually, and eroded the bed most satisfactorily, and an extraordinary quantity of water went overbank, particularly to the west because of the greatly decreased vegetation. It thus happened that this record flood, confined between levee banks only 1 500 ft. apart, rose to only an average of about 6½ ft. below the top of the levee, varying from a minimum of 6 ft. to a maximum of 7 ft. The water got against the levees for their whole length, however, testing the muck-ditch construction thoroughly, and in no case was any weakness apparent.

The water-table throughout the region was raised above the bottom of the borrow-pits in many places, so that a considerable quantity of water, in some cases 2½ ft. in depth, slowly seeped into these pits. This water was always perfectly clear, came in very slowly, and gauge readings, kept in many of them and in pits nearby, showed that the levels in them fluctuated with the adjoining water-table at all times. As the flood went down, these waters lowered and disappeared, and a rapid growth of willows started, so that a very large part of the borrow-pits is now overgrown with a dense growth, many bushes attaining a height of 20 ft. in 2 years.

Much difficulty has been found in keeping Indians from clearing away such growths and utilizing the borrow-pits as garden patches. Indeed, the Mexican officials practically take the position that, though the land is private property belonging either to the Mexican Co. or the C. M. Co., the nomadic Indian tribes have for many years been free to live their Gipsy life therein; that the levee system has cut off the annual inundation on which these people depended for their garden crops; and that it is unreasonable to insist on preventing them from taking these borrow-pits for gardening purposes, particularly as they are prevented from making clearings and utilizing inundated land in front of the levee.

A very striking occurrence was the complete filling up of the diversion channel between the river and the Hind-Clarke Dam. In many places this was more than 45 ft. in depth and probably averaged

20 ft. for 2 800 ft. up and down the river and 3 300 ft. at right angles thereto, an area of 210 acres. When this summer flood had passed, there was only a little pool about 5 ft. deep immediately above the Hind-Clarke Dam where the water had been deepest. Two years later this area was so densely overgrown with willows that it was extremely difficult to believe that the break ever occurred there. Until this silting up in front of the Hind-Clarke Dam began, numerous small boils appeared in the sand bar formation behind the Hind Dam. These at no time were of any importance, and soon ceased. Behind the Clarke Dam, practically no seepage whatever occurred.

The very slight percolation of water under these structures was rather surprising and very gratifying, considering their non-homogeneous structure and the character of their foundation. Nevertheless, it accords with the experience with the wooden and concrete head-gate coffer-dams, and the pumping of water into the Main Canal to keep the *Alpha* afloat, namely, that seepage through the alluvial soil of the region is remarkably small.

The water-table, for considerable distances on each side of the river, rises and falls with the water surface, especially during the summer floods, with small lag in time. The writer has always considered these two facts incongruous, and has never been able to find a satisfactory explanation.

Maintenance of Levees.

Until the summer flood of 1907 had passed, the levees were very carefully patrolled, watchmen being stationed night and day at each telephone house. A considerable store of timber, large and small, has always been kept at the Lower Heading until recently, and a storehouse containing a large quantity of shovels, picks, crow-bars, track tools, and lanterns has been maintained at the upper end of the Hind Dam. In this, from 20 000 to 50 000 sacks are always kept, being drawn on for use in the valley and replenished to avoid deterioration from long storage. Until a number of flashy floods had passed, a work train was always ordered from the Southern Pacific on reports from the head-waters indicating large rises in the lower river, and sacks were taken from the storehouse and distributed up and down the river, 500 at each toolhouse. Confidence in the effectiveness of the dikes soon grew, so that this is no longer being done.

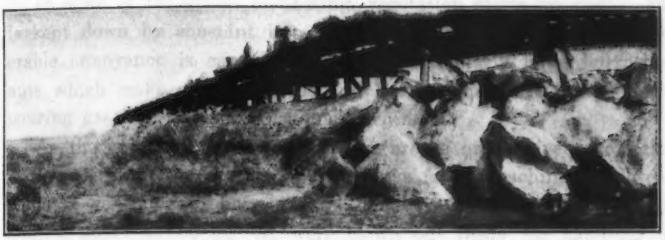

FIG. 55.—SECOND CLOSING. HEAD DEVELOPED, 8 FEET.

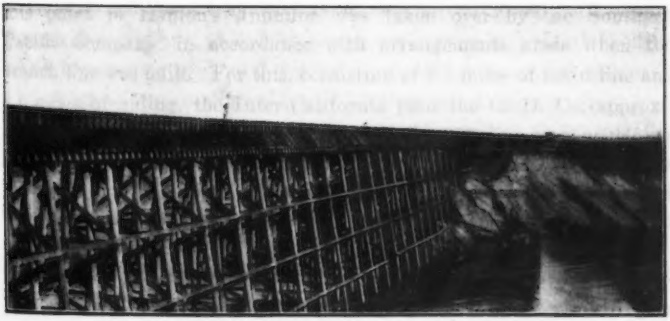
FIG. 56.—REINFORCED CONCRETE FACING, ON LEVEE 25 FEET HIGH, NEAR SACRAMENTO, CAL.



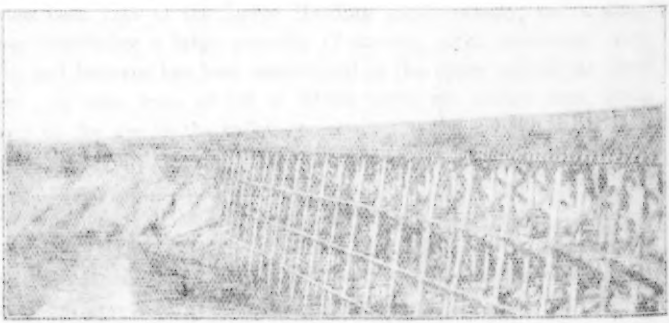


FIG. 57.—WOODEN FLUME OVER NEW RIVER BARRANCA.

In spite of the gravel blanketing, vegetation starts up slowly, and is kept down by constant but relatively inexpensive work. Considerable annoyance is caused by insects, particularly large burrowing ants which make great ant-hills and holes. These are destroyed by pouring gasoline into the holes and burning it.

As the value of rock, in repairing breaks or in river protection work, to prevent the side cutting of banks from breaching the levees, made it advisable to have a large quantity ready in the Andrade quarry, about 50 000 cu. yd. were blown out ready for handling by steam shovels. This was done by "coyoting" or driving 3-ft. tunnels horizontally about 30 ft. into the foot of the rock face, at intervals of 60 ft., and driving cross-tunnels at the ends, 10 ft. on each side. These cross-tunnels were loaded with black powder, which was all exploded at one time. All this rock has been taken away, and has left the quarry with a practically vertical face, averaging 50 ft. in height for a length of 1 000 ft., a very satisfactory condition. An American Hoist Company's 10-ton steel derrick with a 60-ft. boom, erected to handle this rock, proved very efficient and satisfactory. The railroad north of Andrade was raised above flood heights, the quarry lines were thrown over, and a track was laid on the top of the concrete head-gate, stringers being laid on the cellular pier walls. This track was connected with that on the levee, so that a train could be loaded at the quarry and run over the concrete head-gate and down the levee system, using the main line of the Inter-California Railroad only for that portion lying on the Hind-Clarke Dam. In the fall of 1907 this railroad was reconstructed and repaired from Calexico to Cocopah, and extended through to the end of the spur levee. The track from this point to Hanlon's Junction was taken over by the Southern Pacific Company, in accordance with arrangements made when the branch line was built. For this, consisting of 6.1 miles of main line and 2.1 miles of siding, the Inter-California paid the C. D. Co. approximately $65 000. When this was done the branch line was no longer available for use by the irrigation company, but the right to use the east track or siding on the Hind-Clarke Dam was retained, and the Inter-California was specifically released from any obligation to maintain the dam.

It certainly is not often that a diversion head-gate carries a main-line, standard-gauge railroad, and the fact that this does will give

some idea of its size. By thus utilizing it, the heaviest carloads of rock from the Andrade quarry can be hauled over the levee system, and be independent of the Inter-California tracks.

The Southern Pacific Not Reimbursed by the United States Government.

Early in 1907, a bill* was introduced before Congress:

"To reimburse the Southern Pacific Company the amounts expended by it from December first, nineteen hundred and six, to November thirtieth, nineteen hundred and seven, in closing and controlling the break in the Colorado River.

"Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled, That the sum of one million six hundred and sixty-three thousand one hundred and thirty-six dollars and forty cents is hereby appropriated, out of any money in the Treasury not otherwise appropriated, to reimburse and pay the Southern Pacific Company the amounts paid by it from December first, nineteen hundred and six, to November thirtieth, nineteen hundred and seven, in closing and controlling the break in the Colorado River and thereby saving the overflow and destruction of the Imperial Valley in southern California."

This bill was referred to the Committee on Claims, of which Hon. James M. Miller, of Kansas, was Chairman, and consideration was begun on February 24th, 1908. At this hearing Mr. Maxwell Evarts, Counsel of the Harriman Lines, Mr. P. G. Williams, of the Accounting Department, who had been in charge of the accounts of the Epes Randolph, Agent, fund, and the writer, appeared to make explanations and present for examination vouchers covering all items of expense. President Roosevelt was frank and open in urging the justice of the claim, but, of course, was not advised as to whether such amount of money had been expended. Everyone else, however, seemed to be very much afraid of the matter. The Committee on Claims desired information as to the character of the work done and the fairness of the charges therefor, and asked the Secretary of the Interior, James R. Garfield, to have the Reclamation Service Engineers investigate and make a report. The reply was that no funds were available for that particular kind of work. Accordingly, President Roosevelt asked Secretary Garfield, F. H. Newell, M. Am. Soc. C. E., Director of the

* H. R. 13 997, 60th Congress, 1st Session.

Reclamation Service, and Mr. Walcott, formerly head of that Service, to take up the matter and report on what the Government, as a matter of moral and equitable obligation, should pay for the service rendered. President Roosevelt at the time, March 11th, in a letter to the Chairman of the Committee on Claims, advised him that this had been done; recalled the dire need for immediate action at the time; stated that negotiations with Mexico were then under way for future action in concert between the two nations; that he did not think the Southern Pacific people should be obliged to wait for the conclusion of these negotiations between Mexico and the United States with regard to future action, but that a rough estimate should be made as to what the United States should pay as reimbursement to the Southern Pacific Railroad, and that it was an act of justice to deal generously in the matter, for the railroad, by its prompt and effective work, rendered to a threatened community a notable service which could in no other way have been done. To facilitate matters, Mr. Evarts agreed with the Committee that Mr. Grunsky, who had been Consulting Engineer of the Secretary of the Interior on all Reclamation Service matters until a few months previous, and who, of all Government engineers, knew most about the Lower Colorado River and the operations of the Southern Pacific Company, should be engaged by the Committee to report on the work done and the expenditures, and that Mr. Evarts would advance the expenses of such investigation and report.

Mr. Grunsky, with the assistance of the American Audit Company, of New York City, investigated the accounts, and reported on April 1st that the structures along the river were adequate and efficient, and fulfilled their intended purposes; that additional protective work would have to be done in the near future; that charges incurred prior to December 7th, 1906, and subsequent to July 21st, 1907, were not properly chargeable to work done as a result of correspondence between the President and Mr. Harriman; that the quantities of material, such as rock, gravel, and earth, covered by the expenditures could not then be ascertained by measurement of completed structures with any degree of precision; that the records presented by the company showing the quantity of rock, gravel, and clay put into the work from day to day from January 27th to July 18th, 1907, during which time practically all the work of closing the second break and com-

pleting the protection work was done, constituted a reasonable check on the bills rendered, and that the number of carloads of material handled prior to January 27th, 1907, was no doubt correctly reported; that a fair basis for all charges, everything considered, would be cost plus the usual 10% for superintendence, tools, etc.; that this basis had been followed in the accounts, with the exception of the freight, which had been billed at tariff rates and really should have been made at 0.5 cent per ton per mile; that the accounts revised and corrected according to the foregoing showed the total net expenditures to be $1 083 673.97, exclusive of interest.

TABLE 18.—EXPENDITURES ON THE COLORADO RIVER WORK SUBSEQUENT TO DECEMBER 1ST, 1906.

Labor	$275 310.12
Materials and supplies	261 960.04
Fuel	33 339.58
Freight charges on supplies and materials	618 150.84
Freight fuel	19 073.00
Transportation	12 395.23
Work-train service	7 627.17
Rental of equipment	70 507.54
Commissary supplies and labor	8 356.27
Trackage	31 981.00
Construction of additional levees (contract)	255 378.55
Officers' and clerks' salaries	8 449.08
Office expenses	1 279.20
Traveling expenses	1 437.65
Sundry expenses	1 091.39
Duties	34 717.45
Total	$1 636 063.11

Mr. Grunsky's report was clean-cut and fair, the inclusion of freight charges at tariff rates being done against the writer's advice. The Committee on Claims, therefore, now had definite ideas as to the work and cost. The report to President Roosevelt from Messrs. Garfield, Newell, and Walcott (dated March 17th), and mentioned in his letter of March 11th, as to the fair proportion to be repaid the railroad, was forwarded to the Committee, and, after reviewing the situation, including the exchange of telegrams between Mr. Harriman and President Roosevelt on December 19th and 20th, 1906, states:

"Under the circumstances, we do not feel justified in attempting even in a rough way to approximate the burden, other than to state that the principal beneficiaries are six in number: (1) The settlers in the Imperial Valley; (2) the Southern Pacific Co.; (3) the California Development Co.; (4) the Mexican Corporation; (5) the Republic of Mexico, and (6) the United States. Not considering the settlers in the valley, we have five distinct entities among whom the

burden might be distributed more or less equally. Thus, a rough estimate might apportion to the United States 20 per cent. of the money expended to reimburse the Southern Pacific Company for the actual expenditures of repairing the break in Mexico. Such proportion would fully comply with your suggestion that the United States Government should act generously toward the Southern Pacific Company, for by prompt and effective work it rendered a notable service to the threatened community of settlers in the Imperial Valley, quite regardless of the ultimate benefit of such action to the railroad company itself."

This recommendation has always seemed remarkable to the writer. The land interests in the Imperial Valley on both sides of the Boundary Line represent fully two-thirds of the present property values which had been threatened; the Southern Pacific Company about one-sixth; the United States, through its Laguna Weir, about one-sixth; the C. D. Co. and the Mexican Co. nothing, because they were both bankrupt, and the Republic of Mexico practically nothing because its interests conserved were wholly prospective, as well as those of the United States as far as irrigable land farther up the river is concerned. Furthermore, it was known that $950 000 had already been subscribed by the people and corporations in Imperial Valley when the President called on Mr. Harriman to start work, as he did, and at once stopped such subscription. It is obvious that the railroad could at this time in no possible way collect anything from any other source than the United States for such work, so that such payment as might be made by the United States will represent the grand total reimbursement. Just why this Committee eliminated the land owners and then considered the remaining five entities as being equally concerned has always seemed remarkable, especially because, when two years later another call for help from Imperial Valley came to President Taft, Congress at once appropriated $1 000 000 to protect the land owners primarily and almost exclusively.

The Committee took no action in the matter until Congress adjourned, and two years later, at the next session, another bill was presented, this time in the Senate (Senate 417, Sixty-first Congress). The matter was gone over again, and the bill with the amount cut to $773 647.25, or 71.4% of that reported by Mr. Grunsky, passed the Senate. The House Committee on Claims made a favorable report. Five members of the Committee submitted a minority report on January 28th, 1911, stating that they did not think there was any legal,

equitable, or moral obligation on the part of the Government to pay the railroad company any amount whatever for closing the break; that expenditures were made neither at the request of the Government nor for its benefit; and that the appropriation of such sum would be "purely a gratuity, a gift of the people's money to the Southern Pacific Railroad Company * * *.

"We oppose this proposed gift to the Southern Pacific Railroad Co. as well as all other gratuities to private enterprise."

The bill did not pass the House.

Damages Caused by the Runaway River.

The first damage caused by the diversion of the river was the flooding of the salt beds and the gradual burying of the entire plant of the New Liverpool Salt Company in the bed of the Salton Sea. The property was probably worth about $125 000.

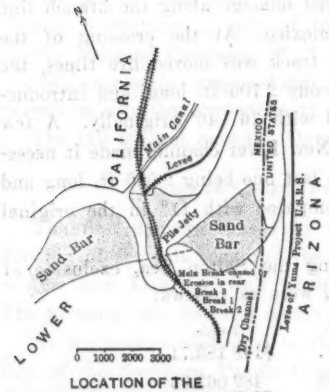
As the waters continued to rise, they began to threaten the main line of the Southern Pacific Company throughout the basin, and in July, 1905, they reached the rails for a considerable distance. Shoofflying was begun and continued from time to time, nothing very aggressive being attempted because of optimistic advices as to when the river would be under control.

Shooflies Nos. 1 to 7, inclusive, were at an elevation of —250 ft. or more. Shoofly No. 11 is 39 miles long, and follows the —200-ft. contour, being determined on when the probabilities of controlling the river before the summer flood of 1906 seemed to be rapidly decreasing. It was built in February and March, 1906, and was located with a view to being safe from the rising waters for at least two years, the estimates being based on the discharge records of the river at the time of building. As a matter of fact, some sections of the track a few feet below the —200-ft. contour were in trouble in the latter part of October, the water then being 47.5 ft. higher than when the line was surveyed. When the second break occurred, Shoofly No. 12, 48.9 miles long and following the —100-ft. contour, was hurriedly surveyed and graded during January and February, 1907, the outside drainage work being completed on April 1st. Track material for this had been gathered at each end—Mecca and Imperial Junction—during September and October, 1906, when Shoofly No. 11 was threatened. Practically none of the bridging was put in on this latter work, and

when only about 4 miles of track were laid it seemed that the river control work would prove effectual, and work was consequently ordered stopped.

The railroad company also suffered damage along the branch line between Imperial Junction and Calexico. At the crossing of the Alamo River north of Brawley the track was moved five times, the present alignment constituting a shoofly 2 706 ft. long, and introducing 105° of curvature, as compared with 16° 40′ originally. A few miles south, the enlargement of the New River channel made it necessary to construct three shooflies, the last one being 9 086 ft. long and containing 121° of curvature, as compared with 11° in the original alignment.

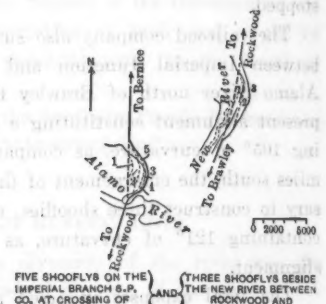
The total expenses incurred along the Salton Sea, exclusive of the cost of grading Shoofly No. 12, were as follows:



Year.	Labor.	Material.	Totals.
1905	.....	.....	$148 183.71
1906	$181 300.37	$307 763.58	489 063.95
1907	49 875.96	37 678.08	87 554.04
			$724 801.70

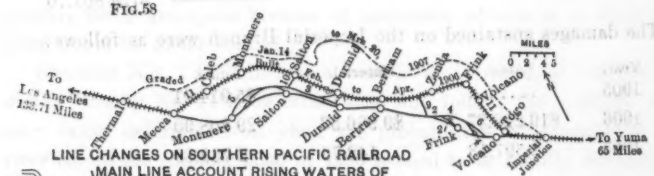
The damages sustained on the Imperial Branch were as follows:

Year.	Labor.	Material.	Totals.
1905	.....	.....	$5 914.01
1906	$19 222.37	$9 986.53	29 208.90
1907	2 597.13	142.76	2 739.89
			$37 862.80



The Inter-California Railroad, beginning at the International Boundary Line, was damaged more or less seriously for about 10 miles, the details being as follows:

Entirely rebuilding the road through Calexico and Mexicali and beyond, being cost less value of material recovered	$ 82 822.49
Repairs to remainder of first 10 km., including water supply	4 259.76
Repairs from 10-km. point to 14-km. point	21 163.73
	$108 245.98



LOCATION OF THE SECOND BREAK DEC. 7, 1906 AND OF SECOND CLOSING JAN. AND FEB. 1907

FIG. 61

Thus the damage sustained by the Southern Pacific on permanent way alone, and not including interruptions to traffic, or expenses of any kind incurred by delayed trains, etc., was $762 664.50, and by the Inter-California $108 245.98, making a total of $870 910.48.

In addition to such damages, the trains of rock hauled during the 3 weeks of the first closing and more than 2 weeks of the second closing, or more than 5 weeks in all, were given rights of way over all except passenger trains, and the slower of these were very frequently delayed in order to hurry material to the front. The demand on the equipment of the road was tremendous, particularly during the second closing, when there were in rock-train service, 1 000 flatcars, 300 "battleships," 4 steam shovels, 10 work trains, exclusive of rock trains from the quarries other than at Andrade, etc. Indeed, for about 10 days, practically no freight was hauled out of the Port of San Pedro because of lack of equipment. The degree of the strain is shown by a telegram the writer received from the Superintendent of the Los Angeles Division, just before the second closing was accomplished, asking information as far in advance as possible "when work will slow up because I want to make arrangements to resume operating the division."

About 3 000 acres of cultivated land and 10 000 acres of uncultivated and public lands were practically destroyed and rendered unavailable for agricultural purposes under existing conditions, the total value of which depends on whether the present or prospective worth is considered. Perhaps a very fair figure would be $50 per acre for cultivated land and $10 per acre for raw lands, making the total damage to the land about $250 000.

Various individual settlers in Mexico and the United States suffered more or less severe injury from inundation of crops, etc., as distinct from land damages, and these probably amounted to not more than $150 000. A number of claims for damages sustained on the American side of the line were combined in a suit totaling $490 000, but this included damaged lands estimated at prospective rather than real and present figures. Judgment has just (October, 1912) been rendered for a total of $78 000.

The most serious injury done to settlers was the entire stoppage of the water supply in the canals of Districts Nos. 6 and 8 from the summer of 1906 until January, 1907. No claim was ever presented for these damages, and nothing more than crude guesses can be made as to

the amount. The result practically forced the depopulation of more than 30 000 acres of land, of which about 12 000 acres were under cultivation. The effect on the development of the valley at the time was not very great, but fear of repetition of a break, as much as anything else, has, until recently, retarded the region to a considerable extent.

Because of the tremendous expenditure involved in re-diverting and holding the river in its course, up to December 5th, 1907, when the Southern Pacific advanced funds for the work directly instead of to the C. D. Co., the original $200 000 loan to the C. D. Co. had grown to $1 100 000, and this was swelled by later bills, interest, etc., to approximately $1 375 000, by January 1st, 1909. In addition to owing this large sum for cash actually advanced, and for which payment could not be disputed successfully, a judgment for $458 246.23, in favor of the New Liverpool Salt Company had been rendered in the United States District Court toward the end of November, 1907, and there were claims from the Southern Pacific Company and others aggregating $1 360 000, two-thirds of which were from the latter company. The runaway river rendered hopelessly bankrupt the C. D. Co. and the Mexican Co.

Benefits.

To almost every cloud there is a silver lining, and this is no exception. It is now known that the diversion would have occurred very soon. The event showed the existence and nature of the danger and the necessity for guarding against it. Much more important was the development and standardizing of methods of closing future crevasses which might occur. Incidentally, the information of this character afforded to the Engineering Profession in general will doubtless prove of much value, though this cannot be considered as a benefit to the region in question.

By far the greatest benefit was the erosion of the great Alamo and New River barrancas and the creation of the main features of a complete and comprehensive drainage system for the entire Imperial Valley. The natural slope of the ground is remarkably uniform, with a grade of about 5 ft. per mile, and the very small, shallow channels of the New and Alamo Rivers were the only rudiments of satisfactory drainage, from an irrigation point of view. The Salton Sink is the natural drainage sump for the region, and its absolute control should have been acquired in the very beginning, either by the irrigating

company or by the land holders of the valley. In the litigation which followed the destruction of the salt works, the New Liverpool Salt Company, as owner of the submerged land, obtained a decree perpetually enjoining and restraining the C. D. Co. from diverting water from the Colorado River in excess of the substantial needs of the people dependent on the canal for water supply for domestic, irrigation, and such other lawful purposes as the same may be applied to, and with a further provision as to the control of the water diverted so that it will not overflow on the lands of the complainant. Later proceedings resulted in a most remarkable construction of the last portion of the injunction, so that now the Salt Company practically cannot object to the use of the basin as a natural sump.

TABLE 19.—ANALYSIS OF WATER OF NEW RIVER.

Sample taken at Brawley, June 6th, 1908, and submitted by Mr. F. W. Roeding, Irrigation Investigations, Berkeley, Cal.

		Grains per gallon.	Parts per 1 000 000.
Alkali	Potassium Sulphate very small, and Sodium Sulphate (Glauber's salts), etc.	12.87	221
	Sodium Chloride (common salt)	389.40	6 675
	Sodium Carbonate (sal soda)	0.99	17
	Calcium Chloride	14.91	256
	Magnesium Chloride	37.26	639
	Calcium and Magnesium Carbonates, etc., large Calcium Sulphate (gypsum) chiefly	94.29	1 617
	Silica	1.22	21
	Organic matter chars, and chemically combined water	57.44	985
	Total	608.38	10 431

Providing for the region an efficient drainage system to carry all the waters into the Salton Sink would have required a large amount of money—so large that the date of its establishment would have been delayed very far into the future, much too far for the valley's real interests. This is true because it is plainly not the business of an irrigation company to supply a drainage system, and all other interests of the valley are very much divided because of the mutual water company plan of organization, and because of the usual lack of co-operation among farmers. Furthermore, the need for drainage of irrigated land is usually not recognized in time, and not admitted when it is recognized.

Indeed, in spite of the rather alkaline character of the lands in Imperial Valley, as already explained, it was not until November 1st, 1911, that any serious suggestion was made for a community drainage canal—in Imperial Water Company No. 8—the reasons then chiefly urged being:

"The loss of ground and bad appearances caused by the ends of the irrigated lands being covered with weeds or wild grass or perhaps nothing at all as the result of standing water."

A few spots in Imperial Valley are beginning to indicate an undesirable increase in alkalinity, and it is most fortunate that the magnificent main drainage ways of the Alamo and New River channels exist.

Salton Sea.

From a geological and spectacular point of view, the creation of the Salton Sea in so short a time was one of the most striking effects of the river diversion. The water filled the basin to a maximum elevation of —197.4 U. S. G. S. datum, or —204.2 S. P. datum, the maximum depth of water being 76 ft. The total area covered at this time was about 445 sq. miles, with a length of 50 miles and a width of from 10 to 15 miles. With the exception of the Great Salt Lake and Lake Michigan, the sea was the largest body of water lying wholly within the United States.

The water rose at the maximum rate during the latter part of June, 1906, when it gained nearly 7 in. per day, or 15.4 ft. during that month. From the reconnaissance map of the Salton Sink, published by the U. S. Geological Survey in 1905, it would appear that the areas of the various contours of the basin are about as follows:

Elevations.	Square Miles.
—280	0
—250	240
—200	445
—150	650
—100	920
— 50	1 150
— 0	1 750
+ 30 (old beach line)	1 950

TABLE 20.—ANALYSES OF WATER FROM THE SALTON SEA AND THE COLORADO RIVER AT VARIOUS SEASONS.

As made by Dr. W. H. Ross, of the Agricultural Experiment Station, University of Arizona, Tucson, Ariz.

	Salton water, surface of deepest portion, June 3d, 1907.	Colorado River water, low winter stage, January 10th–March 26th, 1900. Practically all the water which enters Salton Sea comes from the Alamo and New Rivers, which, under normal conditions, are now important chiefly as drainage channels for the Imperial Valley. Frequently, however, very heavy precipitation occurs in violent storms over small portions of the area draining into the basin, but the run-off, though occasionally of considerable quantity, is not relatively important. The total annual inflow is at present probably 200 000 acre-ft., or sufficient to cover the surface of the sea about 0.7 ft. in depth, while the evaporation is probably between 5½ and 6 ft. and the percolation insignificant.

TABLE 21.—COMPOSITION OF OCEAN WATER.

Bromide (Br)	6
Carbonate (CO_3)	7
	3 500

Quite a little speculation has been indulged in regarding the length of time which would have been required to fill the Salton Sea had the Colorado River not been re-diverted. Most of such computations are based on too low an average flow of the river past Yuma, which it now

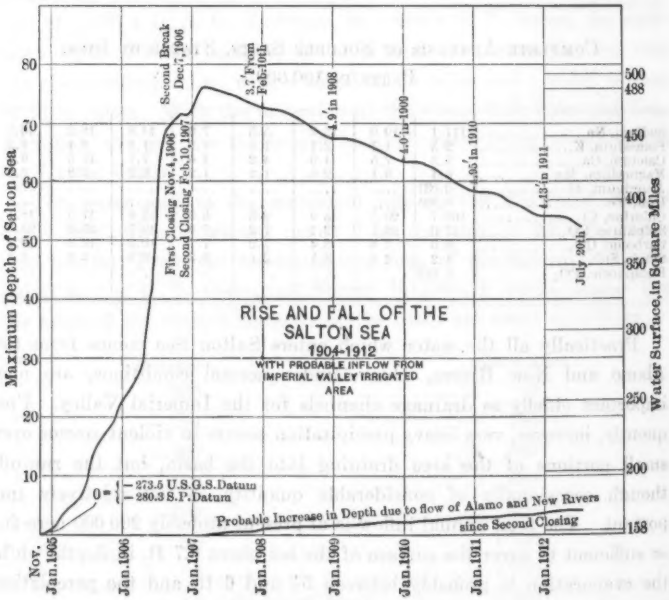

FIG. 62.

seems is in excess of 12 000 000 acre-ft. per annum. As a matter of fact, however, the inflow from the Imperial Valley region will constantly increase, and the quantity evaporated will decrease directly with the decrease in water surface exposed, so that a balance will be reached probably in such time as the inflow will average between 350 000 and 500 000 acre-ft. per annum from all sources, and the exposed surface will cover between 60 000 and 80 000 acres. At such time the maximum depth of the sea will be between 8 and 10 ft.

The sea has already (January, 1912) fallen about 22 ft., and has exposed approximately 115 sq. miles which were under water. The salt beds were dissolved to such an extent as to render the water of the sea quite salt, unfit entirely for drinking purposes, and it was assumed that the land which it covered would be hopelessly alkaline. This does not seem to be the case, and a very considerable acreage of such exposed land is being cultivated with entire success.

Much speculation was indulged in regarding the effect of this body of water on the rainfall and climate of the Southwest. A careless consideration of the precipitation on the drainage area of the river, particularly that of the Gila water-shed, before and after January, 1905, might lead to the conclusion that the effect is quite marked. The period from January 1st, 1905, to date has been one of very heavy rainfall throughout the Southwest, its most remarkable part being early in January, 1905, which was before the formation of the Salton Sea. Professor Alfred J. Henry* points out the fallacy of such an opinion, as follows:

"Admitting, for the sake of argument, that a body of water * * * existed * * * 60 miles long, 8 miles broad, and say 25 feet deep on the average. * * * The cubic contents would therefore be $60 \times 8 \times 0.0047 = 2.2$ cubic miles of water. The normal annual rainfall of Arizona * * * is 11.75 inches [while in 1905 it was 26.6 inches], or an excess of 14.85 inches, an amount more than equal to the normal annual rainfall. * * * As the area of the Territory is 113,956 square miles, * * * the number of cubic miles of rain that fell in Arizona in excess of the average was * * * 27, * * * twelve times greater than the total volume of the Salton Sea. In other words, the total volume of the latter would barely suffice to produce one-twelfth of the surplus rain that fell in Arizona, to say nothing of the rainfall in adjoining regions. The total

* "The Salton Sea and the Rainfall of the Southwest," *Monthly Weather Review*, Washington, December, 1906.

amount of water now in Salton Sea, if uniformly distributed in Arizona, would cover the Territory to the depth of about an inch and a quarter, or the equivalent of one good soaking rain."

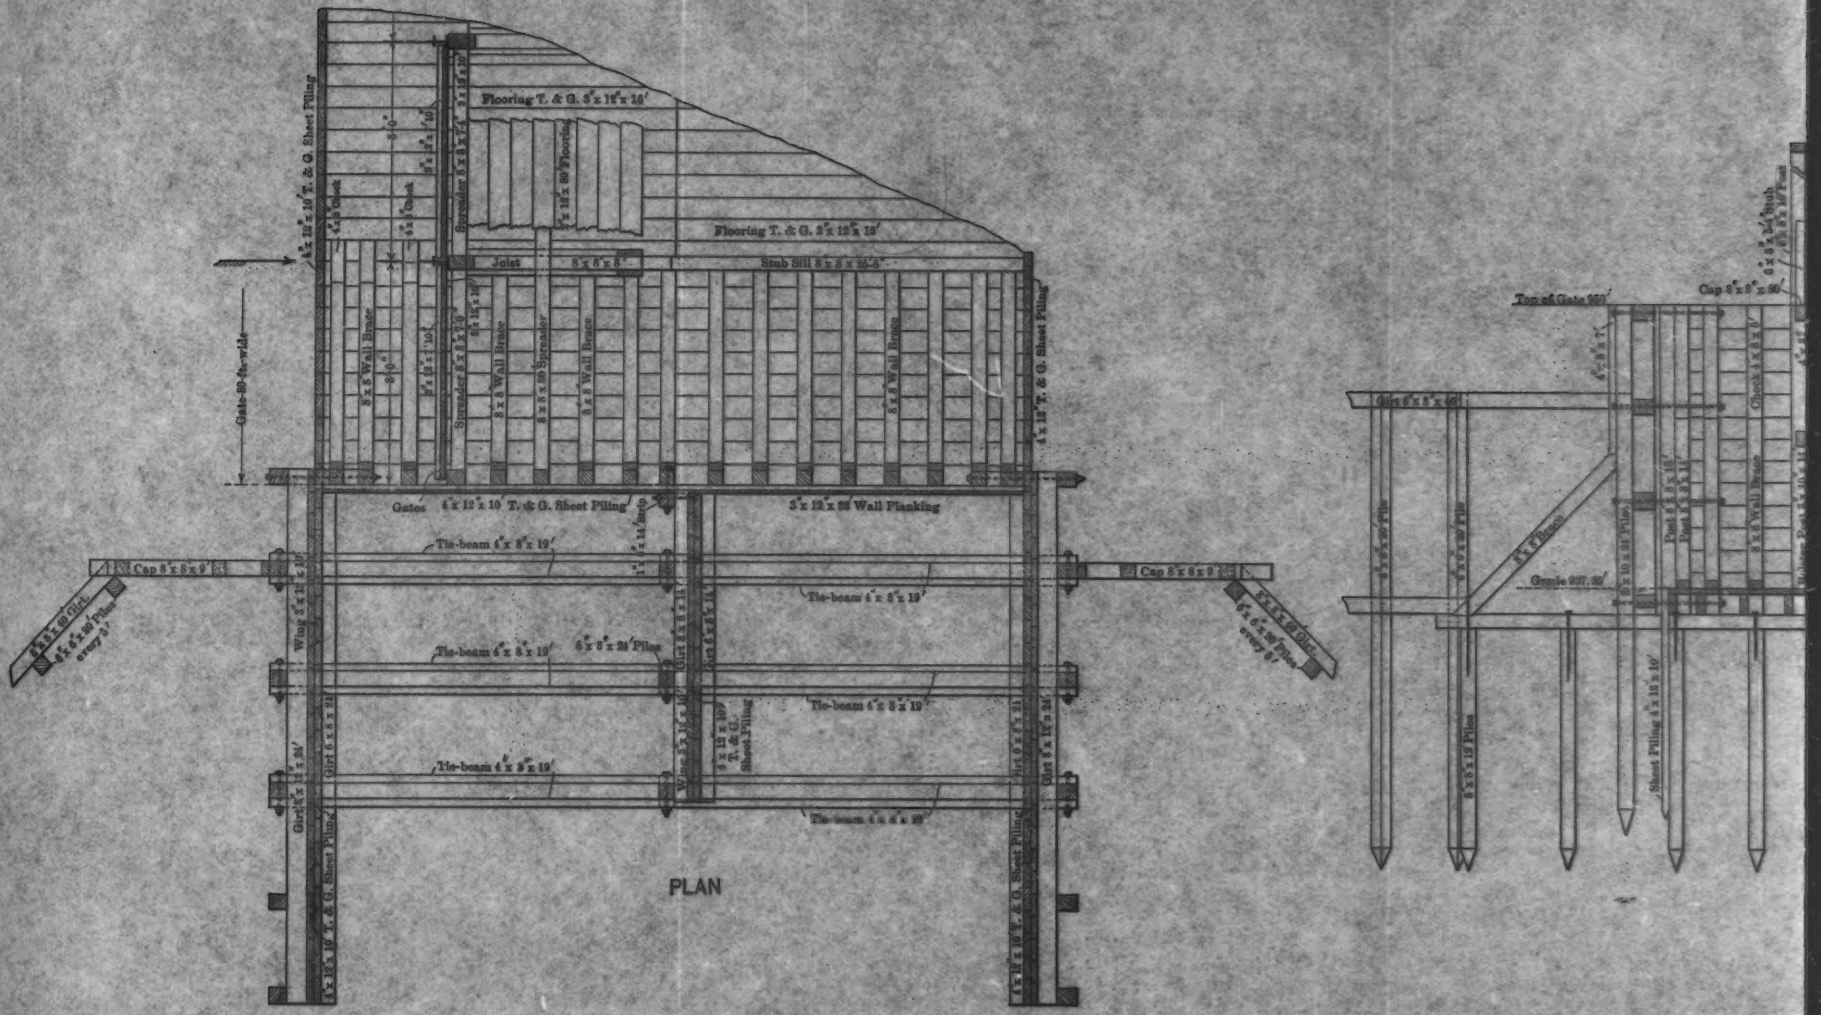
As a matter of fact, the area of the Salton Sea and Laguna Maquata combined are insignificant when compared with that of the Gulf of California, and are just about as far from Arizona. Professor Henry concludes that the Salton Sea has increased the relative humidity in the immediate vicinity in a slight measure; that it is improbable that any considerable portion of the vapor it gives off passes beyond the immediate confines of the desert; and that there might be a tendency toward lower maximum and higher minimum temperatures in a narrow zone immediately surrounding the sea, particularly on the leeward side.

International Negotiations.

When the Mexican Co. obtained its concession from the Mexican Government, Col. Jacobo Blanco, then Chief of the International Boundary Line Commission for the Mexican Government, with headquarters at El Paso, was appointed Inspector of the Mexican Co. and its operations. In 1906, Col. Blanco died, and his successor on the International Boundary Line Commission was Señor Fernando Beltran y Puga, who was also appointed his successor as Inspector of the Mexican Co. The writer considers this appointment an exceedingly fortunate one, as Señor Beltran y Puga is an exceptionally efficient, aggressive, and fair-minded man, and an engineer, with whom it has always been a satisfaction to transact business. Immediately on his appointment he acquainted himself with the conditions along the river and with the affairs of the Mexican Co., and has always acted promptly and with decision.

In the spring of 1908 the United States State Department appointed Mr. Louis C. Hill, Supervising Engineer of the U. S. Reclamation Service, to represent the United States on a joint commission to work out the provisions of a treaty with Mexico for the control of the Lower Colorado River and an equitable distribution of its waters. This appointment was in line with President Roosevelt's promise to Mr. Harriman, and was doubtless in a measure brought about at this particular time by the failure of Congress to take any action on the bill to reimburse the Harriman interests. At the re-

quest of the United States, the State Department of Mexico appointed a Commissioner, and rather naturally selected Señor Beltran y Puga to represent the Mexican Government, this gentleman's appointment being made on May 7th, 1908, and practically simultaneous with the appointment of Mr. Hill. Both gentlemen were instructed to act together and make a study of the works and operations necessary to complete international control of the lower Colorado River and render impossible a repetition of the recent disaster and the complete utilization of the waters of the river, such study to be in whatever detail might be deemed necessary.



This Commission never had a formal meeting, which is very much to be regretted, considering the importance of the matter. Very shortly after their appointment, the Commissioners had an informal meeting at which, according to private conversations which the writer had with both gentlemen, it appears that Señor Puga submitted, in the form of a written memorandum as the basis for discussion, the suggestion that both Governments cancel the existing treaties regarding the navigability of the river; that regulation of the flow of the river by extensive storage works in the upper portions of the drainage basin was desirable; that both Governments determine the priority and extent of existing water rights and fix rules for granting future water rights; that a joint international commission should make all engineering and other investigations necessary, and divide the costs thereof; that all plans or projects existing or proposed along the river should be submitted to the investigation of the joint commission; that a report be made outlining, in a general way, the work to be done, for the purpose of having a full and complete treaty arranged and the necessary definite appropriations set forth; and that it would be agreeable for Mexico to negotiate a treaty, either preliminary or final, at the earliest possible moment. It seems, however, that Mr. Hill could not find time to attend to the matter, nor were special funds placed at his disposal to defray the necessary expenses. At any rate, two years later, nothing having been done, on May 17th, 1910, the United States Department of State replaced Mr. Hill with Mr. Wilbur Keblinger, Secretary of the American side of the International Boundary Commission, with offices in El Paso and Washington. This change of American Commissioners, however, has not had any apparent result thus far.

It is hoped that discussion of this paper may bring out the explanation for the failure of these representatives of the two governments even to have a formal meeting in the 4½ years which have elapsed since the Joint Commission was appointed at the request of the State Department of the United States. Such explanation would be particularly interesting, because the writer knows Mr. Hill to be an unusually tactful, courteous, and aggressive gentleman, and an efficient engineer, and understands that Mr. Keblinger is also an unusually capable man.

In any event, there seems to be no doubt that the Mexican Government has been, and is, not only willing, but anxious, to arrange for a satisfactory joint control of the Lower Colorado River, and that the responsibility for nothing definite having been accomplished in this direction, in large measure at least, rests with the United States.

Building of Volcano Lake Levee.

The extraordinary quantity of water which got into Volcano Lake during the summer flood of 1907 raised it higher than it had ever before been known to be, and a large quantity of water passed northward through the New River outlet. Furthermore, a reconnaissance showed that the large quantity of overflow water had started cutting back fingers from the Volcano Lake region toward the river, which indicated the probability of the diversion of the Colorado River below the divide of the delta cone, along the Pescadero, Abejas, or Paredones. Therefore it seemed that another portion of the complete levee system, as originally planned by the writer to hold back the overflow waters of the Colorado from the Salton Basin, should be constructed—that portion from the mountains on the west side of the valley eastward along the north of Volcano Lake to the low-lying divide or ridge farther on. The C. M. Co., however, objected to this, as Volcano Lake is entirely on its land and its utilization for irrigating a portion of that company's lands was considered, but found impracticable because of the great variation in the water surface, the inundation of a part of the land, however, at flood times was simple, and permitted securing considerable pasturage. The C. M. Co., however, was willing to give the right of way and permit the construction of the protective works provided a permanent head-gate were installed at Cerro Prieto through which water might be let into the New River when the lake was

AS ORIGINALLY CONSTRUCTED

ELEVATION

full. This was finally agreed to, and arrangements were completed under which the Southern Pacific Company agreed to pay the Mexican Co. for constructing this gate on condition that the Mexican Co. would arrange to have 8 miles of levee to the east built. This was done and the gate and levee were completed just before the summer flood of 1908 began to throw its waters into Volcano Lake. After one season the Mexican Government compelled the removal of this intake gate and the levee to be built around in front of it, so that it is not now in service. Plans for the gate and levees were presented informally to the Mexican Government Inspector of the Mexican Co., Señor Puga, and it was understood that their construction was approved and permission verbally given to begin work before filing maps and drawings and having them approved or changed as required by the Departmento de Fomento in such cases—this on account of emergency. It was not so understood by Señor Puga, and the construction of the gate was a needless expense.

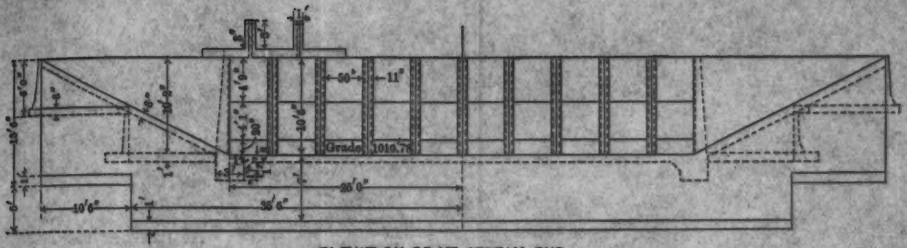
All this work was arranged for and practically done while Congress was considering the payment of the bills for the second closing and subsequent protective work, and when there was no reason to doubt that a fair adjustment would be made.

Reconstruction of Irrigation System.

As soon as the river control work was assured, arrangements were made to ascertain the exact condition of the irrigation system of the valley, and what was necessary and advisable to do in connection with it. Accordingly, Mr. F. C. Herrmann, who was added to the engineering staff on February 1st, 1907, was placed in charge of this work. The damage done by the flood was confined almost entirely to carrying away the flume by which the West Side Main Canal crossed New River, and a similar flume, 20 miles north over New River, carrying water from the Central Main to supply Imperial Water Company No. 8. To rebuild the latter was impracticable on account of the immense barranca which had been created at the old crossing, and it was decided to enlarge the West Side Main and extend it northward so that all the territory west of New River would be served thereby.

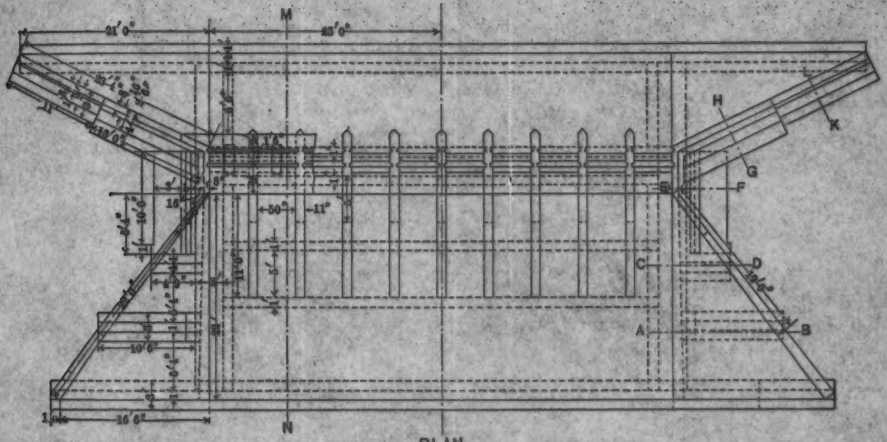
A wooden flume, supported by wooden piling, was designed to cross the New River gorge very close to the location of the original flume,

carried away about March, 1906. Work was begun on the structure and rushed to completion. This flume is worthy of note because of its height, length, and cost, as a quasi-temporary structure. It is 1 860 ft. long and the maximum height of the trestle is 55 ft. It supports a rectangular flume, 16 ft. wide and 6 ft. deep, built of 2-in. redwood lumber with ship-lap joints. It has given excellent service, and the leakage has been notably slight from the time it was first put into service.



Surveys for the reconstruction, enlargement, and extension of the West Side Main were hurried, and contracts were let for the work, which was well under way when the financial panic of November, 1907, occurred. The contractors were forced into bankruptcy, and the work was completed by their bankruptcy trustee, which caused considerable delay, but water was turned through the reconstructed West Side Main late in December, 1907. This canal is 28 miles long—7 miles in Mexico and 21 in California—and has a capacity varying from 800 to 400 sec-ft., with 760 000 cu. yd. of earthwork moved at a total cost of $86 000, and $5 000 for two temporary structures.

Some little time later the Rose Levee, across the Alamo channel at Holtville, was reconstructed, with a waste-gate to pass the excess of water coming through the Holton Power Company's plant and through the Alamo Waste-gate farther up that channel in Mexico, and a head-gate for the Rositas Canal. Both of these are of reinforced concrete, the waste-gate being of interesting design and capable of passing 2 000 sec-ft. with a total drop of 20 ft. In this way water which must be furnished to the Holton Power Company under its contract is picked up below the plant and utilized for irrigation, as was the original intention when the contract was made. These two permanent structures and the earthen dam cost $55 250.



Another important permanent structure, known as the Seven-Foot Drop (Plates LII, LIII, and Fig. 63), was built in the Central Main just south of the Boundary Line at a cost of $23 760, including three small structures adjacent to it, but not exactly a part thereof. This structure takes the place of a wooden 10-ft. drop nearly 2 miles farther on, which, by the way, had passed considerably more water than it was designed for and was in fairly good condition when removed after 8 years of service.

The chute of the Alamo Waste-gate was repaired and again extended down stream, the result being a quite remarkable construction, Plate

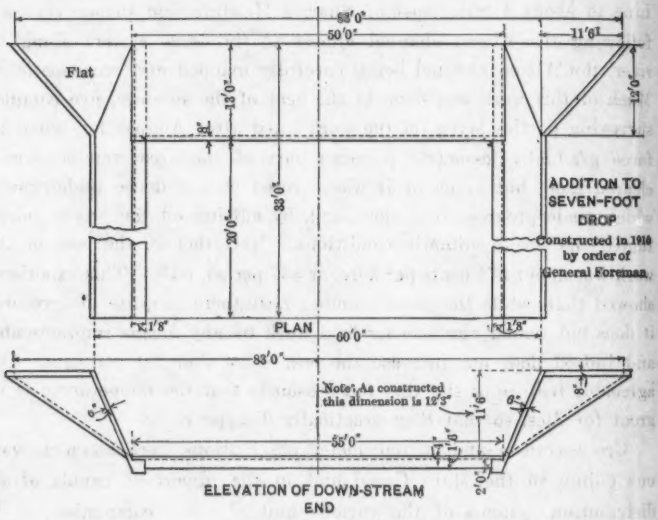
LI, which has never shown any signs of weakness against a head of approximately 35 ft.

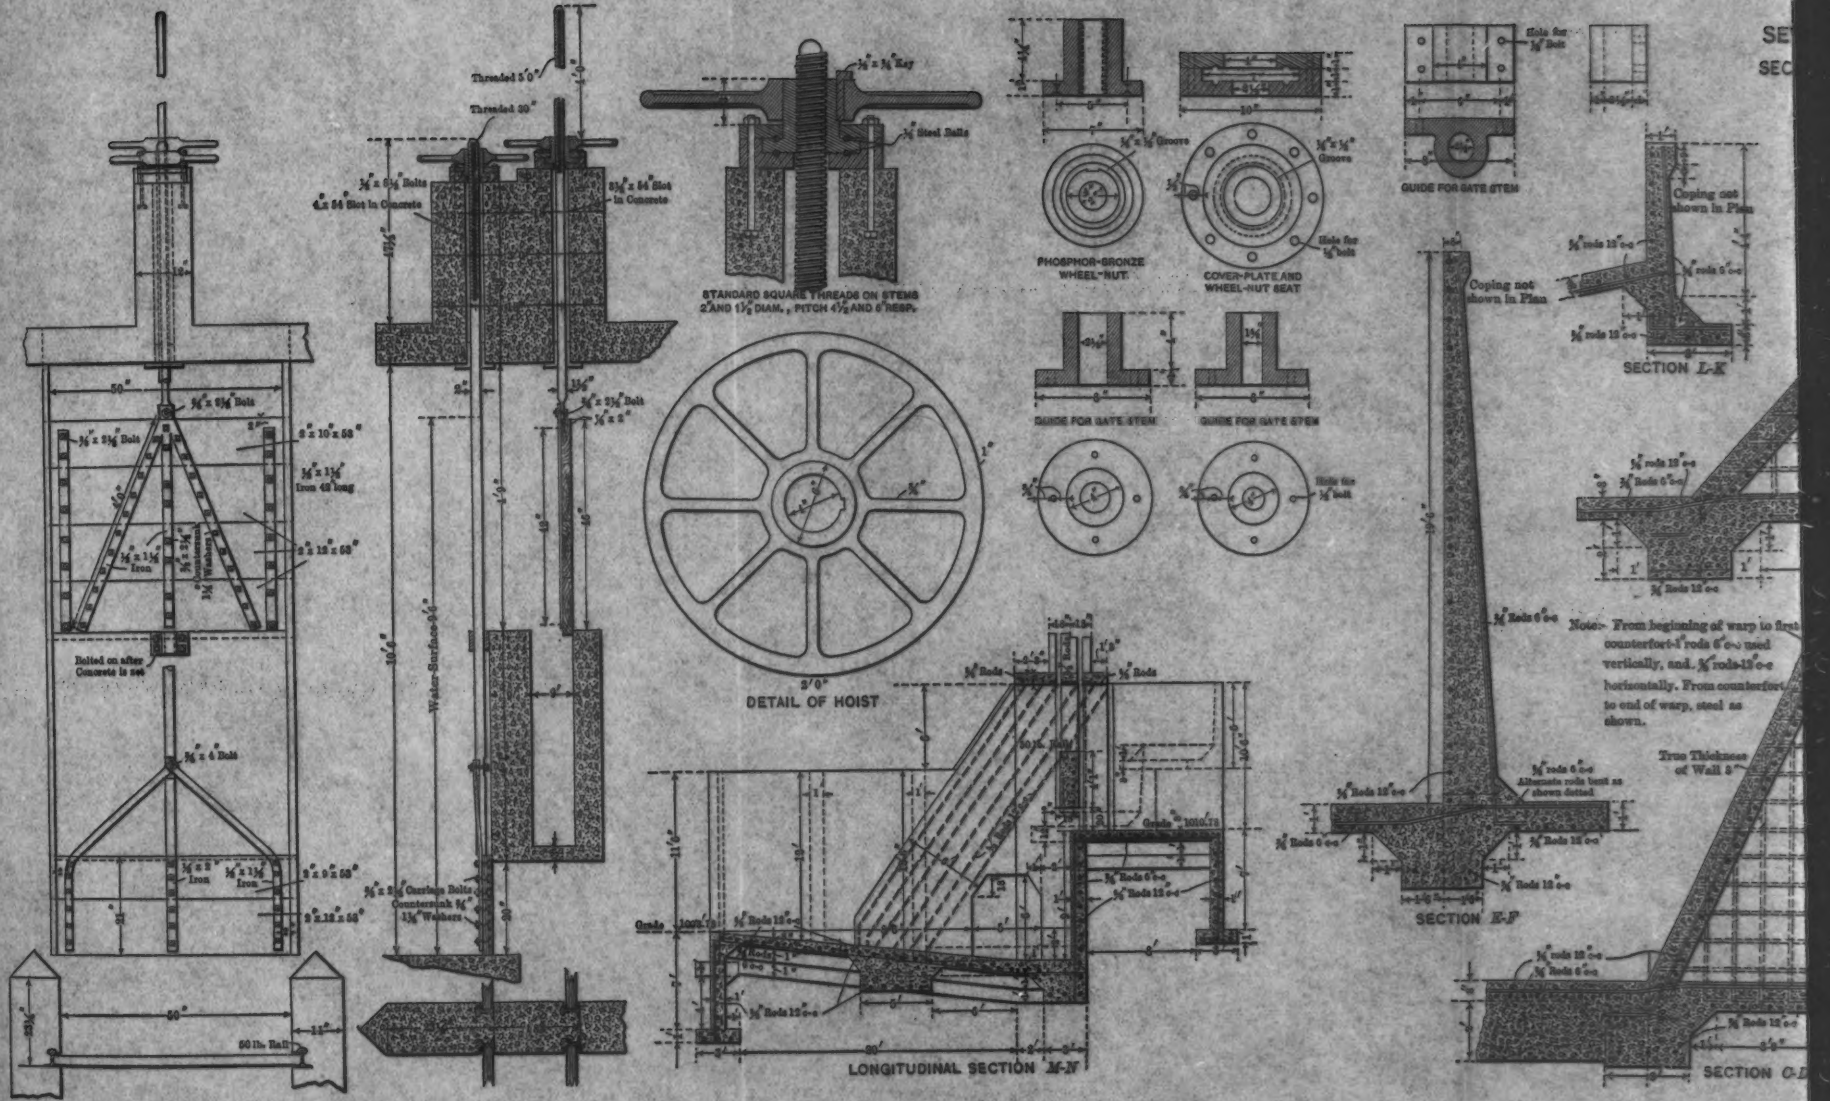
Surveys and Designs for Extensions.—At the same time, surveying parties were assembled and topography was taken, with 1-ft. contour intervals, on 230 sq. miles. This included the west side of New River and a strip in Mexico adjoining the Boundary Line averaging 3 miles wide and running from the West Side Main crossing of the Boundary Line to about 4 miles east of Sharp's Heading and thence generally following the Alamo channel almost to the levee system along the river, the Alamo channel being carefully mapped and cross-sectioned. Much of this work was done in the heat of the summer, five complete surveying parties being on the work until after August 1st, when the force gradually lessened. A large part of the area was practically cleared land, but much of it was covered with a dense undergrowth, which made progress very slow, and, by cutting off the breeze, accentuated the severe climatic conditions. Nevertheless, the cost of this work was about 57½ cents per acre, or $37 per sq. mile. This experience showed that, while the great summer heat there is quite disagreeable, it does not render engineering field work by any means impracticable, and indeed does not increase the cost more than 10 per cent. One agreeable feature of the very hot season is that the temperature is too great for flies, so that they practically disappear.

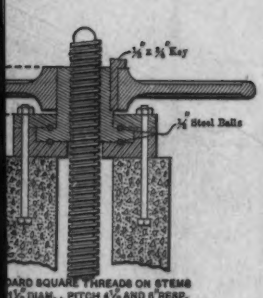
Cross-sections and current-meter observations were taken at various points in the Main Canal and in the important canals of the distribution systems of the various mutual water companies, to determine capacities, losses, etc.

When these data were compiled and put into form, estimates were made for the reconstruction and enlargement of the existing system and for extensions to cover a great deal of new territory. The estimate for this work was approximately $900 000 with temporary structures, and including considerable improvements in the main Alamo channel from the river to the controlling works in the valley; and $2 200 000 with permanent structures at essential points and replacing the Alamo channel with an entirely new twin main canal from a few miles below the concrete head-gate to the mesa ground east of Sharp's Heading. Whatever possibility there was of such fundamental reconstruction and extensions was dissipated by the severe financial stringency in November, 1907.

These designs included the construction of a head-gate on Mexican territory, and the total abandonment of the concrete head-gate, along with diversion, on American soil. The head-gate thus proposed was just behind the levee, about 3 miles below the Boundary Line, with a caisson foundation supporting extensive wing-walls and massive piers, between which there were to be large vertical gates, operated by gasoline motors.







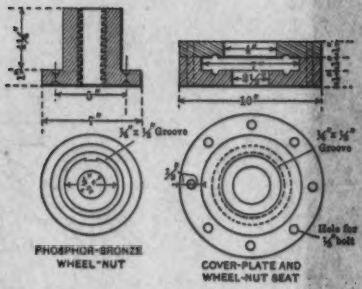


FIG. 63.

Of these designs the only ones constructed were the West Side Main, the Rose Levee and Waste-gate, including the Rositas Heading on the Alamo near Holtville, and the Seven-Foot Drop in the Central Main. The foundations in all cases were merely concrete footings without any sheet-piling, of which the Seven-Foot Drop (Plates LII and LIII, and Fig. 63), the Rositas Waste-gate (Fig. 64 and Plate LIV), and the Rositas Head-gate (Figs. 65 and 66) are quite typical.

The Rositas Heading and Waste-gate together cost $55 250, and the Seven-Foot Drop, together with the little gates which constitute one structure, cost $23 750. Concrete work, generally, has cost about three times as much as wooden structures; it has ranged from $30 to $35 per cu. yd. for the entire cost of completed structures.

Maintenance and Operation.

Until such time as the promised arrangements for river control and levee maintenance by the Government should be fulfilled, the operations of the irrigation interests, under instructions from higher authorities, were made to include levee maintenance and extension as well as supplying water in wholesale to the mutual water companies. The business done by the corporations was in this way much more varied than that of most irrigation companies, although none of the land they owned was under cultivation.

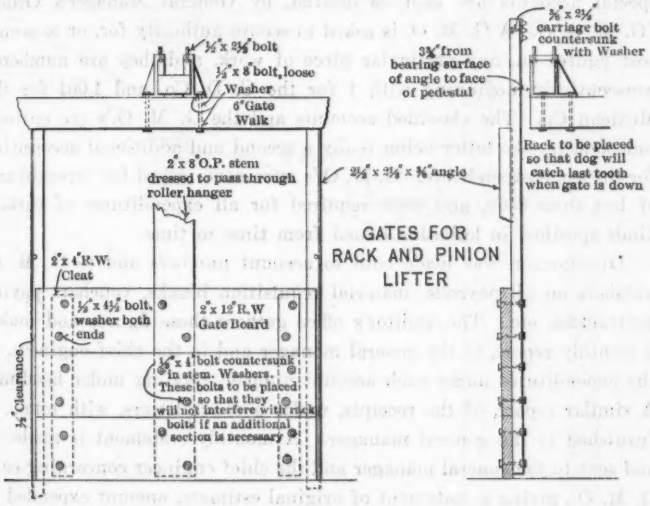

Fig. 66.

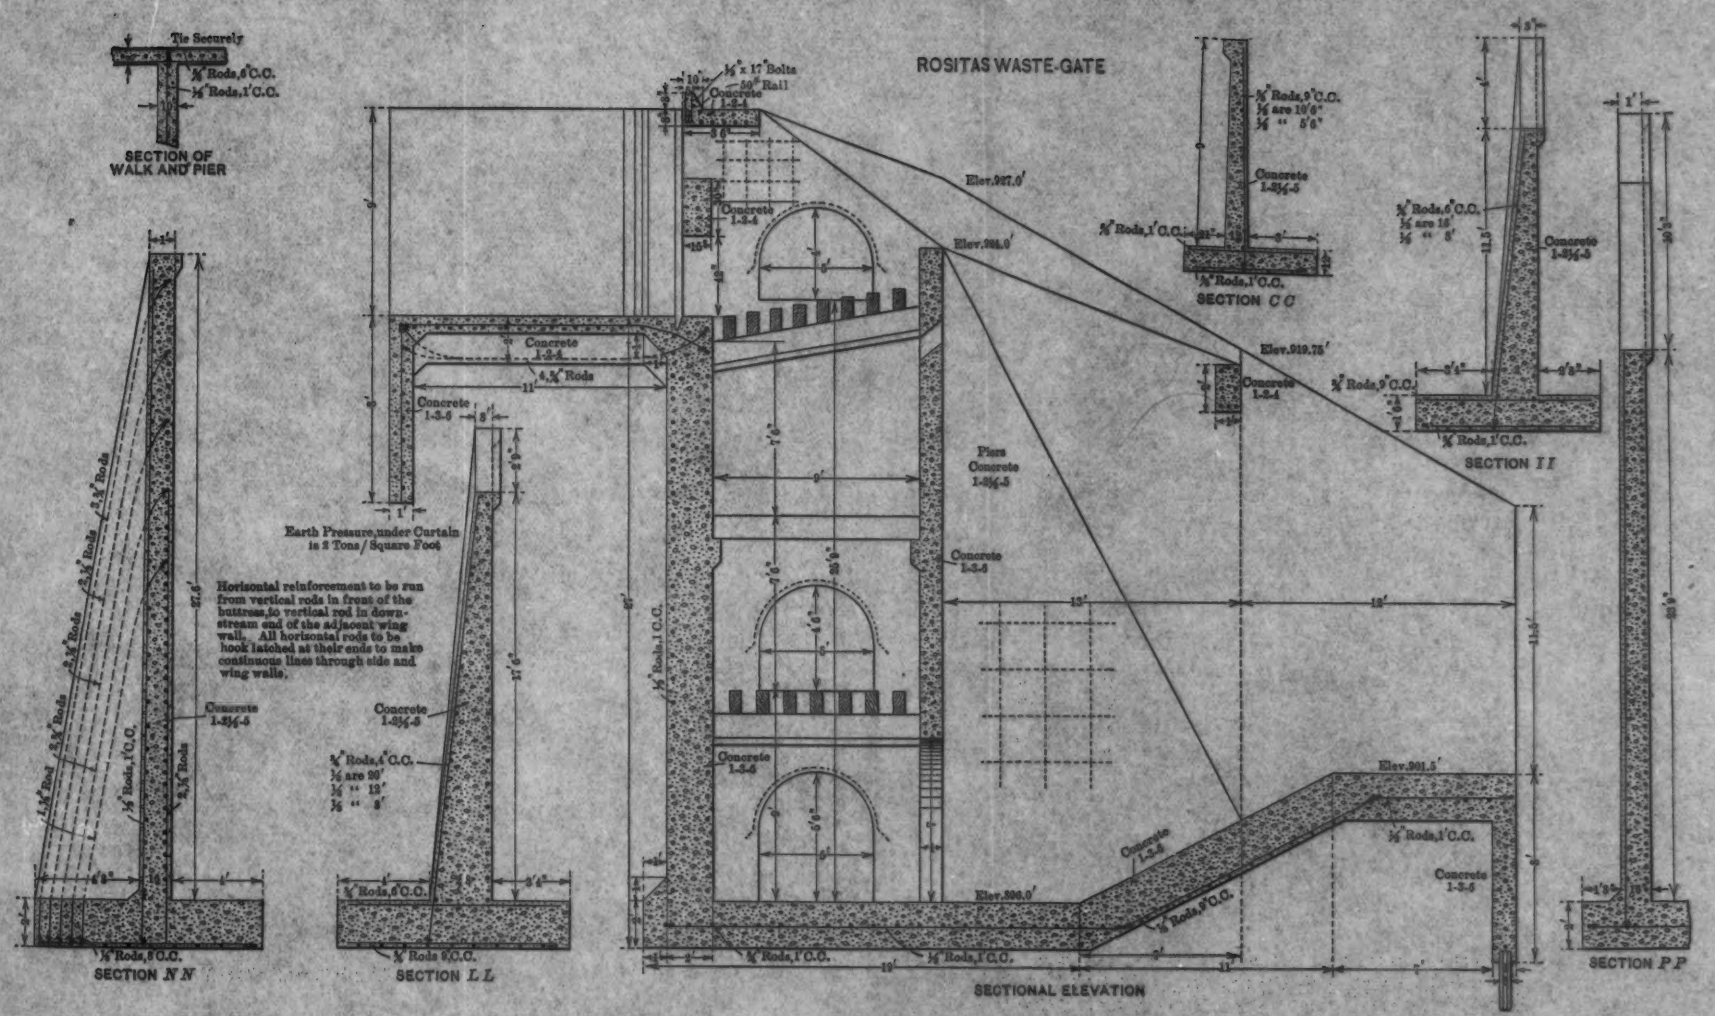
Because of the litigation which seemed inevitable, and indeed which had started ere this, it was deemed essential to have a complete and satisfactory system of accounts. Inquiries were directed to all possible sources of information, including the U. S. Reclamation Service, to discover a system of irrigation accounts similar in a general way to the system of railroad accounts generally adopted and for some time past made obligatory by the Interstate Commerce Commission. No such system was found. The U. S. Reclamation Service has a fairly satisfactory system of construction accounts, but its work, as yet, is almost exclusively construction.

The accounting system, therefore, was worked out, modeled closely after the classified railroad accounts. The account numbers of the Mexican Co. are the same as those of the C. D. Co., except that one thousand is added. Four years' experience with it has resulted in few changes, and in its present form it is extremely satisfactory. Lack of space forbids giving it in full, as there are 146 expenditure and 16 revenue accounts.



In order to ascertain the cost of particular portions of the work—whether new construction, betterments, or ordinary maintenance—special accounts are kept as desired, by General Manager's Orders (G. M. O.'s). A G. M. O. is asked to secure authority for, or to secure cost figures on, any particular piece of work, and they are numbered consecutively, beginning with 1 for the C. D. Co. and 1 001 for the Mexican Co. The classified accounts and the G. M. O.'s are entirely independent, the latter being really a second and additional accounting for the same expenditure. G. M. O.'s were never asked for expenditures of less than $300, and were required for all expenditures of certain kinds specified in bulletins issued from time to time.

Distribution was made both to account numbers and to G. M. O. numbers on all payrolls, material requisition blanks, vouchers paying contractors, etc. The auditor's office gathers these figures and makes a monthly report, to the general manager and to the chief engineer, of the expenditures under each account number, totaling under headings. A similar report, of the receipts, under account letters, with totals, is furnished to the general manager. A monthly statement is made up and sent to the general manager and the chief engineer concerning each G. M. O., giving a statement of original estimate, amount expended to date, and percentage completed. Whenever work covered by G. M. O.'s is materially changed, a new G. M. O. is gotten out accordingly.

With such accounts, occasional trips of inspection, to observe the physical condition of the system, will afford a very complete knowledge of the exact condition of the project at all times.

The relationship between the C. D. Co. and the various mutual water companies was at all times very satisfactory and cordial, until the former was thrown into the hands of a receiver, there being one exception, however, in Imperial Water Company No. 5. Differences antedating the beginning of the railroad management and in a large measure due to dissensions between former President A. H. Heber and

PLATE LIV.

VOL. LXXVI, No. 1270.
CORY ON
IRRIGATION AND RIVER CONTROL,
COLORADO RIVER DELTA.

his Board of Directors, resulted in commencing litigation to compel Imperial Water Company No. 5 to pay up back water rentals. The attorneys of the latter company, in their cross complaint, attacked the validity of the mutual water company and water stock plan of a water right. The suit was before the United States Circuit Court, and in rendering the decision the judge expressed the opinion that the plan was illegal, and, practically speaking, the C. D. Co. was a public service corporation. This was but an opinion, because the State Courts of California have to decide this question finally, as it is a matter of the Constitution and Statutes of the State of California exclusively. The effect of this opinion, however, was to make the Southern Pacific Company feel that it would be unsafe to advance the large sums of money needed to reconstruct and extend the system on the expectation of being repaid ultimately through the sale of additional water stock to cover the new territory which would be brought under the canal. This suit, as much as any other factor, is responsible for the fact that practically nothing has been done on the betterment and extension work outlined. This litigation with No. 5, although begun in August, 1906, has not yet reached a definite conclusion.

When Imperial Water Company No. 1 was organized, the capital stock was placed at 100 000 shares, and the territory embraced within its limits was 135 000 acres. Of the excess land, a large part was found to be well worth reclamation, so that early in 1910 no No. 1 water stock was available. Imperial Water Company No. 1 was unwilling to increase the capital stock without obtaining from the C. D. Co. a contract increasing the quantity of water it would be entitled to demand and so retain the basis of 4 acre-ft. per annum per share of stock. It was impossible for the mutual water companies and the C. D. Co. to agree as to the proper division of the "water right" receipts for such 35 000 acres, so no relief was afforded to *bona fide* settlers who had their land ready and had to have water or lose their filings under the rulings of the U. S. Land Department. A trial suit was instituted, known as Thayer *vs.* C. D. Co., which was decided in favor of the plaintiff on March 17th, 1911, by Judge George H. Hutton, of Los Angeles, sitting for Judge Cole in the Superior Court of Imperial County. Judge Hutton in brief decided that the C. D. Co. was a public service corporation; that the rate for supplying water was 50 cents per acre-ft.; that the C. D. Co. was in a position

to supply the plaintiff without detriment to the other water users; and ordered that it do so. This decision has been appealed to the State Supreme Court. If it is upheld, the mutual water company will not be a necessary factor in obtaining water from the C. D. Co. This decision has not affected the price of water stock in the valley very materially, because the various mutual water companies own the distribution systems, and the difficulties of getting water from the short mileage of the C. D. Co. main canals through other sources than the distribution systems of the mutual water companies are practically prohibitive. The decision, of course, absolutely precludes extension of the irrigated area any farther through such a water stock plan.

Seepage and Irrigation Losses.—It is very unfortunate that a clause in all the triparty contracts requires the actual seepage and evaporation from each mutual water company's distribution system to be reported after a period of 3 years, and that the percentage allowance thus determined should thereafter be made, to the end that the mutual water companies would pay for the quantity of water which could actually be delivered to the individual settlers. All the mutual water companies joined and selected an engineer, Mr. F. C. Scobey, to represent them in making seepage and evaporation determinations, and did quite a little experimenting and investigating. The engineers of the C. D. Co. also made numerous determinations under the direction of Mr. Herrmann, but for various reasons no experimentation was done jointly. The amount of work and expense involved greatly surprised the representatives of the mutual water companies, and proposals of a compromise were made, one thing helping to this being that such representatives agreed that it would be distinctly unsatisfactory to have different percentages agreed on for each of the mutual companies, as must obviously be the result. The C. D. Co. was thrown into the hands of a receiver just as these negotiations were reaching conclusion on the basis of 6% flat allowance. In the confusion following, the companies insisted on a 10% allowance, and this is the present status.

The results obtained by Mr. Scobey have never been given out, but the experiments by the engineers of the C. D. Co. showed a surprisingly small loss. It appears that the very fine silt deposited in the distribution systems of the various mutual companies forms a practically impervious coating on the sides and bottom, the measured

loss in many cases being as small as 0.25% per mile and increasing to a maximum of 1% per mile. From the available experimental data, computation of the losses from the distribution system of Imperial Water Company No. 1, comprising nearly 375 miles of canals, gives the total for seepage and evaporation throughout the year, under present operating conditions, as somewhat less than 7 per cent. The writer has no knowledge of so small a loss by seepage being reported by any authority heretofore.

The experience has been that the mutual water company plan of organization to distribute water, obtaining it from a larger company at wholesale, is highly satisfactory, and it is commended for careful consideration by those who are contemplating irrigation work, if the local laws will permit.

Canal Maintenance.—As far as the physical maintenance of the canal system is concerned, it may be said that the average life of the redwood structures, consisting of checks, drops, turn-outs, waste-gates, etc., is about 5 years for the smaller structures and 8 or 10 years for the larger ones. It must be remembered that water is used every day in the year, so that this experience has narrow application. The chief deterioration is caused by a sort of dry rot beginning about 1 ft. below the surface of the ground and extending down not more than 2½ ft. It appears that deeper than that, regardless of the quantity of water present, the heat does not become great enough to cause trouble, and the upper layer of earth is nearly always so dry that the wood is not attacked. In the thin intermediate layer, which is both damp and hot, and perhaps where enough oxygen is available, dry rot appears very rapidly, and wood wet on one side and in contact with earth on the other has the earth side damaged to a depth of from ¼ to ¾ in., sometimes in 9 or 12 months. Redwood subjected to several kinds of treatment has been tried, but with little success. Oregon pine, for that portion of structures covered by earth in that region, rots very rapidly indeed.

The chief lesson taught by the maintenance of the canals—other than that the cost is unusually large because of tule growths and silt—is that inside berms must be avoided, and when possible all canals except the sub-laterals should have a double or twin cross-section. In the Imperial Valley the absolute minimum quantity of water is approximately 25% of the absolute maximum—a very unusual condition

of affairs. If the sections are identical, it is possible to use one canal for a long time, and have it never less than one-half full, and consequently the velocity of the water is never low enough to deposit the finer silt. This allows a sufficient time for cleaning one canal and then the other every year. When the demand increases beyond the capacity of one canal, both channels are more than half full. In this region, therefore, it is possible with the twin section to control the velocity between the excessive silt-depositing lower limit and the bank-erosion upper limit with absolute certainty. The additional construction expense of the canals for the twin section is much more than justified by the very greatly reduced maintenance charges thereafter.

Duty of Water.—As a basis for estimating the quantity of water required under the Yuma Project, investigations were made, under the direction of the University of Arizona Experiment Station, to determine the water required for various crops in the Yuma Valley. As a result of this work, it was decided that for the average 40-acre unit, 5.8 acre-ft. per annum, measured at the delivery box at one corner of the field, would be required. Such a figure is exceedingly interesting, but was not obtained under the usual operating conditions. Indeed, the satisfactory delivery of water has been made so recently and in such relatively small quantities in the Yuma Valley as not to justify any definite conclusions.

Water has been actually used in irrigation in Imperial Valley for more than 10 years, and although there seems to be no reason why the duty of water there should not be essentially the same as in the Yuma Valley, the quantity used in the former is only about half as much as indicated by the experimental work mentioned.

The crop census taken by the Zanjeros of Imperial Water Company No. 1 for that district during 1911 is as follows:

Alfalfa	44 262	acres
Barley	28 897	"
Corn	12 034	"
Cotton	6 263	"
Melons	2 153	"
Vineyards	1 352	"
Truck	1 092	"
Asparagus	192	"
Miscellaneous	3 327	"
Total	99 572	acres

To supply this acreage, the company bought from the C. D. Co. during the period 274 665 acre-ft. of water, or an average of almost exactly 2¾ acre-ft. per acre under cultivation. This is net, after deducting the 10% seepage and evaporation allowance given by the C. D. Co., as already explained. Of this net quantity, according to the water company's report, 92.3% was delivered and charged to the stockholders, making the average quantity of water used, measured at the farmers' boxes, 2.538 acre-ft.

The quantity of water used in irrigation depends on so very many different factors—quality of the land, nature of the crop, proper preparation and leveling of the land, and time of irrigation—that it is only by such general figures covering large areas that much tangible information for engineers is obtained. It must be remembered, however, that the water supplied is charged for on a quantity basis, which undoubtedly tends to minimize the quantity used, as well as the fact that the farmers know they can have all the water they want at any time they want it, every day in the year. On the other hand, water users—stockholders—are charged their *pro rata* of maintenance and operation expenses, regardless of whether or not they use any water, and also for a minimum of 1 acre-ft. per share of stock. Additional water is 50 cents per acre-ft.

The use of water is increasing in this district, and is in large measure due to the increasing acreage in alfalfa and cotton. The figures are:

1909	214 333	acre-ft., net.
1910	236 631	" " "
1911	274 665	" " "
1912 (Estimated)	320 000	" " "

The figures for other districts are not available, but are probably similar.

LITIGATION.

The Salt Works Suit.—The New Liverpool Salt Company, whose property was inundated and destroyed on March 8th, 1905, began suit for damages to the extent of $180 000 for land and salt deposits and $30 000 for plant, changing the figures to $325 000 and $75 000, respectively, when the destruction became complete. In July, 1906, a compromise was suggested on the basis of $50 000 cash, but the management of

the C. D. Co. declined to consider it. On January 10th, 1908, the case was decided, awarding the Salt Company $456 746.23 damages and $1 500 costs, and a permanent injunction was issued restraining the irrigation companies from diverting more water from the Colorado than would supply the substantial needs of the people residing in the valley. Later, the United States Supreme Court affirmed the decision.

Actions of the Southern Pacific Company.—When this adverse and excessive judgment had been rendered, it was seen that the United States Courts would hold the C. D. Co. liable for all damages caused by the diversion of the river, regardless of the fact that it had occurred in Mexico. All personal property and unsold water stock, therefore, was turned over to the Southern Pacific Company at fair prices, and future payments for water rentals were assigned to the Southern Pacific Company until the moneys loaned by it should have been repaid. At the same time, suit was brought in the United States Court for damages sustained in America, and suit was filed in the Mexican Courts for damages sustained in both Mexico and the United States, and all real property in the respective countries was attached. The suits in the United States are still pending. Judgment was rendered in the Mexican Courts for $900 000, gold, against the Mexican Co., and enough property of that company was ordered to be sold to satisfy this judgment. Another Mexican corporation was formed by the Harriman interests, and permission to hold the concession of the original Mexican Co. was obtained from the Mexican authorities. At the sale, held on January 28th, 1911, this new Mexican Company bid in all the real and personal property of the Mexican Co., including the concessions from the Mexican Government, for the sum of $325 000, gold, which was less than 40% of the judgment. Thus nothing now remains of the original Mexican Co. except the organization, with a $575 000, gold, judgment against it, and additional suits aggregating nearly $2 000 000 in the Mexican Courts, and absolutely no property.

The new Mexican Corporation, called the Lower California Land and Water Company, *Compañia de Terreños y Aguas de la Baja California, Sociedad Anonima,* owns practically all the parent irrigation company's holdings in Imperial Valley having any value, but has not yet taken possession. Shortly after the sale by Court decree, fraudulent dealing was alleged, and on November 18th, 1911, it was advertised that the Judge of the First Instance at Mexicali would hear any and all

complaints in the matter. No one appeared, and it seems probable that the validity of the sale must therefore be confirmed. In that event, the new company will be free of any contracts with the mutual water companies, the C. D. Co., or any one else, and is probably quite beyond the reach of the American Courts. This, however, means little to the water users living in either the United States or Mexico, as the Mexican Government has issued rules and regulations by which water must be sold under the Mexican concession, and these fix the price at 50 cents per acre-ft., and practically in no wise affect the conditions under which American users now receive water.

The C. D. Co., in that event, would be a mere shell; it owns only 65 miles of main canals which produce no revenue whatever, cost no little to maintain, and are hence liabilities instead of assets; it also owns its office, grounds, and buildings, all of which are under attachment, and its liabilities exceed $2 000 000.

Appointment of Receiver.—On December 16th, 1909, the Title Insurance and Trust Company, trustees for the bond issue of the C. D. Co., applied to the Superior Court of Imperial County to declare the C. D. Co. insolvent and appoint a Receiver, which application was granted. The Southern Pacific Company has bought approximately $325 000 worth of Receiver's certificates, which, together with the major portion of the water rentals received from the mutual water companies, has kept the property going. Application has been made to sell the property, but this has been delayed as long as possible by the attorneys representing the bondholders, the New Liverpool Salt Company, and the old stockholders of the C. D. Co. In a few months, however, it seems probable that this will be accomplished.

Formation of Imperial Irrigation District.—Because of the various difficulties and the serious litigation, the people of Imperial Valley, on July 14th, 1911, by a vote of 1 304 to 360, elected to form the Imperial Irrigation District. According to the present law of California, this district can condemn property, even of a public service corporation, and all taxable property within the district is assessable for its needs. It is authorized to incur a bond issue of 50% of the assessed valuation of the property of the district, and the five directors are elected by all voters in the district just as in the case of county and State officials. The assessed valuation of Imperial County this year is $16 161 923; the value of its products is $10 000 000.

It is intended to acquire all the property of the C. D. Co. and the main canals and works in Mexico, giving bonds of the Imperial Irrigation District in exchange therefor. It has not been decided definitely whether the mutual water companies are to be retained, or whether the district is to own and control the entire water system—probably the former will be done.

The present law of California, under which this district was formed, is extremely interesting to water supply and irrigation engineers. It is a considerably changed form of the Wright Irrigation Act, under which, some 20 years ago, a number of irrigation districts were created in California, all of which resulted disastrously. It is believed that in its present form the law is a practicable one, and experience with it will be awaited with much interest.

The Abejas Diversion.

The excessive overbank flow during the summer flood of 1907 started cutting back fingers, as has already been stated. The flood of 1908 continued the work, and made it evident that the deep finger which first would have its grade receded to and through the bank of the Colorado, and thus again divert the entire river to the west, was one of the feeders of the Abejas, and that such diversion would occur about 20 miles below the International Boundary Line.

The situation was carefully watched, and the various interests affected were fully advised of developments. The United States Government had taken no tangible step to repay the moneys expended in closing the second break and in subsequent levee protection work, nor anything definite whatsoever with the Mexican Government looking toward a joint and satisfactory control of the situation. All interests, nevertheless, seemed to feel that the Southern Pacific Company would advance funds to protect the valley when a critical stage should be reached. The writer, in local charge of the situation for that company, had become fully convinced that the truest and best interests of all concerned would no longer be served by the railroad company standing in the breach, and recommended doing absolutely nothing further in protecting the valley than to maintain the existing levee system. In almost everything there comes a time to decline longer to carry the entire load. This recommendation was approved by the higher officials. When the summer flood of 1909 had passed, the

expected diversion was an accomplished fact, and as a result the entire low-water flow followed through the Abejas, spread out in a wide sheet without any defined channels, gathered into Volcano Lake and Hardy's Colorado and thence reached the Gulf.

The water in the river at the break dropped somewhat, and, as the river fell to its low-water stage, the water surface for a given discharge was found to be unusually low. The reasons for this have already been explained, but were not then fully understood. The demand for water in the valley increases greatly late in January, on account of the barley crop, and a serious water shortage seemed very probable.

Submerged Weir.—On urgent representations to the War Department, backed by the recommendation of the Reclamation Service engineers, permission was granted in March, 1910, to build a temporary obstruction in the river opposite the concrete head-gate, in order to raise the water a few feet and increase the flow in the canal. Work was started, but the river began rising and rendered it temporarily unnecessary. When the summer flood receded, in July, the situation was again critical, due to the large requirements in the valley, and work was resumed.

A trestle consisting of 4-pile piers, 15 ft. from center to center, was driven across the river at an angle of about 70 degrees. On this a railroad track was laid, and a little brush and considerable rock was dumped therefrom. Of course, there was no difficulty in developing a head of 2½ ft. This weir or obstruction prevented any danger of water shortage in the valley, but, not being square across the river, it produced eddy currents, just below it on the Arizona side, which cut away the bank to some extent and necessitated considerable expense in bank protection work.

The permission of the Government was given for this construction, on the understanding that it was to be temporary, and would be removed before the next spring flood. In March, 1911, all the piling was blown off, not pulled.

Late in 1910, arrangements were made to obtain the large suction dredge, *Imperial,* and with it in service no further immediate difficulty in diverting sufficient water is anticipated. (See page 1283.)

A very important fact, however, was developed in the construction and attempted removal of this weir, namely, that the small quantity

of rock dumped from the trestles which was required to raise a head of 2½ ft. at low-water stages—about 10 000 sec-ft.—was not undermined and did not settle except to a slight extent in a few places, with the summer floods of 1911 and 1912. These floods were ordinarily large, and, passing over it, had little effect in taking it away. This result was surprising, even to the proponents of rock fill methods of building weirs. The length of time it finally requires to eliminate all effects of this weir from the river flow at that point should be kept track of and reported to the Profession from time to time.

All Parties Frightened.—All the interests in jeopardy were now thoroughly frightened. It was finally realized that the Southern Pacific Company would no longer supply money for river control, and that the diversion was not only an accepted fact, but that the prophesied lowering of the river at the concrete head-gate had taken place. The fear had been that the bed of the river would be lowered at the Abejas break approximately from 5 to 8 ft. and that this lowering would rapidly run back up the river and have such an effect opposite the concrete head-gate as to prevent diverting enough water to supply the needs of the valley. This fear is now known to have been in large measure unfounded, as the permanent lowering of the water surface at the Abejas probably has not been more than 3 ft., and opposite the concrete head-gate not more than 2 ft., if indeed that much at either place.

Another fear was that the Colorado would now discharge directly into Volcano Lake, and during severe flood periods raise this body of water so high that it would flow northward and into the New River channel, thus cutting back a connection, permitting the river again to reach the Salton Sea, but by a course approximately 40 miles longer.

As the summer flood came on, the overflow covering the low lands on each side of the Abejas, especially in the vicinity of Campo Lino, was higher than any existing marks on trees, etc. To prevent this water from getting over the low divide to the north and thence to the Salton Basin, disconnected portions of the remaining gap in the levee line were partly built, the C. D. Co. through its Receiver paying the bills. While the work was in progress, the water, for long stretches, came within a few inches of the top of the fill being thrown up, and was held south of the divide only by strenuous efforts. Probably no

very serious results would have followed in any event, although the New River flume of the West Side Main might have been damaged.

The people of Imperial Valley were now thoroughly frightened, and urgent applications were rushed to President Taft, in which the civic and commercial bodies of California, especially Southern California, and the State officials joined. These applications pointed out the inability of American interests in jeopardy to handle a menace originating in Mexico, and the injustice they suffered.

CONGRESS APPROPRIATES $1 000 000.

In response to these applications, President Taft sent a special message to Congress, and on the eve of adjournment the two branches of Congress joined in a resolution, approved June 25th, 1910, providing:

"That the sum of $1 000 000, or so much thereof as shall be necessary, is hereby appropriated out of any money in the Treasury not otherwise appropriated, to be expended by the President, for the purpose of protecting the lands and property in the Imperial Valley and elsewhere along the Colorado River, within the limits of the United States, and the President is authorized to expend any portion of such money within the limit of the Republic of Mexico as he may deem proper, in accordance with such agreements, for the purpose, as he may make with the Republic of Mexico."

On June 8th, 1910, the acting Secretary of the Interior, Mr. Frank Pierce, addressed to the President a communication based on information and recommendations furnished by Mr. Hill, Supervising Engineer of the United States Reclamation Service, advising as follows:

"The ascertainment of what is necessary to be done for the purpose of accomplishing permanent avoidance of these recurring menaces to life and property on both sides of the International Boundary Line will require a thorough examination of physical conditions which, to be effective, should have the co-operation of both governments, and will consume considerable time. In the meantime, unless prompt relief is afforded, a water shortage, if not famine, is probable in the Imperial Valley within the next two months.

"In a country where the heat reaches an intensity of 120° and even higher, the great loss of property and the menace to both animal and human life which may result, should such a catastrophe occur, renders it imperative that prompt measures be taken toward averting the same. To that end, I respectfully recommend that you designate

an engineer having familiarity with problems involving river control to proceed immediately with an examination for the purpose of determining whether such emergency exists, and if so, to take the steps necessary to avoid the same."

On the recommendation of Gen. W. L. Marshall, Consulting Engineer to the Secretary of the Interior, John A. Ockerson, President, Am. Soc. C. E., and for many years Member of the Mississippi River Commission, was, on July 19th, 1910, appointed by President Taft. He at once went to Yuma, arriving there on July 30th, by which time Mr. F. L. Sellew, Engineer of the Yuma Project, on Mr. Ockerson's request, had made a survey covering the immediate vicinity of the C. D. Co.'s intake, and had prepared a plat which showed clearly that the bed of the river was above the bottom of the head-gates and that the deficiency of water in the canal was due mainly to the silting up of the intake above and the canal below the concrete head-gate.

There were two possibilities: one was to get dredging machinery into place as rapidly as possible and dredge out the canal; the other was to raise the water in the river by a submerged dam, the latter being temporarily necessary because of the time required to build dredges to do the necessary work. As explained, the weir was begun in the latter part of July and completed within a month, and the contract was not let for an efficient suction dredge until late in December, the delays in starting the latter being in part due to difficulty in arranging funds therefor, and in part due to a belief in some quarters that, with the submerged weir in place, a dredge was unnecessary.

Mr. Ockerson made an inspection of the Imperial Valley during the latter part of August, and about the middle of that month put out a surveying party which ran a stadia line along the Colorado River from about 6 miles below the Boundary Line to the Abejas break; thence down the dry bed of the Colorado for about 25 miles; down the Abejas River from the point of diversion about 5 miles; and made several cross-sections of the Abejas for the purpose of selecting the best site for a rock fill barrier dam—all of which required about 6 weeks.

On October 4th, Mr. Ockerson reported to the Secretary of the Interior that the Imperial Valley would never be safe from the menace of western diversions due to flood-waters until ample works were con-

structed to confine such flood-waters to narrow limits along the river proper; that there had been no appreciable lowering of the river bed on account of the Abejas break; that in extreme cases diversions to the west might depress the low-water plane opposite the concrete headgate and render it difficult to supply water to the Imperial Valley with the present diverting works; that the maintenance of levees consists not only in keeping up the cross-section, freeing it from weeds, brush, and burrowing animals, but also in holding in check the tendency of the river to erode the banks and threaten to breach the levees; that a levee located 3 000 ft. from the westerly bends of the stream would probably remain intact for a long time; that if the C. D. Co. levee line had been carried down along the river instead of where it was built in 1907, it would have reached a point 6 miles below the Abejas break, and no break would have occurred there; that completing the upper levee would undoubtedly protect the Imperial Valley from floods for a short time, but constituted only a partial solution of the problem, and even that only temporarily; that, finally, the proper protection of lands in the Imperial Valley required that the Colorado River be restored to its former channel and an effective line of levees be built from a point on the existing levee system about 6 miles below the International Boundary Line and following along the west side of the stream to a distance of about 3 000 ft. from the westerly bends of the river, approximately 25 miles, where the flood height would be at an elevation below the ground line in the vicinity of Volcano Lake and any diversion of the water would not cause a tendency to flow north.

It was estimated that such a levee would require about 1 300 000 cu. yd. of earthwork and 450 acres of clearing and grubbing; and it was recommended that the top be 8 ft. wide, the slopes 3 to 1, and the berm between the toe of the slope and the edge be 40 ft. wide, and that borrow-pits be on the river side, with traverses 50 ft. wide at intervals of 400 ft.

In commenting on the situation early in September, 1910, Gen. Marshall recommended completing the northern line of levees, as originally designed by the writer, to prevent the water from getting north, and providing a suitable and practical intake for the canals of the C. D. Co. He also suggested that, if the present intake (concrete heading) be closed and the Imperial Canal be extended to the Laguna

Weir, the matter would be solved, as far as American interests were involved.

River Levee Plan Adopted.—A month later Mr. Ockerson went to Washington for a conference, the result being that the work suggested by him was ordered begun. On November 25th bids for the levee construction were opened in Yuma. According to the specifications, the contractor was to assume all risks of interruption of the work by floods, and as the season was by this time far advanced, the prices were deemed too high and endeavors were made to get the work done on force account.

At about the same time it was discovered that the Mexican Government—as would naturally be expected—could not consistently permit the United States Government, or any of its officials acting as such, to perform work on Mexican soil. For six years, the need for making satisfactory arrangements and agreements with the Mexican Government regarding the Colorado River and its control, and proper and equitable division of its waters, had been fully understood, but practically no progress had been made. That fact, however, makes it even more surprising that requests on the part of the United States should have been made to enter Mexican territory and do work therein. The difficulty was very easily overcome, of course, by operating through the medium of a Mexican corporation, as the Southern Pacific had done, and the C. M. Co., which, as has been explained, is a very large land company, was chosen. Consequently, nothing was done in the name of the United States, but the engineer in charge acted under power of attorney from the C. M. Co., there being a gentleman's agreement between the United States and the C. M. Co.

In this way, on December 12th, contracts were awarded for levee construction, the first 9 miles, aggregating 425 000 cu. yd., at from 19 to 22½ cents; the next 6 miles, aggregating 336 000 cu. yd., at 23 cents; and the remainder, aggregating 325 000 cu. yd., at 36 cents. These figures were afterward considerably increased, the total quantity being 1 277 984 cu. yd., and the total cost, including $20 000 paid for duties, $452 434. The work in the immediate vicinity of the Abejas break and the small quantity of grading on 4 or 5 miles of temporary track was done by the C. M. Co. on force account. President Lovett, of the railroad company, offered to supply, essentially at cost, all the organization, men, equipment, and supplies required for closing the break and for doing any other work that might be deemed necessary.

The Mexican Government had given assurances to the American Minister that duties on stock, material, and supplies would be remitted, which was considerably more than had been done when the railroad had the work in charge. The Government officials, however, were not satisfied with this, and thought that all material should be passed free—a matter very much more difficult to arrange under Mexican laws, as it would require Congressional action, and that country was already in the throes of a revolution. However, after a delay of 2 weeks in getting stock across the line, it was decided to arrange for the duties and depend on a refund later. The contractors began work early in January. At about the same time one pile-driver was put to work on a trestle across the Abejas, and by February 2d (river discharge, 11 000 sec-ft.) the temporary track was completed to and over the trestle, and rock dumping began.

The method was that developed in closing the first and second breaks, and used later in closing the gap in the Laguna Weir, one trestle being deemed quite sufficient, as the maximum head was not expected to exceed 7 or 8 ft. At the Andrade quarry there were approximately 15 000 cu. yd. of rock ready to load with steam shovels, and the quarry was well developed, having a face about 900 ft. long and averaging 40 ft. high. Two 4-cu. yd. steam shovels were secured from the Southern Pacific Company, and a 2½-cu. yd. shovel of the Reclamation Service was brought down from the Laguna Weir. Work trains, men, and "battleships" were obtained from the railroad, as required, and rails and track material were furnished on a rental basis.

On February 7th, a sudden rise (maximum discharge, 23 000 sec-ft.) caused a breach in the trestle; this was closed 10 days later. On March 7th another small rise in the river carried away seven bents, and 6 days later another rise (maximum discharge, 35 000 sec-ft.) brought down a mass of drift and wrecked a considerable length of the bridge, caused the loss of a pile-driver and one steel "battleship," and drowned one man. On the 28th the pile-driving was resumed and the operations were continued without further mishap until May 15th, when work on the dam was shut down.

In making this closing, the rock fill was not kept at uniform height for the entire length of the trestle, the overpour for some of the time being confined to three places with a total length of from 260 to 275 ft. It is probable that this explains in large measure the breaking of the

trestles by floods and drift, after obtaining an effective rock mattress, such as is provided by dumping two or three cuts of "battleships" all along. In building the Clarke Dam, floods (maximum discharge, 32 000 sec-ft.), with heavy drift, threw the trestle out of line in only one place after rock dumping began, and caused no other damage.

The number of cars unloaded in the Abejas closing work is given in Table 22.

May 1–2	41	3	....	8
Totals	3 996	161	43	182

The total quantities were: 139 860 cu. yd. of "battleship" rock, 193 cu. yd. of flatcar rock, 516 cu. yd. of Declez rock, and 1 092 cu. yd. of quarry rock in dinky cars, a total of 143 400 cu. yd. up to May 2d. The total quantity of rock used to May 15th, when work closed down, was about 180 000 cu. yd. The total cost of the dam is given as $347 500.

About 140 000 cu. yd. of rock were used before the water was practically shut off in making this closing. The reasons for requiring such a large quantity probably are that relatively little flatcar rock of large size was used, the fact that the rock fill was not carried along at a uniform height for the entire length of the overpour, and the slow rate at which the rock was unloaded. The first methods of quarrying were not well adapted for giving the maximum output, consisting of operations along the top of the rock mass by the edge of the quarry face, but, later, horizontal tunnels were driven into the quarry face at intervals along the bottom and large charges of explosives were used, after which the output was much increased.

The levee work went along very rapidly, the contractors fortunately encountering no flood difficulties or delay, and on April 7th the last of the grading outfit left the work.

While operations were in progress, the Revolution in Mexico began, and resulted in the abdication of President Diaz. On February 21st, the Revolutionists captured Algodones, and took possession of a work train for half a day. On April 16th a large body of Mexican Federal troops arrived at the break and remained guarding the work from interruption until May 10th.

Damage to the Work.—The 24.6 miles of levees were constructed in accordance with the recommendation, namely, with a top width of 8 ft., side slopes of 3 to 1, borrow-pits on the river side 400 ft. long, with intervening uncleared traverses 50 ft. wide, a berm width of 40 ft., the entire ground covered by the levee and the berm cleared, and roots and stumps grubbed, and a muck-ditch, of such depth as would

reach through the adobe soil under the construction, dug out and filled with good material under the axis of the levees. Except for a very few cases of logs and brush in the levee section, and inefficient muck-ditching reported to have been disclosed where the levees were broken, the dikes were very well constructed in accordance with the specifications. The levee was built to a grade of "5 ft. above the high-water marks of the 1909 summer flood, chiefly for the purpose of having excess material wherewith to remedy deterioration, rather than through any fear of overtopping from floods." No railroad track or gravel blanketing was put on the levees, because of the belief "that it would be better to extend the levees as far as practical, rather than dissipate available funds for mere convenience of maintenance."

A low levee was built along the south side of the break, extending from the dam a short distance up stream, to prevent water from getting into the levee borrow-pits until the grading outfits had finished work in the vicinity. As the water in the river was gradually raised, partly by increased discharge (total, 19 000 sec-ft.) and partly by increasing the height of the rock fill across the break, this low levee was, on April 21st, overtopped and almost at once about 1 000 sec-ft. of water started down the borrow-pit clearing, about 2 000 sec-ft. going into the old Colorado River channel. When the water hit the uncleared traverses it cut the berm and side-wiped the levee at almost every traverse for several miles. Work on the rock fill dam was stopped, and the men were set at work protecting the levee. Later in the day this was stopped, and work on the dam was resumed. The latter was facilitated materially by the waters breaking over into the borrow-pits, the elevations of the water surface above and below the dam being quickly changed from 79.6 and 71.6, respectively, to 78.6 and 71.0, the depth of overpour being reduced 1 ft. and the head on the structure 0.4 ft. By dumping rock and filling the holes where the confined overpour occurred, the situation there was soon in hand, and 8 days later (April 29th) the elevation of the lowest point of the dam was 80.6, or 1 ft. higher than the water surface up stream, where the water broke into the borrow-pits, and the flow over the structure was stopped.

By that date the levee to the south was cut entirely through in several places in the first 6 miles, and it was evident that the water

would soon merely detour around the dam and continue to follow the Abejas channel below. The river discharge then was 21 900 sec-ft., and about 4 000 sec-ft. were going down the old channel, the remainder running through the levee breaks and toward the west. On May 7th, the discharge of the river had increased to 32 800 sec-ft., of which perhaps 9 000 sec-ft. were running down the old channel of the Colorado, and the water varied in height from 4.3 to 6 ft. below the top of the levee in the 2 miles immediately north of the dam.

The rock fill was then up to the track all across, and the total percolation through it was reduced to about 120 sec-ft. The eddy currents below the dam, 9 days later, weakened the earth fill about 300 ft. from the north end of the dam, until the water broke through, and in a few hours the entire discharge of the river (except a little overbank flow) was going through it and down the Abejas. Soon the earth fill on the south was cut through, and thus the rock fill dam was made an island in the Abejas channel, which is the situation at present.

The final injury on the levee work prior to the summer flood was three breaks and several places side-wiped on the north levee, totaling about 16 000 cu. yd., and thirteen breaks, varying from a few hundred feet to more than 2 miles in length, and much side-wiping in the first 8 miles of the south levee, totaling about 200 000 cu. yd., or about 50% of the original earthwork in this stretch. The fact that such disaster was caused by so small a quantity of water reaching a maximum depth of only 4 ft. on the levee shows clearly the ease with which the material of the region is eroded.

The protective measures used were sand bags and brush placed to check erosion and the dynamiting of the traverses which, with the drift their vegetation caught, deflected the water to the levee section. The latter procedure had the bad effect of converting the borrow-pits into a continuous canal, but with severe eddy currents caused by the remains of the traverses. These endeavors had little effect; indeed, to hold long stretches of embankment against such action is practically impossible.

Board of Review.

On June 1st, Mr. Fisher, Secretary of the Interior, called a Board of Review consisting of Mr. F. H. Newell, Director of the U. S. Reclamation Service; Gen. W. L. Marshall, Consulting Engineer to the

Secretary of the Interior; J. B. Lippincott, M. Am. Soc. C. E., formerly a Supervising Engineer of the U. S. Reclamation Service and now an Assistant Engineer of the Los Angeles Aqueduct; Mr. C. E. Grunsky; Mr. J. A. Ockerson, Engineer in charge of the work; and Gen. Harrison Gray Otis, President of the C. M. Co., to report on the work done under the appropriation. All the members of the Board have examined the territory and understand the situation fully, although none of them except Mr. Ockerson has been on the ground since the Abejas diversion occurred.

On June 7th this Board made a report based on information as to the recent work done and results obtained, supplied by Mr. Ockerson, and answering specific questions submitted by Secretary Fisher. The full text of this report is as follows:

"1.—A breach in the west bank or levee of the Colorado River, if made at or within a mile south of the California boundary, or south of Mile 18, below Yuma Bridge, will result in water flowing directly into the drainage areas of the Alamo and New Rivers and thence into Salton Sea, which would be disastrous to property in the United States.

"2.—A breach in the river bank at any point between Miles 18 and 55, below Yuma Bridge, will result in spreading water over the Delta of the Colorado River, with a flow into New River *via* Volcano Lake, menacing Imperial Valley.

"3.—(*a*) The best practical method for the protection of land and property in the United States against a discharge directly into the Imperial Canal and thence through Imperial Valley into Salton Sea, is to protect and maintain the levees as at present located for a distance of at least 10 miles south of the California boundary and to hold the river by adequate bank revetment practically on its present alignment. (*b*) This levee, if extended to a point opposite the south boundary of Arizona, or about Mile 27, will also prevent a discharge directly into the Paredones.

"4.—(*a*) As a remedial or precautionary work to prevent damage which might result from a crevasse directly into the Imperial Canal or Alamo River, we have considered a secondary levee west of the river levees, across Imperial Canal, and large channels leading to the natural depressions, or diverting works, conducting the water southwesterly into channels leading into Volcano Lake, but it is believed that the cost of any such secondary defence could be better expended in maintaining the main line of defence at the river. (*b*) As a necessary defence against the northerly flow of any water reaching Volcano Lake, whatever be the treatment of the Lower Colorado River, there should be an embankment well protected against wave wash on its

south slope, constructed about on the line of the levees already built extending from high ground north of Volcano Lake to a connection with the levees already built by the California Development Company, southwesterly, toward this region from the Colorado River. The top of this embankment should at its western end be not less than 10 ft. higher than the rim land at Volcano Lake. This embankment is an essential requisite as a protection of Imperial Valley, against menace from the south, and should be constructed without delay.

"5.—(*a*) The maintenance of the works constructed in 1906 and 1907, closing the breaks of the Colorado into the Alamo, and the maintenance of these and of the river levees since constructed as far south as the head of the Abejas are essential requirements. Suitable arrangements for their repair and maintenance should be made with Mexico through the proper authorities. We do not consider the immediate closure of the break into the Abejas and the reconstruction of the levees below the break as essential to the protection of property in the United States. The ultimate treatment of this section of the Colorado River in co-operation with Mexico may well be determined by negotiations between the governments of the two countries. As a feature of the permanent solution of the river problem it is desirable that the Abejas break be closed, that the levee constructed in 1911 be repaired and maintained, and the Colorado River restored to its former course. (*b*) Provided the water of the Colorado is discharged into the Gulf of California through the Abejas into the Pescadero and Hardy Rivers, there is little probability of the cut back affecting the Laguna Dam. Such cut back will not injuriously affect the heading of the Imperial Canal or levees adjacent thereto, with a possible exception of requiring the lowering of the intake of the Imperial Canal a few feet. This is not a serious matter, and is one that should be dealt with by the California Development Company itself when necessary. The diversion by the California Development Company should be facilitated during low-water stages by dredging, or by lowering the sill of its intake, rather than by placing obstructions in the channel of the river below the intake.

"In view of the existing emergencies along the Colorado River, arrangements should be made with the government of Mexico to provide for the early creation of an International Colorado River Commission, embracing in its membership both American and Mexican engineers, invested with large powers and ample authority to examine into and to submit a basis for the adjustment of all questions relating to the conservation, use, and control of the waters of the Colorado River with a view to such governmental action as shall result in a complete, just, and final settlement of all such matters at issue between the two nations. We recommend that further work should be undertaken at once and in approximately the following order:

"(*a*) The levees north of Volcano Lake should be raised, strengthened, and extended.

"(*b*) The existing levees along the west bank of the Colorado River to the Abejas should be repaired and protected. For this purpose and to meet emergencies, there should be immediately available the sum of at least $1 000 000. This sum provides only for the temporary maintenance of levees, and does not include the systematic revetment of the river banks.

"The conference ventures to suggest certain international questions which are involved and which will inevitably have to be met sooner or later:

"(*a*) The matter of the permanent protection of existing works on both sides of the international boundary line, the construction of further works, and the conditions under which the present and future projects may be carried out on Mexican soil, with the consent and co-operation of the government of Mexico for the benefit of both countries, to the end that the greatest practicable quantity of water of the Colorado River may be made available for irrigation by means of storage reservoirs and otherwise, and the least possible quantity be permitted to flow unused to the sea, and to what extent the cost of such maintenance should be chargeable to properties benefited and to what extent chargeable to either government.

"(*b*) That permanent agreements with the government of Mexico shall be entered into, having in view the just apportionment of the waters between the two countries, irrigation to be paramount to navigation.

"(*c*) The method by which either nation may acquire rights of way for canals, levees, and related works, each within the territory of the other, and the authority to maintain such works.

"(*d*) The modification of the boundary line between the United States and Mexico with a view to facilitating the solution of the entire Colorado River problem. An authoritative, just and final determination of this important question, now a matter of public discussion, will have the effect of removing existing doubts in the public mind and of settling the matter for the benefit of all concerned.

"The members of the conference desire to call attention to the fact that the plan and execution of the work accomplished during 1911 followed well-established principles of good engineering. That so large an amount was accomplished in such a brief space of time, under adverse circumstances, is worthy of the highest commendation. That the restoration of the Colorado River to its former channel was not realized is chargeable to the delay in the negotiations, which prevented prompt inauguration of the work and the prosecution during the low-water season, and also to the disturbed political situation and strike which demoralized labor conditions. The members of the conference,

in addition to the conclusions above reached, present also a statement of physical and related facts embodied in an abstract of the data available, and found largely in the reports of J. A. Ockerson and of C. E. Grunsky. Also in the printed hearings before a subcommittee of the Senate Committee on Claims, referring to Senate 4170, January 21, 1909."

When President Taft received the report, he sent a special message to Congress recommending the appropriation of another $1 000 000 to continue the control work, but Congress failed to comply. It is desired to call particular attention to the last part of this report containing Suggestions *a*, *b*, *c*, and *d* regarding certain international questions involved, which sooner or later must be met. These suggestions contain the crux of the entire situation, and it is to be hoped that they will be expeditiously followed out. It is perhaps desirable to call attention to the wording of Suggestion *d* regarding modification of the Boundary Line between the United States and Mexico, the suggestion being implied that the matter be taken up more with a view of putting a quietus to the proposition, than with the idea of obtaining any territory from the Mexican Government.

Surveys by the New Mexican Company.

As soon as the summer flood of 1911 began to recede, and the extent of the damage sustained by the new work was ascertained, the Harriman interests controlling the new Mexican Company deemed it wise to ascertain how effective the line of levees north of Volcano Lake would be in holding back the waters of a very large summer flood. Accordingly, three surveying parties were put out early in July under the immediate direction of Mr. Hind. The surveys were carried down the river to The Colony and as far west as Volcano Lake, much of the territory being covered quite thoroughly. The field work was completed during the latter part of September, and the data were assembled and mapped. Mr. Randolph analyzed these data and compiled a report which was forwarded to Mr. R. S. Lovett, Chairman of the Executive Board in New York City, recommending:

1st.—That the westerly portion of the Volcano Lake levee be raised and extended so as to occupy a plane 6 ft. above the then present crest; and

2d.—That an effective levee system, including a rock dam shutting off the Abejas diversion, be constructed along the river to a distance

of 16 miles below such dam; that the entire levee should be blanketed with gravel; and that a railway track be laid thereon in good condition for further operation when necessary.

Mr. Lovett, on December 13th, 1911, made a formal offer to President Taft, on behalf of the Southern Pacific Company, to return the Colorado River to its original channel and to maintain the levees necessary to keep it there for one year, providing the Southern Pacific Company be repaid for the work done in 1906-07 at President Roosevelt's request, in the sum of $1 083 673.97, being the amount reported as proper under the circumstances by Mr. Grunsky in his statement to the Committee on Claims during 1908; and provided, further, that an additional appropriation of $1 500 000 be placed at the disposal of the President of the United States with which to pay the actual cost of the work to be done and the cost of maintaining it for one year, the Southern Pacific Company to stand any excess of cost over and above such an amount; that the transportation charges of the Southern Pacific Company in connection with the work should be in accordance with the arrangements in effect during the work under Mr. Ockerson's direction; and providing, further, that should the Southern Pacific Company fail to return the Colorado River to its former channel and to retain the levee for one year thereafter, then in that event the Southern Pacific Company should receive no compensation or reimbursement for the work which it would do under that offer.

This proposition was referred to Gen. Marshall, Consulting Engineer for the Department of the Interior, who, under date of January 5th, 1912, reported in substance that the work proposed should not be done either by it or by any other agency on behalf of the United States at this time, nor until the entire subject of improving the Colorado River and utilizing its water should be investigated by an International Committee representing both the United States and Mexico. The following day, the Secretary of the Interior, W. L. Fisher, forwarded Gen. Marshall's report to President Taft and approved of its conclusions, stating that the suggestions constituted the most important recommendation of the Advisory Board of June 7th, 1911, and adding:

"I consider it of great importance that negotiations should be immediately opened and vigorously conducted with a view of arriving at a treaty with Mexico covering this subject."

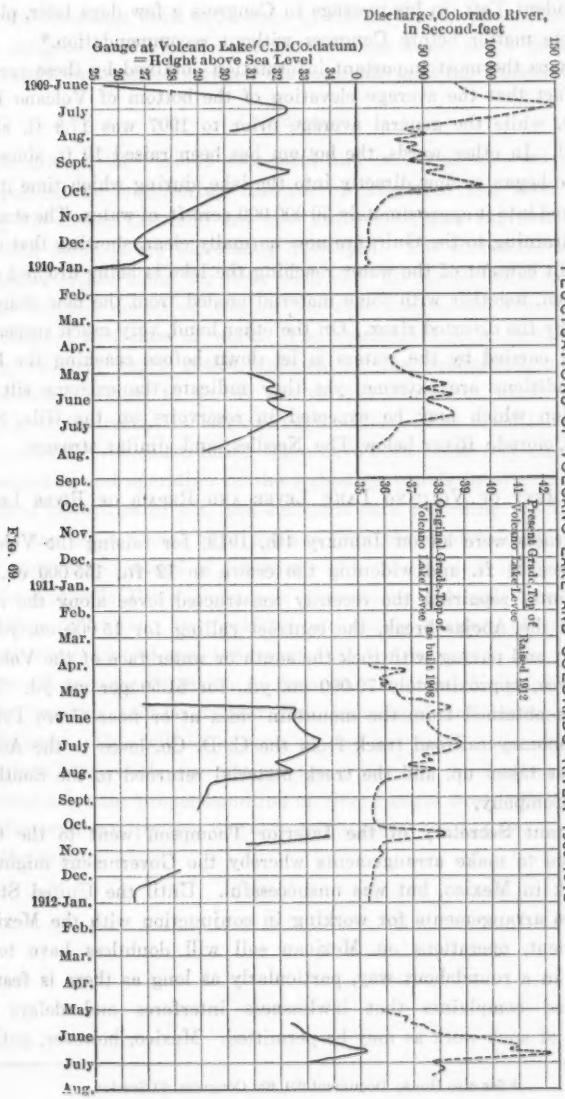

FIG. 69.

FLUCTUATIONS OF VOLCANO LAKE AND COLORADO RIVER 1909-1912

President Taft, in his message to Congress a few days later, placed the whole matter before Congress without recommendation.*

Perhaps the most important information obtained by these surveys is the fact that the average elevation of the bottom of Volcano Lake is 28 ft. while the general average prior to 1907 was 17.8 ft. above sea level. In other words, the bottom has been raised 10 ft. since the Colorado began to flow directly into the lake, during which time it has discharged into it approximately 30 000 000 acre-ft. of water. The streams below, draining to the Gulf, are now normally clear, showing that most of the silt content of the water reaching the lake is being dropped over its bottom, together with some material eroded from the new channels formed by the diverted river. On the other hand, very much suspended material carried by the waters is let down before reaching the lake. The conditions are extreme, yet they indicate the extreme silt deterioration which may be expected in reservoirs on the Gila, Salt, Verde, Colorado River below The Needles, and similar streams.

Improvement of Volcano Lake Levee and Repair of River Levee.

Contracts were let on January 4th, 1912, for raising the Volcano Lake levee 3½ ft. and widening the crown to 12 ft., 155 000 cu. yd. at 25 cents; repairing the recently constructed levee along the river north of the Abejas break, the contract calling for 15 000 cu. yd. at 22 cents; and paving with rock the south or water face of the Volcano Lake levee, approximately 70 000 cu. yd., for $1.50 per cu. yd. This rock was obtained from the mountain sides at or near Cerro Prieto. The temporary railroad track from the C. D. Co. levee to the Abejas break was taken up, and the track material returned to the Southern Pacific Company.

Assistant Secretary of the Interior Thompson went to the City of Mexico to make arrangements whereby the Government might do this work in Mexico, but was unsuccessful. Until the United States concludes arrangements for working in conjunction with the Mexican Government, operations on Mexican soil will doubtless have to be handled in a roundabout way, particularly as long as there is fear of unfounded complaints that lawlessness interferes and delays the progress of such work as may be permitted. Mexico, however, author-

*See also House Document 204, 62d Congress, 2d Session.

ized the foregoing work to be done by the C. M. Co. through the engineer assigned by the United States to do the work, and a gentleman's agreement was reached between that company and the United States.

Conclusion.

Because of the various successful and unsuccessful work done in the region, the engineering features of irrigation and river control along the Lower Colorado are now understood, and engineering construction methods are thoroughly developed. The successful attempts in closing breaks along the river with rock fill barrier dams according to the method developed during the first and second closings have standardized this class of work. The Southern Pacific Company can easily, on very short notice, furnish all the equipment, men, and organization needed to do all the various classes of work involved, directly or indirectly, in controlling the river. The essential features of successful levee construction there have been made very clear. The maintenance and operation of the irrigation canals involve caring for excessive quantities of silt, and sufficient data regarding the silt problem in the Main Canal have not yet been obtained to decide on the most economical method of diversion.

The Colorado River Delta now presents no unusual, unsolved engineering difficulties; its problems are chiefly matters of statecraft, in both river control and irrigation. At the conclusion—in the near future—of existing litigation in American Imperial Valley, irrigation of the territory will be notably free from legal and managerial entanglements. This will be as soon as, and not until, reasonable treaty provisions between the two nations are arranged. Such a treaty is indispensable for the proper handling of river control work. Fortunately, both Governments profess not only willingness, but impatience, to adjust the matter.

DISCUSSION

Mr. Le Conte.

L. J. LE CONTE, M. AM. SOC. C. E. (by letter).—This interesting paper furnishes valuable information relating to the troubles of the irrigation engineer and the irrigators. A record of the memorable struggles with flood-waters in the Colorado Delta in recent years will always be a source of valuable information.

The rich fertilizing qualities of the silty waters of the Colorado River are well known. The important point to keep in mind is the fact that the rich and desirable sediment always comes down with the first rising river waters, and the undesirable barren sandy silt during high water and the falling river stages. It follows, therefore, that the desirable silt is to be had largely from the rising river waters, and that suitable management and wise control of the scouring sluices and regulating gates at each end of the Laguna Weir are of the greatest importance in the maintenance of the entire canal system. In order to reduce silting troubles to a minimum, the mean velocity of flow throughout the entire canal system should be as nearly uniform as practicable.

For this purpose the formula given by Mr. R. G. Kennedy,* is very useful, namely:

$$\text{Velocity} = 0.84\, d^{0.64},$$

hence, comparing one channel flow with another, we have practically the ratio:

$$v : v_1 : : \sqrt[3]{d^2} : \sqrt[3]{d_1^{\,2}}$$

but, after all, the main feature to keep constantly in mind is that the mean velocity varies as $\sqrt{R\,S}$, and that S is the slope of the surface of the water and not the slope of the bed of the canal. With the best of management, however, there will always be some silting up, but the silt ought to be largely of valuable character, and when dredged and deposited on the bank adjoining the county roads the farmers will eagerly cart it away for fertilizing purposes. The clean, barren, sandy silts which are so undesirable, should not be allowed to enter the head-works of the canal to any large extent. The cost of the Laguna Weir, $434 per lin. ft., when compared with the cost of the Kistna Anicut, in India, $104 per lin. ft., seems to be unreasonable, but such comparisons are always odious, especially when all circumstances are not known. The annual revenues from the Kistna system amount to $1 500 000, and if the Laguna Weir system approximates this figure, in the course of events, all will be satisfied.

The author's remarks about a "rating curve" are commendable. No official record is so absolutely unreliable as the conventional rating curve for any given gauging station. It is worse than no record

* *Minutes of Proceedings*, Inst. C. E., Vol. CXIX, p. 281.

Mr. Le Conte.

whatever, inasmuch as it is a worthless official record which will have to be officially disproved in Court before one can get authority to proceed. Experience everywhere on sedimentary rivers shows that all the cross-sections of a rising river are enormously increased in area by the scouring out effect of the down-rushing flood-waters laden only with lighter sediment. The heavy sandy sediments gradually crawl down river much more slowly than the rushing flood-waters, hence they do not show until the river begins to fall. It follows that all the cross-sections of a falling river diminish rapidly in area and return gradually to the usual low-water cross-section. These being the facts on every flood, how is it possible for any sane man to get up a rating curve which has any practical value whatever? This is particularly true in the case of a gauging station on the main river just above a large tributary stream.

When the tributary stream is in high flood, the water in the main river is not only high, but the current is often running up stream, which potent fact alone destroys completely the value of the rating curve.

The author's proposed plan of building a wide rock fill dam, without any concrete cross-walls whatever, seems to be plausible, in view of the valuable experience in closing the big breaks in the Colorado River banks leading down to the Salton Sea.

These rock fill dams have now stood the ravages of severe floods for the past 6 or 7 years, and are still intact and water-tight, for all practical purposes. The main object of the concrete cross-walls in the Indian dams is to shut off leakage through the broken-stone fill and hold the stones together. As the low-water flow of the Colorado River is small (6 000 cu. ft. per sec.), it becomes very important to hold all the water possible. If a successful, wide, water-tight dam can be made, as described, without them, all well and good. The writer is of the opinion that it is well worth trying, from a financial point of view, particularly at such a site as the Laguna Weir, where the slope per mile is only 1.2 ft.

In India, the anicuts are generally built where the slope per mile is 3.5 ft. and the river bed is pure sand of unlimited depth.

Mr. Knowles.

MORRIS KNOWLES, M. AM. SOC. C. E. (by letter).—This excellent and exhaustive paper is a most fascinating story of the ever-changing Colorado. The reader can almost picture himself on its banks, witnessing the frequent breaks, overlooking the vast overflows, and taking part in the repeated attempts at closure. The Engineering Profession can indeed feel gratified that it has members who will patiently chronicle events, analyze situations, and faithfully tell of failures.

Much is related of irrigation needs, local causes and effects of floods, notable works built and projected for the former, the great emergency construction to overcome the latter, and studies and plans for future

Mr. Knowles.

protection and control. Little has been said, however, of the possibilities of prevention, of great works that might be built to hold back the flood flows and let out at other times the increased quantities that would make for greater irrigation possibilities, increased navigation stages, if otherwise possible, more water for power, etc.

Within a short time, and brought to a focus by the work of the Pittsburgh Flood Commission, the country has realized that we can no longer be indifferent to the vast and universal country-wide problems of regulating the flow of our streams. Without going into details of the many correlated benefits to be obtained from storage of flood flows, the devastations of the Ohio, Missouri, and Mississippi Valleys, those of the Southern Appalachian regions, as well as those of the Pacific Coast and great Colorado, so vividly portrayed in this paper, have awakened people, all over this land, to the fact that here is an important problem to solve, in which the factors have some relation, wherever we go, and from the solving of which, much other good will come.

That this is also true of the Colorado Basin is evident from the author's remarks on pages 1206 and 1208 and from Table 2. It would be of still further interest, therefore, to know whether the storage of approximately 10 000 000 acre-ft. exhausts the possibilities on the Upper Colorado, and what effect such impounding at several selected points would have in decreasing the flood discharge and increasing the low-water flow. It is possible that it would not apparently diminish the interest and intensity of the problem of protection below Yuma, on account of the peculiar local characteristics, yet it is probable that the cost of such works would be less and safe results more certain.

If data are available to show the effects of such storage of flood peaks, as is illustrated by the Pittsburgh report, it is hoped that the author will present them in his closure. If not now obtained, perhaps this discussion may call attention to the need, and emphasize the fact that here is another place and a further reason for the Nation, by its Central Government, to take hold of its water problems as a great national question, and to study, plan, and treat each group of streams as a unit from source to mouth.

Mr. Sellew.

FRANCIS L. SELLEW, M. AM. SOC. C. E. (by letter).—Turning the Colorado out of Salton Sea was not so much an engineering triumph as a triumph of engineers, of red-blooded fighters, who did not know when they were whipped, but realizing that the end justified the means, fought on to victory unmindful of its cost. All honor to them. The writer will go to the limit in expressing appreciation of results attained in the face of odds as great as any with which river engineers may expect to be confronted; but when the closing of this crevasse, which, from the nature of things, had to be accomplished by rough and ready

methods, is heralded as a solution of all engineering problems pertaining to the Lower Colorado, the writer's protest is immediately entered. Mr. Sellew.

Having been an innocent bystander while some of the work described was in progress, this paper has been read with much interest. The record of the operations incident to the return of the river to its former channel is extremely complete, although partly obscured by a mass of legal and financial entanglements which properly have no place in a purely engineering article.

Lack of time will confine the writer's discussion to an examination of some of the more important points. The data submitted in regard to the discharge of the stream and the degree of reservoir control possible vary materially from the writer's ideas on these subjects. It is also doubtful if the control attainable by reservoirs will greatly reduce bank caving, which is the real problem along this river. Although what follows is based on the best data in existence, it should be understood that, before definite conclusions can be drawn, much more detailed and extended examinations should be made.

Flood Prevention on the Lower Colorado.

It is apparent that if the flood discharge of the Colorado could be reduced materially, thereby bringing the fluctuations between low and high water within reasonable limits, the erosion of the bed and banks would be much reduced. There might still be a limited amount of bank protection required, but, if the control was such as to keep the river within banks, the cost of protective works would be greatly lessened. We have recently heard much about the control of streams by storage works; and, with reference to the Colorado, one advocate claims that storage near the head-waters will reduce flood levels so much that levees will be a thing of the past; that the flow of the stream may be entirely devoted to irrigation, thereby putting water on 5 000 000 acres of land; and also that immense quantities of electrical energy may be developed as the water is released from the places in which it is impounded. As the question of stream control by storage reservoirs has received much attention in most civilized portions of the earth, the writer has made a somewhat extended examination of the literature on that subject.

On page 406 of the "Report upon the Physics and Hydraulics of the Mississippi River," by Humphreys and Abbot, the following appears, in regard to the reservoir system:

"The plan, in theory, is admirable, and has long been a subject of discussion among European engineers. Artificial lakes for protection against floods were constructed as early as 1711 upon the upper Loire, and they have since been advocated, both for improving navigation and for restraining floods, by eminent writers, * * *."

Mr. Sellew.

From page 407 of the same publication:

"Little consideration is necessary to make it apparent that this system is not applicable to restraining the floods of all rivers. Certain topographical conditions are essential to its success. The valley must be of such a character that dams of reasonable dimensions can be constructed, which shall keep back *the identical water which otherwise would make up the flood.* It is not sufficient for this purpose, as for improving navigation, that a large volume of water may be collected by the accumulations of months. The floods of great rivers are torrents, caused by rapidly melting snows and by widely extended and heavy rains. The greater part of this water does not drain from the remote mountain sides, and issue from the distant mountain gorges. It falls in the valley itself; and the nearer to the main river, the more sudden and disastrous will be its effects; partly from the more rapid accumulation in the main stream of the contributions of the tributaries, and partly from the absence of the natural reservoir furnished by the various channels, which must be filled before a freshet originating near the sources can reach the lower part of a river. To control such floods with certainty and economy by artificial reservoirs, it is, therefore, essential that certain important tributaries which drain relatively large portions of the basin shall debouch near their mouths from narrower gorges, where dams can be constructed at reasonable cost, and where artificial lakes can be formed without injury to other interests."

From page 408:

"In order to give a more definite character to these conclusions, they will be reduced to figures by aid of the data collected respecting the great June flood of 1858, by which the merits of all these different plans of protection are to be tested.

"To have protected 'the whole delta and the borders of every stream in it, primary or tributary' against this flood, not more than 1 050 000 cubic feet per second could have been allowed to enter the head of the alluvial region. Even this quantity would have submerged much of the lower country, had not the tributaries below the Ohio been so very low that their united contributions, joined to this amount, would only have been sufficient to maintain the river at full banks. The conditions of this flood were then the most favorable possible for the reservoir system.

"During the thirty-six days in 1858 from May 25 to June 29, inclusive, the total amount of water passing the latitude of Columbus exceeded by 648 172 800 000 cubic feet that which would have resulted from a discharge per second of 1 050 000 cubic feet. Reservoirs situated above the mouth of the Ohio, and sufficient to have kept back *in a single month* fully 600 000 000 000 cubic feet of water [14 000 000 acre-ft.] would, therefore, have been essential to the security of the delta, if this system had been depended upon for restraining this flood."

From a report on the examination of reservoir sites in Wyoming and Colorado, by Hiram M. Chittenden, M. Am. Soc. C. E., Captain (now General, Retired), Corps of Engineers, U. S. A.:*

* Annual Report, Chief of Engineers, U. S. Army, for 1898, Appendix PP, p. 2845.

"In no other portion of her works has nature left so much to be done by the engineer to supplement her deficiencies as in the modification of the natural flow of her streams, for in no other respect are her works so ill adapted to the uses of man. The ideal stream would be one in which the flow should be uniform from one year's end to the other, or, if not uniform, varying directly with the magnitude of the uses to which it is put. Mr. Sellew.

* * * * * * *

"It is not surprising, therefore, that one of the chief concerns of the engineer is the amelioration or prevention of the evils of this unfortunate arrangement of nature. Millions of dollars are annually expended to make up for the deficiency of water in seasons of drought, and like sums to prevent or alleviate the evils of excessive flow. Singularly enough, the measures generally adopted are put forward in disregard of one of the commonest rules of scientific practice. If an evil condition of things is to be corrected, the rational method of procedure is to remove the cause. In all river engineering, however, the measures adopted look only to the palliation of results, and leave the cause untouched. River channels are dredged out in low water and levees are built to protect from floods in high water. Scarcely anywhere is the effort made to prevent the occurrence of either high or low water. It would naturally follow that, if great evils result from the variable flow of streams, the primary and fundamental object of the engineer who is called upon to correct them would be to make this flow uniform. Whether or not this object is possible of realization (and if it is, by what means) is therefore one of the first questions which should be settled in any comprehensive project for the regulation of the flow of streams.

* * * * *

"* * * The only possible method by which uniformity of flow can be secured must therefore be by storing the surplus waters in seasons of flood and releasing them in seasons of drought.

"There is an additional motive for the use of reservoirs besides that of securing uniformity of flow. Over a large portion of the land area of the earth in civilized countries the climate of winter prevents any considerable use of the streams. Even if the flow were entirely uniform, that portion which takes place in the season of cold weather would mostly be lost. To derive any benefit from it, it must be stored and held over for the season of warm weather.

"These two purposes, viz., the attainment of uniformity of stream flow and the transfer of the winter supply to the summer months cover the entire argument for reservoir construction.

* * * * *

"At first thought it would seem that in storage reservoirs lies the whole solution of the river problem. To store the surplus in flood season and use it in season of drought ought apparently to strike at the root of the whole difficulty, and to render unnecessary those palliative measures which alone have hitherto received the sanction of the hydraulic engineer. Why so obvious a remedy has never yet been extensively applied will appear in the course of this report.

* * * * *

Mr. Sellew.

"It is the *cost*, not the physical difficulties, which stands in the way. It may be stated that as a general rule a sufficient amount of storage can be artificially created in the valley of any stream to rob its floods of their destructive character; but it is equally true that the benefits to be gained will not ordinarily justify the cost.*

* * * * *

"We now come to the specific question of reservoir construction in the arid region west of the one hundredth meridian, as exemplified by the reservoir sites examined in Wyoming and Colorado. Are there direct and primary motives which would justify reservoir construction in this country, apart from or in addition to those arising from their effect upon the regimen of the lower rivers? The answer must be that in no other part of the United States, nor anywhere else in the world, are there such potent and conclusive reasons, of a public as well as a private nature, for the construction of a comprehensive reservoir system as in the region here in question.†

* * * * *

"* * * in many sections the natural flow has been used as far as it is practicable to do so. The only resource left is to store that portion of the flow that runs away in nonirrigation seasons and the surplus in times of annual flood and sudden freshets and make these also available for use. Not until that is done can a stream be said to be really utilized to the fullest extent.

* * * * *

"While there are these clear and positive arguments in favor of the storage of the surplus flow of our Western streams, there are none of weight against it. It may be set down as a rule, to which there are very few exceptions, that every artificial body of water created in the West, by which the surplus water of its streams is held back, will be a positive benefit.

* * * * *

"The foregoing examination has led up to the following conclusions:

"First. A comprehensive reservoir system in the arid regions of the United States is absolutely essential to the future welfare of this portion of the national domain.

"Second. It is not possible to secure the best development of such a system except through the agency of the General Government.‡

* * * * *

"The total extent of a reservoir system in the arid regions which shall render available the entire flow of the streams will not exceed 1 161 600 000 000 cubic feet [approximately 27 000 000 acre-ft.]. If the construction of such a system were to consume a century in time, it would represent an annual storage of about 11 600 000 000 cubic feet, or 266 300 acre-feet. At $5.37 per acre-foot this would cost $1 430 031 per annum. This amount, distributed among the seventeen States and Territories of the arid region, gives an average annual expenditure in each of $84 119. The annual value of the stored water

* *Loc. cit.*, p. 2860.
† *Loc. cit.*, p. 2864.
‡ *Loc. cit.*, p. 2872.

would return the original cost and maintenance in an average period of three years."* Mr. Sellew

In a paper on "Reservoir Systems and Their Relations to Flood Protection,"† by C. O. Sherrill, Captain, Corps of Engineers, U. S. A., presented at a special meeting of the Louisiana Engineering Society on June 25th, 1912, the following appears:

"The most vital question of the moment for the people of the lower Mississippi Valley is how best to secure protection from disastrous floods, such as the one now passing, and in the proper solution of this question the sympathy and assistance of the entire country should be ready to aid. Every flood brings forth a multitude of plans, each purporting to be the only one capable of providing the necessary cure, and most of them are brought out as something entirely new, yet each one will, on examination, be found to have been carefully considered and thoroughly investigated years ago. One of these propositions, renewed recently with great energy, has been to control these floods by means of reservoirs located near the headwaters of the tributaries.

"In view of the fact that adequate reservoir systems for the control of floods in all streams would strike directly at the seat of the trouble, it seems remarkable that this method should not have been used long ago instead of the merely defensive method of elevation of overflow land or the erection of levees.

* * * * *

"* * * The question, therefore, is, Can this stream flow be made uniform; if so, how and at what cost? * * * I must answer that a reasonable degree of uniformity of flow can be secured by adequate systems of reservoirs properly located along streams where the topography is particularly adapted to such reservoirs; but as to the possibility of such control for the Mississippi below Cairo, or of the practicability of the scheme, if possible, it is hoped that the following remarks will be of some assistance in determining."

This paper concludes:

"Taking the above brief summary of the facts into consideration, I must conclude that the control of the Mississippi floods by reservoirs is impracticable of accomplishment and that the next best thing must be relied upon, namely, the levee system with bank protection, which should be completed as rapidly as possible."

The Pittsburgh Flood Commission, in a comprehensive and voluminous report covering a recent investigation, concluded that the maximum flood crests of the Ohio at Pittsburgh can be lowered approximately 8 ft. by the storage of about 1 000 000 acre-ft. of water, in seventeen reservoirs on the Allegheny and Monongahela, at a total cost of about $20 000 000.

From the foregoing it appears that the desirability and practicability of reservoir construction depend on existing conditions in the drainage area of the stream under discussion; therefore, each stream

* *Loc. cit.*, p. 2878.

† *Journal*, Association of Engineering Societies, September, 1912.

Mr. Sellew.

should be subject to careful analysis before definite recommendations can be made. As the Colorado receives almost its entire supply from melting snows at the head-waters, it would appear to be an ideal stream for reservoir control.

Existing Storage Works.—Before discussing the feasibility of reservoir control on the Colorado, attention is called to Tables 23 to 27, which show what has been accomplished by storage systems in various countries, with their extent and approximate cost.

Table 23 contains data on ten projects of the Reclamation Service having a total capacity of about 3 800 000 acre-ft., which have been constructed at an average cost of $2.65 per acre-ft.

Table 24 shows other existing reservoirs in America with an aggregate storage of 2 383 500 acre-ft., built at a total cost of $2 629 800, or an average of $1.10 per acre-ft. In this list the storage at the head-waters of the Mississippi was by utilizing natural lakes, the outlets of which were controlled by low, inexpensive dams, the average cost being only 36 cents per acre-ft. If this system be excluded, it appears that the remainder amounts to only 283 500 acre-ft., which cost about $6.65 per acre-ft. In this table there are also five sites in Wyoming and Colorado, suggested by Gen. Chittenden, aggregating 939 200 acre-ft., estimated to cost $2 709 500, or an average of about $2.90 per acre-ft. This table also shows 70 415 acre-ft. of storage in Europe and Australia, which have cost $74 per acre-ft.

Table 25 contains data on ten works in France, having a total capacity 38 593 acre-ft. and costing $3 518 900, or about $91 per acre-ft. This table also shows that 38 400 acre-ft. of storage in Austria has cost $232 per acre-ft., while in Canada reservoirs containing 3 800 000 acre-ft. are being created on numerous lakes on the Ottawa River at an estimated cost of 20 cents per acre-ft.; and further, that about 700 000 acre-ft. in South Africa have been built at an average cost of $14 per acre-ft.

Table 26 gives a list of eleven projects in Germany, volume 488 111 acre-ft., cost $22 449 874, or $46 per acre-ft.; shows that Russia has 800 000 acre-ft. on the Volga (no records of cost); and that five systems in India, aggregating 775 250 acre-ft., cost $6.77 per acre-ft. The storage of about 1 900 000 acre-ft. at the Assuan Dam, in Egypt, has cost about $10 per acre-ft.*

The completed storage (Canada being excluded as under construction) is summed up in Table 27.

Although there are many storage dams for water supply and power in various parts of the world, they are of such relatively low capacity and high unit cost that they have no place in a discussion of this kind. The foregoing data are not submitted as complete, but include all the larger systems for river control, of which records are available

Mr. Sellew.

to the writer; and it is believed that they cover the field quite thoroughly. Mr. Sellew.

It appears that the storage in the United States (which is about 50% greater than that of the rest of the world) as listed in these tables, has cost on the average only one-ninth as much per unit of volume, while the maximum cost, that of Austria, is about 116 times the average in America. The low cost of the storage created by the Reclamation Service, when compared with that of the rest of the world, is shown in a most remarkable manner.

TABLE 27.—SUMMARY OF COMPLETED RESERVOIRS.

	Acre-feet.	Cost.
FOREIGN.		
Egypt	1 900 000	$19 750 000
France	38 593	3 518 000

Miscellaneous foreign	70 415	5 171 000
	4 010 465	$74 913 000
$\frac{74\,913\,000}{4\,010\,465}$ = $18.70 per acre-ft.		
UNITED STATES.		
Reclamation Service	3 799 300	$10 005 000
Other systems	2 383 500	2 629 800
	6 182 800	$12 634 800
$\frac{12\,634\,800}{6\,182\,800}$ = say, $2.00 per acre-ft.		

Determining Factors.—The feasibility of controlling a stream by storage will depend largely on:

(1) The cost, including the value of the area flooded, when compared with the benefits to be derived;
(2) The quantity of storage required and whether sufficient volume is available.
(3) The situation of such storage, whether it is placed so as to control properly the water-producing zone of the drainage area;
(4) The character of the water to be impounded, whether it is clear or so charged with sediment that the silting will unduly shorten the life of the works.

Mr. Sellew.

These factors, as applied to the Colorado, will be considered in the foregoing order.

The Cost.—From what has already been written, it appears that, where storage exists in the arid regions, its cost is reasonable. Assume that the cheapest sites have been taken up and that future storage will cost twice as much as that already created by the Reclamation Service ($2.65 per acre-ft.), and we have $5.30 per acre-ft. This is in close agreement with Gen. Chittenden, who, as previously stated, estimated $5.35 for all storage needed in the Arid West. Of course, each site must be carefully examined, and detailed estimates must be prepared, which will no doubt vary considerably from the foregoing, but, from what has been stated, the figure given appears to be a fair and reasonable one to use in this discussion.

Volume of Storage Required.—An intelligent discussion of this phase of the matter would be greatly aided by continuous discharge measurements on the Colorado River at various points, and extending over a long period. Unfortunately, however, such measurements do not exist. The most complete records are those made at Yuma since November, 1902, by the Reclamation Service. These observations include current-meter measurements three times each week. Previous records of the flow at Yuma are based on such insufficient data—being a few scattered meter measurements from which a rating-curve was constructed—that they are of no value in this discussion. The wide variation in the quantity flowing for the same gauge height, due to the change in cross-section caused by scour, renders observations without a meter measurement practically worthless.

Table 28 shows the total discharge of the Colorado (excluding the Gila) by months, in acre-feet, the mean monthly discharge in second-feet, and also the total discharge in acre-feet per year from 1903 to 1912, inclusive. This table shows that the yearly discharge has varied from a minimum of 9 800 000 acre-ft. in 1904, to a maximum of 25 300 000 acre-ft. in 1909. The total monthly discharge has varied from a minimum of 182 500 acre-ft. in February, 1903, to a maximum of 6 397 000 acre-ft. in June, 1912.

In considering the uses of the stream for irrigation, it is proper to forecast as nearly as possible the lowest flow that is to be anticipated. In doing this, the writer has compiled Table 29, showing what may be called an "ideal minimum year", and also the monthly use of water for irrigation at Yuma. This table has been constructed by selecting from Table 28 the minimum January discharge, the minimum February discharge, etc., for all months included in the latter table. This gives a minimum year containing a total discharge of 8 315 500 acre-ft., and these discharges are shown in monthly totals on the diagram, Fig. 70.

Mr. Sellew.

For the present, the duty of water in this vicinity is assumed as 5½ acre-ft., its use being distributed throughout the year as shown in Table 29. It is hoped, and indeed expected, that this use of water will be reduced considerably as larger areas are put under cultivation and the settlers become more skilled in the application of water, but

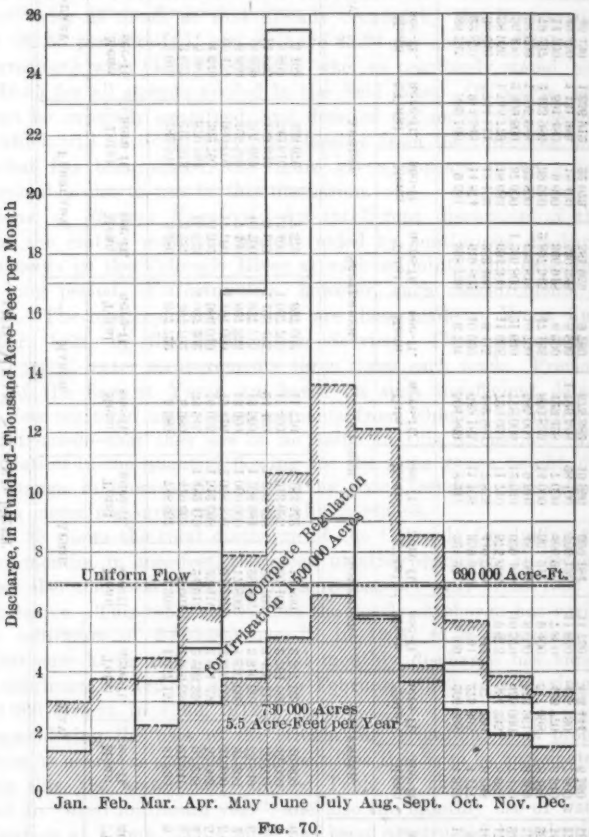

FIG. 70.

for the present this appears to be the best distribution for calculations, in view of the fact that the use now is considerably in excess of 5½ acre-ft. On Fig. 70 is also platted the use which can be made of the stream for irrigation without any regulation whatever. This was ascertained in the following manner: The use of water in February

Mr. Sellew

being about 0.25 acre-ft. and the lowest run-off in that month being 182 500 acre-ft., it was found that this quantity was sufficient for the watering of 730 000 acres. This was assumed as the limiting month. If greater areas were placed under cultivation, there would be a shortage in that month at a time when the new crops are usually going in. Taking this 730 000 acres as a basis, and platting the monthly duty in the ratio shown in Table 29, it appears that the volume of water used will be that shown by the shaded area in Fig. 70. This arrangement may create a slight shortage in September, but the use in that month is so near the minimum run-off that the danger is considered of slight importance and is neglected.

TABLE 29.—MINIMUM MONTHLY DISCHARGE OF COLORADO RIVER AND DISCHARGE IN RATIO OF MONTHLY DUTY.

Month.	Minimum discharge, in acre-feet.	Monthly duty.	Percentage of total yearly duty.	Monthly discharge for year in ratio of duty.
January	185 407	0.20	3.6	302 801
February	182 531	0.25	4.5	378 000
March	367 702	0.30	5.4	453 500

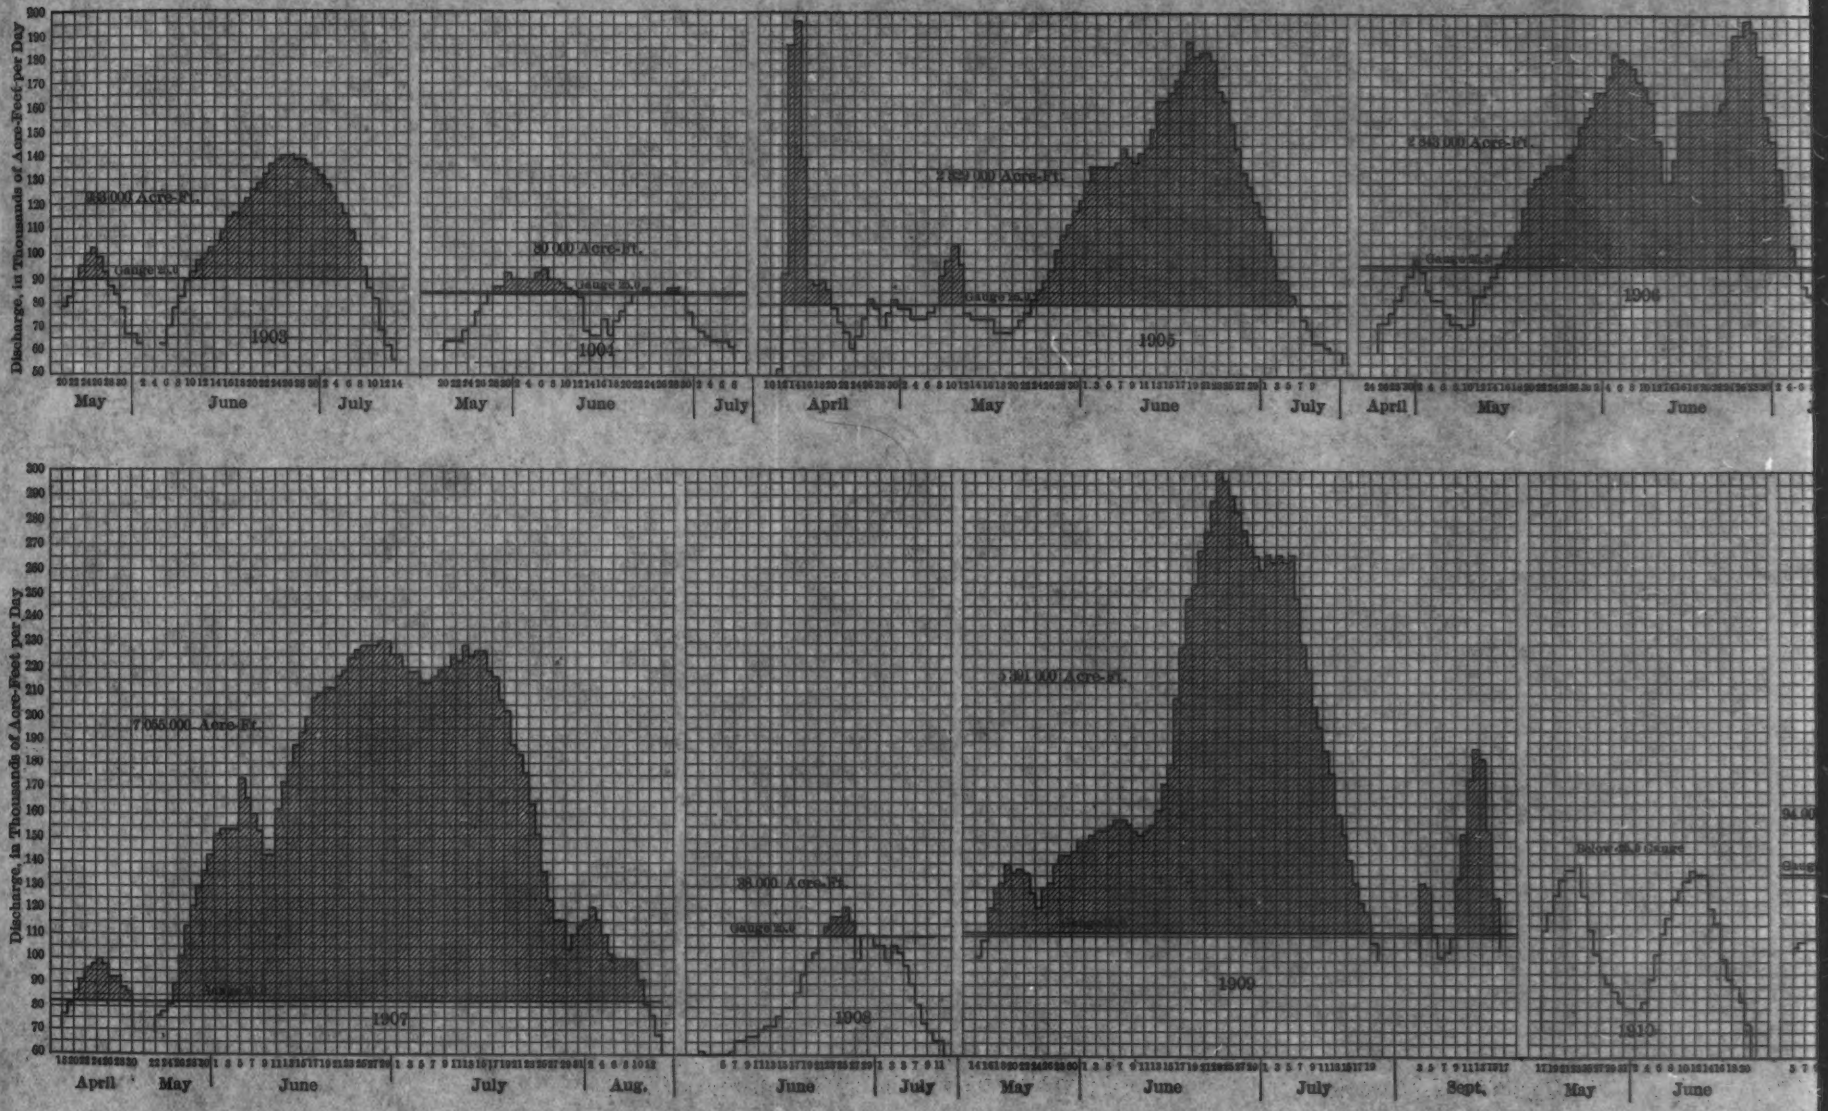
May	1 670 000	0.52	9.4	786 100
June	2 550 000	0.70	12.8	1 058 100
July	904 476	0.90	16.4	1 360 700
August	591 480	0.80	14.6	1 209 500
September	366 948	0.56	10.3	846 701
October	429 428	0.38	6.9	574 500
November	321 271	0.26	4.7	393 150
December	266 598	0.22	4.0	332 651
Totals	8 315 504	5.50	100.0	8 315 504

It is well to remark that the continuous irrigation of 730 000 acres depends on the diversion of the entire river, and is substantially all that can be accomplished, unless the stream is regulated, even should the duty of water be increased, for it is seen that the use of water at the extremes of the year is as low as can be anticipated, and although a saving may be made in the summer months, it will allow an increase in the cultivated area only during those months, because the crops which can be grown continuously for twelve months in the year are limited by the small quantity of water available during low flow.

There is drawn on Fig. 70 a line showing the uniform flow throughout the year, which would be at the rate of 690 000 acre-ft. per month. The establishment of such uniformity in discharge would be of value in controlling the floods and also for power purposes, but it is extremely wasteful toward the irrigation interests, because this line is practically coincident with the maximum use of water in July for 730 000 acres. The reinforcement of the low flow by this method would not allow an increase in the area under crop in the summer. It would cover more ground, however, during the winter.



Mr. Sellew.

Table 29 also shows the percentages of irrigating water required per month, and on this basis the discharge of the low-water year of 8 315 500 acre-ft. has been distributed. This assumes complete regulation of the river, entirely in the interests of irrigation, and the distribution throughout the year is shown by the shaded line. Under such regulation, 1 500 000 acres (which agrees with the author's estimate) could be irrigated. This is the area that could be served with the flow of the Colorado past Yuma as observed during the years under discussion. The lower Gila is so erratic in its discharge that it is not a very dependable supply, for which reason it is omitted. To the foregoing should be added any area existing in the upper reaches already under cultivation and which it is assumed has received its supply. To regulate the river as indicated would require a storage capacity of about 2 400 000 acre-ft., which, at $5.30 per acre-ft., would cost $12 720 000. Such regulation in low-water years would also have a very beneficial effect on the flood discharge. The maximum monthly volume would be about 1 400 000 acre-ft., equivalent to approximately 50 000 acre-ft. per day, or 25 000 sec-ft. The effect of this discharge on the bed and banks would be but slight, as compared with what goes on at the present time, and would keep the lower river well within its banks.

Although this amount of storage would make the river an ideal one for irrigation during periods of ordinary low flow, it would have little beneficial effect on floods in the maximum years, as will be seen from an inspection of the diagrams on Plate LV. Here the daily discharge in acre-feet during the flood periods is shown for the years 1903 to 1912, inclusive.

When the river at Yuma rises above 125 on the local gauge, overflow occurs at various points within the limits of the Yuma Project, and levees become a necessity. If the control of the stream by storage is to regulate the discharge in such a way that levees will not be required, the volume passing when the gauge is above 125 must be stored. On the diagrams referred to, a horizontal line has been drawn representing 125 on the Yuma gauge, and the volumes of discharge above this gauge height in various years are clearly marked. They were:

In 1903	933 000	acre-ft.

PLATE LV.
TRANS. AM. SOC. CIV. ENGRS.
VOL. LXXVI, No. 1270.
SELLEW ON
IRRIGATION AND RIVER CONTROL,
COLORADO RIVER DELTA.

Mr. Sellew.

And in the season just passed. . . . . 2 417 000 acre-ft.
A total of 21 680 000 acre-ft., or an average of 2 168 000 " "
for the ten-year period.

If storage is to be created for the maximum of these quantities, 7 055 000 acre-ft.—and this is necessary if all overflow is to be prohibited along the lower river—the cost of storage, if sufficient sites existed, would be $37 391 500, estimated at $5.30 per acre-ft. Should this be considered an excessive provision to make, and it were thought better to take what damage would come from a flood of this kind (which might be of infrequent occurrence), and storage were provided for the next largest year, which is 1909, 5 391 000 acre-ft. would be required, which would cost, on the same basis, $28 572 300. This would give a protection that would have been ample during the last 10 years, with one exception. If we take the average of the excess discharge at Yuma above the 125 gauge for the last 10 years, we get 2 168 000 acre-ft., which is about that required to regulate the low flow in the interests of irrigation. The cost of creating this amount of storage at $5.30 would be $11 490 400. With such control of the river, however, overflow would have occurred in 5 years during the last 10.

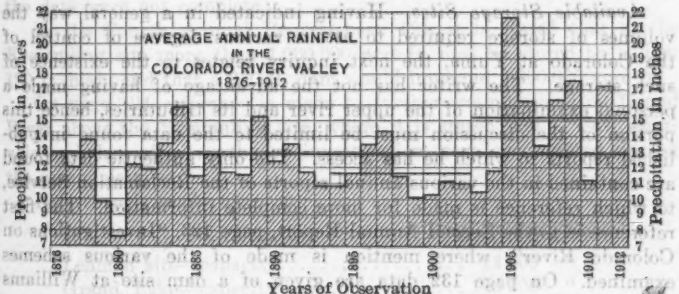

FIG. 71.

Attention is directed to Table 3, which is an exhibit of the annual discharge of the river from 1894 to 1911, inclusive, a period of 18 years. The first 9 years have an average discharge of 7 220 000 acre-ft., and the last 9 years show an average of 17 556 000 acre-ft., indicating a most remarkable, sudden, and continued increase in run-off. Such an increase might be possible with a small drainage, but, with a tributary area of more than 250 000 sq. miles, the variation appears to be altogether too much. To aid in the examination of this question, various publications of the Weather Bureau have been used in the preparation of Fig. 71. For the northern part of the water-shed, no continuous observations within the drainage area appeared to be available, there-

Mr. Sellew.

fore Denver, Salt Lake City, and Cheyenne were used. These stations are probably indicative of conditions within the area under consideration. For the central and southern portions, the records of Prescott, Tucson, Yuma, Phœnix, and Flagstaff were taken. The average precipitation for the entire period is 12.92 in., shown by the heavy line. That for the period 1894 to 1902 is 11.73 in., and for 1903 to 1912 is 15.20 in. These latter amounts are indicated by the shorter and lighter lines. Thus it appears that although the run-off in the latter half of the period covered by Table 3 is about 2.4 times that of the first half, the increase in precipitation was only 1.3 times. Furthermore, it appears that the sudden increase in precipitation did not occur until 2 years after the change indicated by the table. There is no doubt that there is considerable difference in the run-off of the two periods, but it is not nearly as great as Table 3 indicates. The explanation is clear: In November, 1902, careful and systematic gaugings of the stream were inaugurated at Yuma by the Reclamation Service, and the data since collected are dependable. The data prior to that time are based on a rating-curve constructed from so few observations that the results are worthless. The first half of Table 3 should not have been presented.

Available Storage Sites.—Having indicated in a general way the volumes of storage required to attain various degrees of control of the Colorado at Yuma, the next inquiry relates to the existence of such storage. The writer has not the advantage of having made a personal examination of the upper river and its tributaries, hence this portion of the discussion must be limited to the data found in published reports to which he has access. The only authentic data found are contained in the various annual reports of the Reclamation Service, to which reference is made for more complete information. The first reference is to the Second Annual Report, page 123, "Investigations on Colorado River", where mention is made of the various schemes examined. On page 132 data are given of a dam site at Williams River, where 1 300 000 acre-ft. of storage may be created. The statement is made that investigations of a site at Bulls Head were abandoned because of poor foundation. A 100-ft. dam at this point would provide storage for 845 000 acre-ft. The lower end of Pyramid Canyon was examined. Surface conditions appeared to be favorable for a high dam, but no suitable foundation was found. If it were possible to build dams at these points, the scheme would be impractical because the reservoirs would soon be filled by the deposition of sediment, which will appear from data given later. Reference is made to this difficulty in the Second Annual Report, page 155, where we may read:

"In connection with this question of the study of reservoirs which silt up, it seems most necessary that a thorough investigation be made of the reservoir possibilities upon the head-waters of the Colorado,

above the points where the streams carrying large quantities of silt enter, so that permanent reservoirs may be established in anticipation of the time when all the irrigable lands along the Colorado will be under ditch." Mr. Sellew.

Thus the Second Annual Report shows no available storage sites for the permanent control of the river.

The Third Annual Report, page 70, has the following:

"Colorado River Storage Projects.—As it has been thought necessary to store water in the Rocky Mountain region for the regulation of the flow of the Colorado River, with a view to the reclamation of about 600 000 acres of land along the lower Colorado in Arizona and California, certain reservoir sites have been withdrawn in western Colorado, two of these being on Grand River, in Grand County, and two on Yampa River, in Routt County. Preliminary examinations have been made of all these sites, and some of them have been surveyed."

On page 217, the Kremmling site is credited with a capacity of 1 500 000 acre-ft. At Grand Lake about 23 000 acres are reported as withdrawn, but no capacity is given. Two sites on the Yampa were located and 100 000 acres withdrawn, but no capacity is given, as the data were not complete.

In the Fourth Annual Report, page 121, it is stated that at the Kremmling site more than 1 000 000 acre-ft. may be stored by a dam 180 ft. high, and that a 230-ft. dam would impound 2 200 000 acre-ft.

On page 124 reference is made to further examinations on Grand River above the Kremmling site, where it is stated that: "Few reservoir and dam sites worthy of investigation were encountered during the reconnaissance."

Reference is made to:

Windy Gap site—capacity	100 000	acre-ft.
Lehman site—capacity	24 000	" "
Grand Lake—capacity	140 000	" "
	264 000	acre-ft.

The first site is crossed by a railroad; would require a large dam; and 75% of the area flooded would be ranches already under cultivation. The second site would cover valuable land under cultivation, and is of slight consequence in size. Regarding Grand Lake, the report says, on page 127:

"Considered as a site for storing irrigation water for use along the lower Grand and Colorado rivers, Grand Lake, as will be readily seen from the foregoing, would be of little value."

It appears, then, that this report shows no storage sites of value except the Kremmling, with a possible capacity of 2 200 000 acre-ft.

Mr. Sellew.

The Fifth Annual Report states, on page 114, that the field work in connection with reservoir sites on the Colorado was brought to a close late in 1905, and no additional examinations have been made since those described in the Fourth Annual Report. The Sixth Annual Report gives no additional information regarding this matter. On page 57 of the Seventh Annual Report reference is made to investigations for storage reservoirs along the Green River and its tributaries, from which the following is obtained:

Flaming Gorge site—capacity	350 000	acre-ft.
Island Park site—capacity	150 000	" "
Browns Park site—capacity	2 500 000	" "
	3 000 000	acre-ft.

No additional information is contained in the Eighth, Ninth, or Tenth Annual Reports.

Taking from the foregoing those sites which appear to be available for storage on the tributaries of the Colorado, we have:

	Capacity in acre-feet.
Grand River: Kremmling site	2 200 000
Green River: Flaming Gorge site	350 000
Island Park site	150 000
Browns Park site	2 500 000
Total	5 200 000

Railroad interests have secured control of the Kremmling site, therefore its future development may prevent the creation of reservoirs of any magnitude. Such a result would remove the only known reservoir capable of controlling the Grand River, and would reduce the known available storage for uses on the Lower Colorado to 3 000 000 acre-ft., all confined to the Green. This is but little in excess of that required for minimum-year control in the interests of irrigation, and furnishes little relief in the years of maximum flow, when, as previously shown, 7 000 000 acre-ft. must be stored in order to prevent overflow, unless dependence is placed on levees. The foregoing data are not sufficient to determine with accuracy the feasibility of reservoir control on the Colorado River. Before conclusions can be properly drawn, investigation should show the total available storage, its geographical distribution, and whether it is placed so that it will control the run-off from the various parts of the catchment area. Should sufficient storage exist to save the surplus of the maximum years for use in years of low flow, the irrigable area along the Colorado could be increased correspondingly.

The Quantity of Silt.—As previously stated, reservoirs created on the lower portion of the stream would very soon fill with deposits, as

the Lower Colorado is a notorious silt carrier. Professor R. H. Forbes* says, regarding Colorado silt: Mr. Sellew.

"Beginning with January, the regular low winter water averages about 62 parts of sediment in 100 000 parts of water during January, February, and March. These sediments are probably chiefly the result of erosion upon the upper river channel, rather than surface sweepings into the drainage. During April, as the river rises with the melting snows of its highest water-shed, and its erosive power increases, the sediment rises to an average of 112 parts; during the highest waters of May and June, to an average of 374 parts; decreasing with the lowering waters of July and August to an average of 122 parts. The summer rain-storms of September, October, and November, partly within Arizona, bring the silt to its maximum (2 072 parts, Oct. 8-13), after which the quantity sinks to the normal amount for winter waters, averaging 151 parts in 100 000 during the two months ending Jan. 24, 1901.

"* * * The average acre-foot of Colorado river water for the year of observation carried 7 291 pounds of silt, varying from 1 182 to 56 410 pounds as shown by 6-day composite samples.

"On the basis of the profile constructed from available data for the volume of flow of the Colorado, and of the year's silt determinations made in this laboratory, it is estimated, conservatively, that the river during 1900 brought down about 61 000 000 tons of sedimentary material, which, condensed to the form of solid rock, is enough to cover 26.4 square miles one foot deep; or, to make 53 square miles of dry alluvial soil one foot deep; or, to make about 164 square miles of recently settled, submerged mud one foot deep, reckoning the whole amount of mud for the year to average 6.2 times the bulk of the solid sediment."

From these extracts it appears that in 1900 the volume of sediment varied from 0.062% in January, February, and March, to 0.374% in May and June, and that following desert rains it was as high as 2.07 per cent. An area of 164 sq. miles of mud 1 ft. deep equals 105 000 acre-ft. Since May, 1909, the Reclamation Service has observed the quantity of sediment passing Yuma, the results being as shown in Table 30.

TABLE 30.—QUANTITY OF SEDIMENT IN COLORADO RIVER.

Year.	Total discharge, in acre-feet.	Number of silt observations.	Average percentage of silt, by weight.	Acre-feet of submerged mud annually.
1909.....	25 967 577	8	0.65	321 010
1910.....	14 332 692	23	0.50	136 660

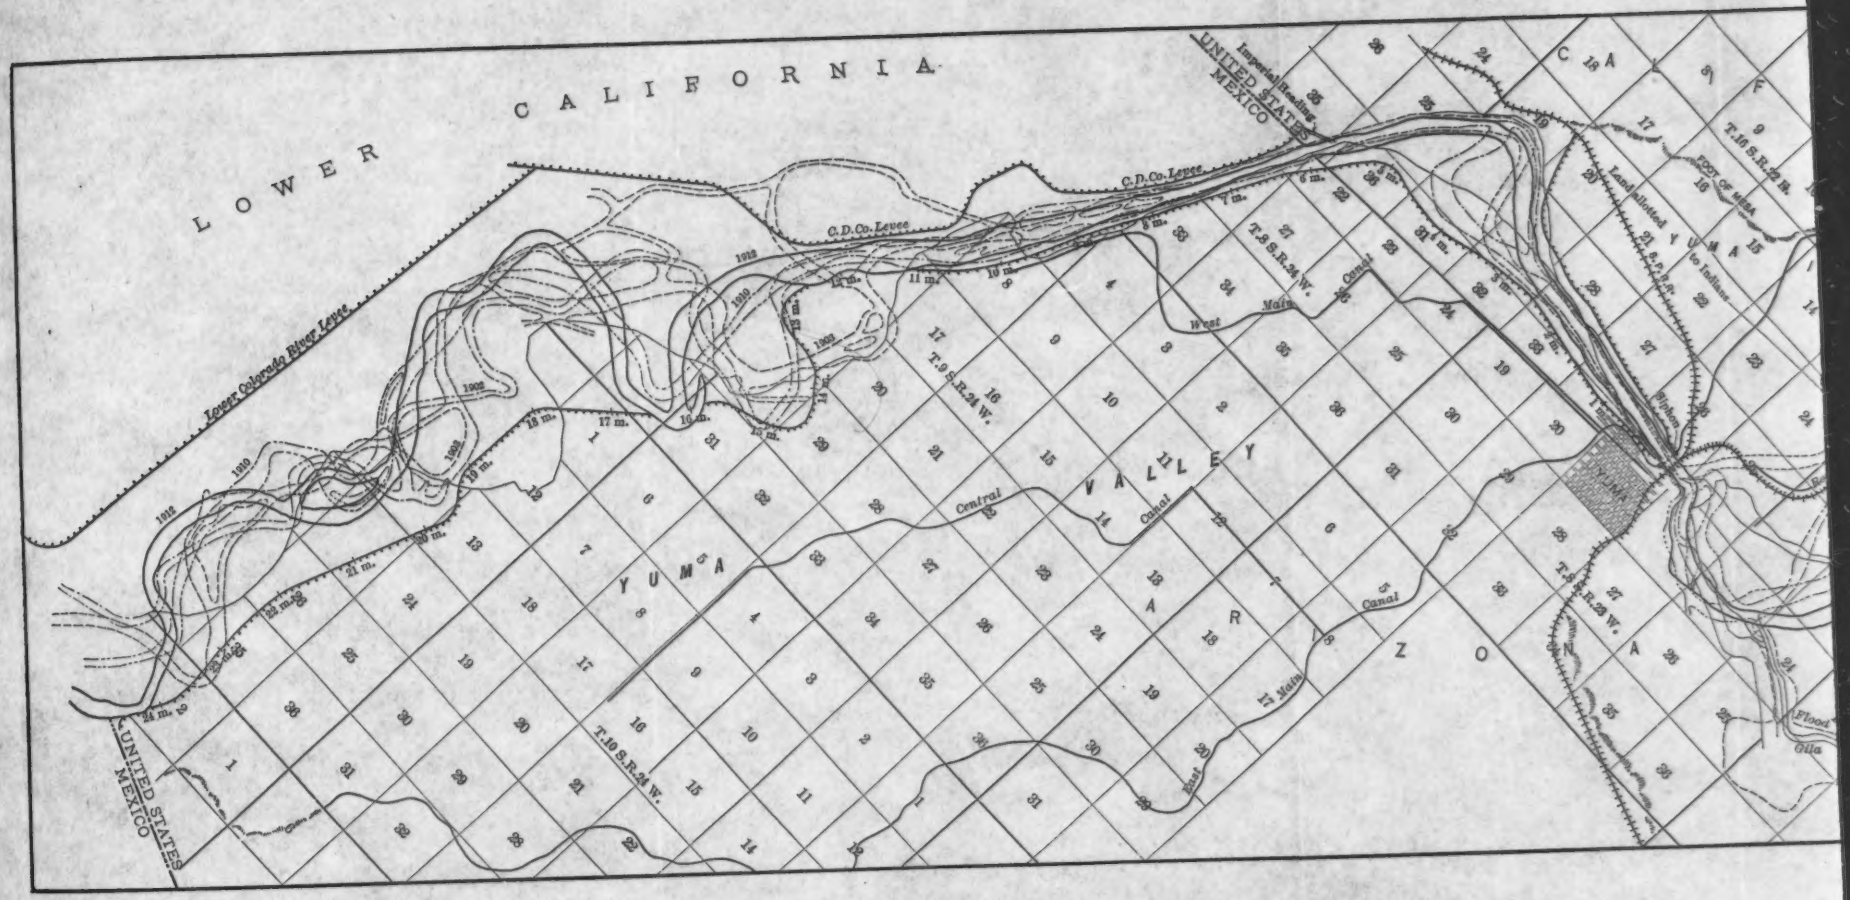
Total..	.....	.....	.....	1 114 519

*Bulletin No. 44, Arizona Experiment Station, pp. 198 and 200.

Mr. Sellew.

The observations of 1909, although few in number, covered the period from May 26th to October 7th, and should give a fair average. Those of 1910 extended from April 19th to December 31st. In 1911 they extended from January 11th to December 28th, and in 1912 from January 4th to November 30th, the discharge being estimated to December 31st. As shown in Table 30, the total quantity of sediment passing Yuma during the last 4 years, when measured as submerged mud, has exceeded 1 000 000 acre-ft. This proves conclusively that reservoirs for the permanent control of this stream must be placed on the head-waters where clear water exists.



The author shows in Table 2 an approximate storage of about 10 000 000 acre-ft., and although he qualifies the table by stating that it is "theoretically possible" and would have to be reduced for "commercially feasible developments," the table is so at variance with facts as to be misleading in its present form, and likely to lead uninformed persons to erroneous conclusions. Storage on the Gila is out of the question, as this stream carries more silt during its flowing season than the Colorado. Little Colorado, Bill Williams Fork, and San Juan must be eliminated for the same reason. The Kremmling site is in the hands of interests foreign to irrigation or storage development. The only site of value contained in Table 2 is Browns Park on the Green, which has a capacity of about 2 200 000 acre-ft., as previously indicated. This analysis reduces the author's "theoretically possible" 10 150 000 acre-ft. to 2 200 000; reservoirs which will silt up in a few years or are controlled so that they cannot be developed, are not in the "possible" class.

There are some statements which the writer cannot reconcile with the facts as they have come under his notice. The area of the Yuma Project is some 130 000 acres, instead of 90 000. Table 4, showing mean monthly discharge from 1894 to 1911, is valueless, for the results from 1894 to 1903 are based on erroneous data, as previously shown.

Rise of Bed.

The data in regard to the rise of bed at Yuma are based on observations made largely by the Reclamation Service, but are not considered by the writer as sufficiently definite to justify the conclusions. Although the advance of the delta into the Gulf will tend to raise gauge heights at points above, certainly many more observations are necessary before definite relations can be established between the rise on the Yuma gauge and the memory of a steamboat captain.

There is at least one other cause for variation in gauge height at different points on the stream, which is entirely dissociated from any advance into the Gulf. There are two points on the lower river in this vicinity which may be regarded as definitely fixed. They are Laguna Dam and the conglomerate hills at Yuma between which the river

PLATE LVI.
TRANS. AM. SOC. CIV. ENGRS.
VOL. LXXVI, No. 1270.
SELLEW ON
IRRIGATION AND RIVER CONTROL,
COLORADO RIVER DELTA.

Mr. Sellew.

passes. The floods of 1909 and 1912 carried substantially the same quantities at their crests, 150 000 sec-ft., but the difference in the elevation of water surfaces between the Yuma gauge and Laguna Dam was 4 ft. greater in 1912 than in 1909. The casual observer might think that this indicated a rise in the bed of the stream. It is found, however, that the slope per mile was substantially the same, being 1 ft. in 1909 and 1.04 ft. in 1912. The rise is not due to any silting up of the channel, but is plainly caused by the meanders of the river. The records show that the distance from Laguna Dam to Yuma has varied as follows:

In 1856	13	miles.
1895	11¾	"
1902	14	"
1909	13¾	"
1911	15¼	"
1912	17	"

Some of these various meanders are indicated on Plate LVI. The river in 1912 between the points mentioned was 3¼ miles longer than in 1909, and this accounts for practically all the increased difference of elevation in the water at the two points. The same phenomenon is true on the lower river, and, assuming a given elevation at the Mexican boundary, the increase in length of the stream due to meanders will give an increased height on the Yuma gauge, whether the river is advancing into the Gulf or not.

The author's description of the works of the Yuma Project and remarks relative thereto, indicate unfamiliarity with the subject. A very excellent account of the work at Laguna Dam may be obtained from articles* by the Resident Engineer, Edwin D. Vincent, M. Am. Soc. C. E. The Colorado Siphon has been described by the writer.† These cover the main features of the work. Levees and canals are so common, and those at Yuma present no unusual conditions, that description appears to be superfluous.

The author's statement, that a rock fill such as was used for closing the crevasses which he discusses could have been used in place of Laguna Dam, is open to serious doubt. What he built has been used as a levee, which purpose it answers admirably. How it would act as an overflow weir, carrying 150 000 sec-ft., even if covered with concrete, is problematical. In addition to a concrete top, crest and footwalls appear to be necessary to prevent the top from being undermined, and, if these are provided, the resulting structure will not differ materially from Laguna Dam either in design or cost.

Levees.

Mr. Sellew. The statement that the flood of December 7th, 1906, caused levee failures on the Yuma Project due to the absence of muck-ditches, is not correct. In October, 1906, the writer took charge of the Yuma Project, and his first act was to order muck-ditches under all new levees. The slight damage done here by the flood of December 7th, was caused by burrowing animals and the overtopping of work which was incomplete.

Regarding the advantages and disadvantages of land-side and river-side borrow-pits, the writer has fully expressed himself,* so that it is not necessary to comment further. Particularly is this so when the author states that he "realized that this was not in accordance with the usual practice." Based on a personal examination made a few hours after the break of December 5th, 1906, the writer hazards the opinion that the damage caused by a head of 15 in. against the levee was due primarily to the presence of land-side borrow-pits, although small quantities of water came under the levee itself in many places due to the absence of a muck-ditch and the improper grubbing of the foundation.

Regarding the loan of a grading camp by the Reclamation Service, which outfit the author declares did work at excessive cost, the following is submitted:

Immediately following the break, in December, 1906, the writer discussed with Mr. Cory the feasibility of assembling a sufficient force to construct levees required before the coming of the annual freshet. At that time it was not known how much levee work would be done, as the surveys were incomplete. Consequently, no contracts were let, and the size of the outfit which could be immediately available was not known. Because of various interests at stake, the writer suggested that, to assist in overcoming the difficulty, one camp of Government stock then operating on the Arizona levees be transferred for the use of the California Development Company. Mr. Cory welcomed this suggestion; authority was secured from the Department; and the camp was immediately transferred. It was supposed when the transfer was made that the camp was to work for the California Development Company and not for a contractor. However, shortly after the move was made, the superintendent of the camp informed the writer that he was working under the direction of a contractor, and it was next to impossible for him to obtain the proper supplies to keep his camp up to efficiency. A visit to the camp showed the facts to be substantially as stated, and a personal appeal was made to Mr. Cory to remedy the matter. This was remedied, in a measure, but conditions continued to be such that, as soon as it was evident that the camp was

* *Engineering News*, February 15th and April 11th, 1912.

not necessary to secure the completion of the levees in advance of the annual flood, the men and equipment were brought back to the United States. Mr. Sellew.

The camp that was loaned the C. D. Co. had been at work for considerable time prior, for the Reclamation Service, and continued to be thus employed for several years thereafter. It was one of the most efficient camps which the Service has had on levee construction. There have been completed on the Yuma Project about 50 miles of levee, aggregating more than 2 600 000 cu. yd. of excavation, the accomplishment of which compares most favorably in every way with any levee work which has come under the writer's notice. Criticism of Government work seems to be a general pastime of people who are not responsible for it, and certainly if a contractor desired to place a Government camp in an unfavorable light, Mr. Cory granted him a most excellent opportunity to do so.

Under the head of "Criticism of Levee Work Done" the author shows that after a Consulting Board from the Reclamation Service had advised on the methods of levee construction, their recommendations were ignored and a second Board was necessary before the recommendation as to the location of borrow-pits was complied with. The author states that the use of the checker-board system of borrow-pits increased the cost of the work about 6¾ cents per cu. yd. Experience on the Yuma Project has shown that an increase of 2 cents per cu. yd. is ample to cover this kind of borrow-pit, and the writer believes that the protection thus afforded fully justifies the additional expense.

International Negotiations.

International agreements are necessary to a comprehensive plan for the control of the Lower Colorado. Such agreements must be preceded by diplomatic action, and while such negotiations may be in progress, discussion of this phase of the matter appears to be inopportune.

The Abejas Diversion.

The author is correct in the statement that this diversion has had little effect on river levels at the entrance of the Imperial Canal. The observations show that it has had no effect whatever. The writer has little first-hand knowledge of the work at the Abejas, carried out under the direction of John A. Ockerson, Past-President, Am. Soc. C. E., so does not feel qualified to discuss it. He wishes to state, however, that the delay in starting the work, due to causes over which Mr. Ockerson had no control, which exposed the operations to the menace of the flashy winter floods, had much to do with the progress. It is believed that the Ockerson plan to levee the river to the range of tidal influence is the correct one; until this is done and the levees are made

Mr. Sellew. secure against the attack of the current, the Lower Colorado cannot be regarded as under control.

The Real Problem.

The author concludes:

"Because of the various successful and unsuccessful work done in the region, the engineering features of irrigation and river control along the Lower Colorado are now understood, and engineering construction methods are thoroughly developed.

* * * * * *

"The Colorado River Delta now presents no unusual, unsolved engineering difficulties; its problems are chiefly matters of statecraft, in both river control and irrigation."

After more than 6 years of service, during which time about 45 miles of the lower river has been in his charge, the writer wishes to state that, in his judgment, the real problem of this river is not generally understood. This problem, for the solution of which the author offers no aid, is bank protection. Construction methods for its accomplishment are not developed, and it cannot be attained by statecraft, however high the talent engaged. Relief from this menace will come only from hard work and a liberal expenditure of money on the immediate banks. When levees are undermined while the stream is below bank-full stage, it is clear that many years must elapse before a river of this magnitude will be controlled by reservoirs in such a way that caving banks will be eliminated. A plan by which these banks may be made stable will now be outlined, but, before proceeding with it, a short sketch of the flood of 1912 may be of interest.

Lower Colorado Flood of 1912.

The annual freshet of 1912 first made its appearance on the Yuma gauge on March 12th, the reading then being 117.8 ft. and the discharge 12 800 sec-ft. It continued to rise until June 22d, when the gauge was 129.1 and the discharge was nearly 150 000 sec-ft. During this rise the erosive action of the current was causing radical changes in the bed and banks of the stream, as may be seen by Fig. 72, showing conditions at the gauging station. It is there seen that at low water the width of the river was 420 ft., its average depth about 3½ ft., maximum depth 8 ft., and the area of the flowing prism 1 420 sq. ft. At the crest these dimensions had become, width 600 ft., average depth 35 ft., maximum depth 53 ft., area 20 740 sq. ft., the discharge having increased 43 times and the area about 15 times. This increase in area, of 19 320 sq. ft., is made up of 7 440 sq. ft. caused by the rise on the gauge and 11 880 sq. ft. (60%) which was the increase in section due to scour. These modifications in cross-section were probably maximum at the gauging station, where the width of the stream is restricted; but

similar changes, although less in magnitude, are characteristic of the lower river. Mr. Sellew.

During the rise, extensive meanderings were in progress at various points, the first attack which required defense being between 10½ and 12 miles below Yuma, on the Arizona side, where the levee had been cut out by the river in 1909. During 1909 and 1910 efforts were made to hold this portion of the bank with fascines and other light brush protections, but such work was soon carried out, and resort was then had to permeable dikes of piles and brush. About seventeen permeable dikes have been built, beginning in May, 1911. Some of these dikes are shown on Figs. 73 and 74. At this point the Steamer *Searchlight*, with a pile-driver barge, worked throughout the flood of 1912, building dikes and defending the bank between them with

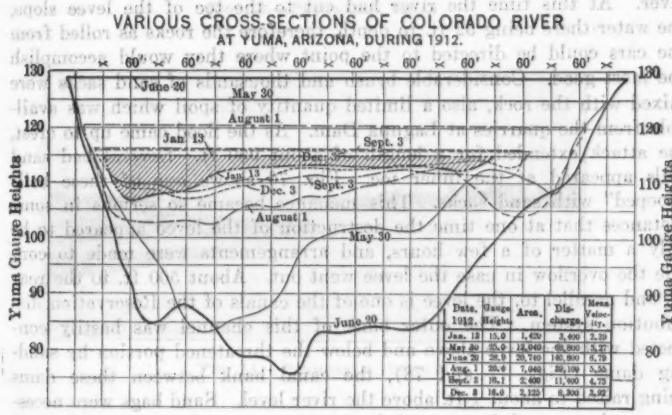

FIG. 72.

fascines. A temporary levee also was thrown up when the river threatened overflow. The efforts here were successful, the dikes holding well and preventing further recession of the bank line, and the temporary levee removed all danger from overflow.

The first attack on the Reservation levee was at the point, *C*, on Plate LVI. At the beginning of the rise, the bank at this point was some 800 ft. from the levee, but on June 15th bank caving set in, and on June 17th, when the river was within 150 ft., defensive operations were commenced. As all our floating plant was engaged below Yuma, the fight here had to be made from the shore. When the stream went overbank the bottoms were flooded to within 150 ft. of the levee, making defensive operations impractical until the caving reached this point. Fascine mats weighted with sand sacks were hung over the face of

Mr. Sellew.

the bank, but, as the water was more than 30 ft. deep, such defenses would not reach the bottom, and, although our work delayed the advance of the stream, it was slowly undermined, demonstrating that a strong revetment would be necessary to hold the river in check. Conditions along the front at this point are shown on Fig. 75. Fortunately, the Reservation levee furnishes the location for the Potholes Branch of the Southern Pacific Railroad, therefore, rock, which was the only material that would save the day, could be delivered at the site of the works and dumped directly into place. Rocks weighing from 1 to 6 tons were ordered from the Declez granite quarries some 200 miles west of Yuma on the main line of the Southern Pacific. The railroad expedited the shipment, and within 36 hours after the order was placed the first train load, consisting of fifteen cars, was being thrown into the river. At this time the river had cut to the toe of the levee slope, the water there being 32 ft. in depth, therefore the rocks as rolled from the cars could be directed to the point where they would accomplish the most good. Considerable brush and thousands of sand sacks were mixed with the rock, also a limited quantity of spoil which was available from the quarries at Laguna Dam. As the flood came up to crest, the attack extended for a length of about 900 ft. Several bad sand boils appeared at the inner toe. Fig. 76 shows one of these boils "hooped" with sand sacks. This menance became so serious in some instances that at one time the destruction of the levee appeared to be only a matter of a few hours, and arrangements were made to confine the overflow in case the levee went out. About 500 ft. to the rear of, and parallel to, the levee is one of the canals of the Reservation distribution system. The outer bank of this channel was hastily connected with the levee above and below the threatened portion by sandbag dams (Figs. 77 and 78), the canal bank between these dams being raised to about 1 ft. above the river level. Sand bags were necessary as the ground, because of the seepage, was under several inches of water, and stock could not be worked upon it. These dams and the canal bank would have confined the overflow to this area had the levee gone out. It was also intended to flood this enclosed area to a depth of 2 ft. or more to check the sand boils, water for this purpose being supplied from the canals, but the boils were checked by a liberal use of sacks along the front before such action was necessary. Figs. 79 and 80 show the character of the rock used for protection, and Fig. 81 is a view of the Steamer *Searchlight* engaged in dragging the larger rock from the cars with her steam capstan, the boat having been temporarily transferred for this purpose from the work below.

The flood crested at about 1 A. M. on June 23d, and then fell rapidly. By June 25th there was no further danger of overflow, but dumping the spoil, in order to blanket the outer slope and reinforce the levee, continued until August 18th.

FIG. 73.—PERMEABLE DIKES.

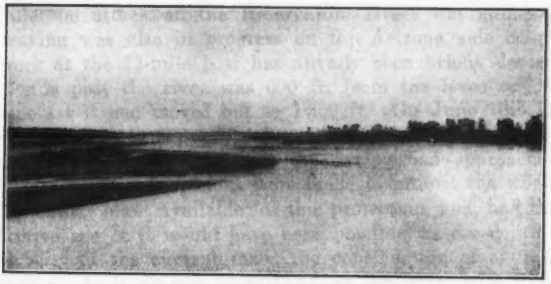

FIG. 74.—PERMEABLE DIKES.

FIG. 75.—CONDITIONS ALONG THE FRONT.

Mr. Sellew.

While this attack was in progress, another was initiated by the river at the point, *A*, on Plate LVI. Here the caving banks came to the levee toe with a water depth of 30 ft., and the defense was practically a repetition of the one just described.

On June 25th, the river having fallen below the overflow line, shipments of Declez rock were stopped; a steam shovel was placed in commission at Laguna Dam, and a work train and crew were obtained from the Southern Pacific Company, which, with assistance from our dinky engines, continued to dump rock and spoil at the points, *A* and *C*, until August 18th, when 18 000 cu. yd., including 1 300 cu. yd. of Declez rock, had been placed. On this date the threatened levees were safe from further attack, and the work was stopped. At the present time the river lies against the rock slope of the levee at *A* for 1 500 ft. and at *C* for 1 000 ft. Should these conditions remain until the next flood, further rock revetment will probably be necessary immediately above and below each of these points, therefore steam shovels, cars, and engines are being placed in condition to do this work if required.

While the attack on the Reservation levees was going on, rapid bank caving was also in progress on the Arizona side below Yuma. The work at the 12-mile post has already been briefly described. At the 16-mile post the river was 600 ft. from the levee on May 25th. On June 1st it had moved out to 1 300 ft. On June 10th it had returned to within 500 ft., on June 20th about 300 ft., and on June 25th it cut through the levee. When the caving had approached within 300 ft. of the levee, provisions were made to protect the work. There was no floating plant available for this protection, and, had there been, no effective use of it would have been possible, as the depth of water and velocity of the current made the construction of spur dikes impracticable. As there was no railroad on the levee, rock could not be obtained, as the roads to the nearest quarry, 12 miles away, were impassable for heavy loads. The only defense that could be offered was to protect the bank by fascine mats, there being plenty of suitable willow brush near at hand. The force employed, consisting mainly of Cocopah Indians, was rather indifferent labor, but by diligent efforts the rate of caving was delayed so much that, when it reached the levee on June 25th, the river had fallen below the natural bank level and no overflow occurred.

Shortly after the cutting out of the levee the river swung away for several hundred feet, and later came back for a portion of this distance, the present position of the river being shown by the meander line on Plate LVI.

About July 1st, the river being well within its banks, the patrol which had been maintained during the flood was removed. On this date no serious cutting appeared at any point between Yuma and the International Boundary Line, on the American side of the stream.

Mr. Sellew.

On August 10th it was found that the river had cut through the levee at the 24-mile point, but the bank here being above the river level, no overflow had occurred. On June 20th, or a few days prior to the crest of the flood, the bank at this point was 1 300 ft. away from the river, and there appeared to have been no material change on July 1st, when the patrol was taken off; thus it appears that the caving here must have been extremely rapid.

All work of bank protection was continuous, day and night, while the danger of overflow existed. During this period the temperature in the day averaged 106° and at night about 73 degrees. Because of the extreme heat, the work was very hard on the men, and at times our efforts were greatly hampered by lack of labor. All the Indians in the vicinity were pressed into service. Wages were temporarily increased to attract idle men in the Town of Yuma, and on the Reservation the settlers whose lands were threatened turned out practically to a man and fought valiantly in the defense of their homes.

Future Bank Protection.

The work of bank protection should be directed:

(1) Toward holding existing levees and regaining lost ground, in order that work which has been destroyed may be rebuilt near its original position, thus maintaining as nearly as possible the irrigable area;

(2) To cause the river to occupy a position about midway between the levees in order to prevent, if possible, the erosion of one season from reaching the embankments; or the river slopes of the levee should be made impregnable to river attack.

It is also desirable, in order to prevent meandering—which, as shown previously, may result in a rise in plane—to confine the stream to the shortest route consistent with a fall of about 1 ft. per mile.

Regarding the recovery of lost ground, the writer is aware that the building of levees on their old locations has not been generally practiced. The following, relating to the Mississippi, is from *Occasional Papers No. 41,* Engineer School, U. S. A., page 278:

"*Location.*—The two objects of levees, protection of land and concentration of flood discharge, will be most efficiently obtained by building the levees as close as possible to the river bank, and, as owing to the general slope of the bottom land, the banks are usually higher than the land farther back, their location close to the river satisfies generally the two conditions of maximum usefulness and minimum cost, and if the river were straight and its banks stable no better location could be sought; but the river is not straight and the banks cave rapidly, and a location close to the river therefore has some disadvantages. On some of the long points of the river a levee following the bank will have, compared with a line across the point, a length

FIG. 76.—SAND "BOILS" HOOPED WITH SAND SACKS.

FIG. 77.—SAND-BAG DAM.

FIG. 78.—SAND-BAG DAM.

not justified by the small additional amount of land protected. In a rapidly caving bend a levee close to the river bank must in a short time be destroyed. Complications are also frequently introduced by the existence of the old river lakes caused by cut-offs. The short and direct line would pass between the lake and the river, but such a location requires usually a high and large levee and involves danger from the nature of the soil recently deposited in the old river bed and the probable existence of permeable sub-strata liable to be washed out by hydraulic pressure during floods. On the other hand, the line around the lake, though safe, is apt to be of extreme length. Mr. Sellew.

"The question of levee location is, therefore, not a simple matter and should receive careful consideration, but such consideration has, unfortunately, not been always given to it. Most of the existing levees have grown up gradually by the incorporation in the main system and successive enlargement of old levees built by private parties for their own protection, and the location of these old levees, having been made without any reference to a general system, is, of course, in many cases, faulty. Even where the levee has been built entirely anew the location has been most usually fixed by the local boards, who are, of course, subject to local influences, and many levees have thus been located too close to a caving bank, in order to include special farms.

"But even when a new levee is to be located with reference only to its general use, the question is not an easy one. If the banks of the river cave with any regularity, the cost of a new levee and its life in any location could be balanced against the value of the additional protection obtained by this location. But the caving does not go on with any sort of regularity; some places that may not have caved for years will suddenly begin to cave rapidly, and at other places where caving has long been going on the caving will sometimes somewhat suddenly cease. In placing levees near caving banks, therefore, a careful study must be made of the locality and of the river for some miles above, and, in general, it is considered a good location for the levee if this study indicates a probable life of about twenty years."

Although 20 years was formerly considered economic practice on the Mississippi, recent developments have modified it, as shown by the following:*

"It is the judgment of the Commission that these revetment works and some others which will be imperative within a short time are required for the preservation of the levee system. Without them a permanently completed system will be impossible. The increasing height and cost of the levees and the rapid development of the country protected by them greatly augment the disaster of crevasses. A break in an embankment 5 or 6 feet high resulting in the thin overflow of a sparsely populated country is a small calamity compared with a break in a levee 20 feet high, discharging over a thickly populated country threaded with railroads and filled with towns and factories. Owing to the increased height now necessary to control the floods the expense of replacing an undermined levee by a new line going far around a lake or impassable swamp is enormous. The point of development

* Report of Mississippi River Commission, Appendix PPP—Chief of Engineers, 1908, p. 2655.

Mr. Sellew.

has come at which the only economical way to maintain the levees is to hold the banks against caving—not everywhere, but in all places where the special conditions exist which have just been described. This is a distinct stage of the work only recently reached."

The area protected by the Colorado levees will be occupied by farms of rather small area, and consequently a comparatively large population will be dependent on them. Intensive farming will be practiced, and the preparation of the land will be expensive, therefore it appears that overflow should be prevented by all possible safeguards. The integrity of the levee system will depend principally on bank protection. There are two general methods by which this may be accomplished: (1) to give the bank a revetment which will protect it against erosion; (2) to keep the main current away from the banks, so that erosion cannot occur.

Revetment may be continuous throughout the river, or salient points which are strongly attacked may be treated first, the work being extended as occasion demands. The most extensive revetment in the United States, if not in the world, is to be found along the Mississippi River and its tributaries, where the General and State Governments and local levee boards have engaged in protective works for many years. The standard revetment consists of a woven brush mat or fascine mattress protecting the bed of the stream for a short distance from the shore and the side of the channel below low water. Above low water, where brush deteriorates rapidly, the bank is graded to a uniform slope and paved with rock. Such work is very expensive.

The magnitude of bank protection and river control on a large stream is seen in a "Report by a Special Board of Engineers on a Survey of the Mississippi from St. Louis to its Mouth,"* with a view to obtaining a channel 14 ft. deep and of suitable width. On page 52 it is stated that up to the date of the report, 1909, there had been expended by the General Government on the Mississippi from the mouth of the Missouri to the head of the Passes more than $88 000 000. In addition, there had been some millions spent by the riparian States and local levee boards.

Reference is again made to *Occasional Papers No. 41*, Engineer School, U. S. A., being "A Résumé of Operations in the First and Second Districts of the Mississippi Improvement, 1882-1901." This material, which covers the work done by the National Government under the direction of the Army Engineers, has been compiled in detail by E. Eveleth Winslow, Major, Corps of Engineers:

(From page 45): "It is now considered settled that in a plan for the permanent improvement of the channel by the contraction of its low-water width, the work of bank protection should precede the permeable dikes and other structures of that class, and that the latter

* Doc. 50, 61st Congress, 1st Session.

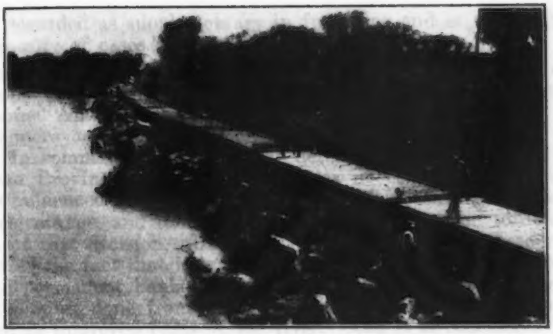

FIG. 79.—SIZE OF ROCK USED FOR PROTECTION.

FIG. 80.—LEVEE PROTECTED BY ROCK.

FIG. 81.—STEAMER "SEARCHLIGHT" DRAGGING LARGE ROCKS FROM CARS.

may be regarded as supplementary in functions and as necessary only in a minority of cases."

(From page 47): "It was recognized from the beginning of the Commission's work that the construction of works of bank protection and channel contraction in detached reaches would be subject to influences more or less unfavorable from changes in unprotected bends above. In commencing work in the detached reaches of Plum Point and Lake Province, the Commission was not oblivious of this fact, but was influenced by other considerations which seemed to overbalance this disadvantage, and it has not since seen good reason to doubt the wisdom of that decision. But the experience gained in those reaches emphasized the fact that it is highly important in any project for general and permanent bank protection to leave no unprotected reaches above the work done from changes in which new conditions may be produced in improved parts of the river. And it is considered by the Commission that in undertaking a complete and permanent system of bank protection the work ought to begin at the upper end of the river at or near Cairo and be carried thence down-stream with substantial continuity. * * *

"It is considered that the annual cost of maintenance of completed work could not be estimated at less than ten per cent of the original expenditure."

(From page 233): "The object of bank revetment is to protect the banks of the river from destruction by the currents. The active agency in this bank destruction is erosion, and bank revetment must therefore prevent this erosion. Perhaps the easiest and most obvious method of doing this is by laying over the exposed surface of the erodable bank a non-erodable covering, and this is the method adopted. This non-erodable covering must, of course, be fairly durable, must have sufficient strength to withstand any strain put upon it, and must be free from interstices through which scour might take place.

"Owing to the fluctuations in the river, the different parts of the bank are subjected to different conditions. Below the low-water line the bank is always wet; above that line sometimes wet and sometimes dry, and this difference in conditions allows, if it does not require, that the portion of the bank above and below low water be treated differently.

"Above low water the bank can be seen and the non-erodable covering can be laid with ease, and it has been found that here a properly laid stone pavement forms an efficient protection. The individual stones of this paving must, of course, be so large that they cannot be moved by the current, and it was found by experience that stones of this size are not of themselves sufficient, as through their interstices scour could take place when the bank was sandy and the current strong. This has been prevented by first covering the bank with a layer of spalls or crushed rock of such thickness and closeness as to prevent scour through them and to hold this down with a layer of larger stone. Such protection, when carefully laid, has been proven to be all that is required for the upper bank.

"Below low water the conditions are different. As it is impossible to construct the non-erodable covering actually in place, the next

Mr. Sellew.

best thing is done, constructing it on the surface of the water above where it is to lie, and when constructed sinking it. In this way the continuity of the covering can be assured, and it can be placed exactly where it is needed. As has been stated, this covering must not contain interstices through which scour can take place, for in such a case not only would the purpose of the covering not be fulfilled, but by such scour its own eventual destruction would be assured.

"The covering actually used has been a mattress of brush and the only kind that has been found to prevent scour in very rapid currents is the fascine mattress. In moderate currents another type of mattress might do, but as changes in current conditions are always likely to happen the fascine mattress only should be used."

(From page 256): "In the early work brush was used as a covering for the upper bank, but, subject as it was here to alternate submergence in the water and exposure to the atmosphere, it decayed rapidly and possessed little strength after about two seasons, and it was this rapid decay of the brush permitting it to be easily broken up and exposing the bank to erosion, that led to its disuse and the substitution for it of an all-stone covering."

(From page 260): "It is probably safe to estimate that a fascine mat built of small brush will be effective for at least twenty-five years and that when a good proportion of large brush is used its life will be considerably extended."

Applying these principles at Yuma, revetment should begin at Laguna Dam and proceed continuously down stream, leaving no unprotected caving banks above completed work.

The portion of the revetment lying above low water should be constructed by grading the bank to about a 3 to 1 slope and paving it with rock. This is necessary, as any brush work laid on this portion of the bank, being subject to alternate periods of submergence and exposure to the air, will deteriorate in about two seasons and be of little use in holding the bank. Below the low-water mark, the sides of the channel and the bottom for 50 ft. from shore should be protected by a fascine mattress. Assuming that the gauge oscillation along the stream is about 12 ft., a slope of 3 to 1 for this height would give an exposed bank of about 38 ft., and, with a stone paving 2 ft. thick, would require 76 cu. ft., or, say, 3 cu. yd. of rock per lin. ft. of bank. By using the quarries at Laguna Dam and Pilot Knob, delivering the stone into barges, and then towing the material into place for use, a fair estimate for the material in place on the bank will be about $2 per cu. yd., or $6 per lin. ft. of bank. In addition, assume that brush mattress will cost about $4 per lin. ft., making a total for revetment of $10 per lin. ft. of bank, or $50 000 per mile. The distance from Laguna to the Mexican boundary is about 45 miles, and probably at least two-thirds of this distance, or 30 miles, will require continuous revetment. At a cost of $50 000 per mile of bank

or $100 000 per mile of river, 30 miles of revetment would cost about $3 000 000. Mr. Sellew.

The foregoing quotations from the Mississippi reports state that the annual maintenance of bank revetment should not be taken at less than 10% of the original cost, which means that expenditures for this purpose must be duplicated each 10 years.

S. Waters Fox, M. Am. Soc. C. E., an assistant engineer in charge of some of the Missouri River improvements, states* that 45 miles of the alluvial portion of that stream had been improved at a cost of $2 500 000, or about $56 000 per mile. The division of this cost was stated by him as follows:

Actual construction	67 per cent.
Care of, repairs, and moving plant	22 " "
Administration	9 " "
Other items	2 " "
	100 per cent.

It is thus seen that, in this particular case, the cost of maintenance was more than double that assumed for the Colorado. Another thing to be considered in the matter of bank protection is the source of the material to be used. The supply of rock in the quarries at Laguna Dam and at Pilot Knob is abundant, but the same cannot be said regarding the brush, which for the best results, should be young, live willow. In *Occasional Papers No. 41,* Engineer School, U. S. A., previously referred to, the following appears on page 46, in an extract from reports of the Mississippi River Commission:

"Another fact now definitely settled is that in the construction of mattresses of the type now employed on a large scale, the supply of material becomes an element of the problem presenting serious difficulty. The area of willow-producing bar necessary to supply material for a mile of fascine mattress 300 feet wide is practically five times as great as that required for an equal length of mattress built in the early years of the work. The quantity of small willow growth used in this form of mattress is so great that the estimate of the yearly supply available along the whole length of the river from Cairo to Vicksburg is not more than sufficient for the making of 15 miles per annum of bank revetment."

The writer is not aware how the growth of willow along the Colorado compares with that along the Mississippi between Cairo and Vicksburg, but will assume for the present that the quantities are about equal. The assumption will also be made that the quantity required for the Colorado will not be more than one-third as much as that on the Mississippi; therefore, if 600 miles of river provide for 15 miles of revetment on the Mississippi, it would provide for 45 miles

* *Transactions,* Am. Soc. C. E., Vol. LIV., p. 280.

Mr. Sellew. on the Colorado. If 600 miles of river will furnish material for 45 miles of revetment, then 45 miles of river between Laguna Dam and the International Boundary would provide for about 3½ miles of such work annually. In the 30 miles of stream to which it is suggested the revetment be applied there would be 60 miles of revetted bank, and at 3½ miles per year it would require 17 years to build this revetment with the ordinary growth. This makes no allowance for the annual repairs, which are estimated at 10 per cent. It would also be impracticable, even with the material available, to construct this revetment immediately, not only on account of the constructive difficulties of doing so much work in a short space of time, for the control of the stream by revetting its banks and contracting its channel must necessarily be slow because the changes which these works bring about cannot occur immediately. On this point the writer quotes from *Occasional Papers* previously mentioned, page 41:

(From the Mississippi River Commission's report for 1889): "This work is still incomplete, although its feasibility and value have, it is thought, been fairly demonstrated. It is, however, well understood now that it is likely to prove a slower process than was at first supposed, for the work cannot be hurried. It must be gradual and progressive."

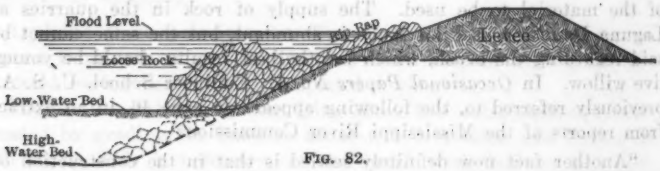

FIG. 82.

Seventeen years is entirely too long a period over which to stretch this work, as the protection of the Government's investment and the welfare of the settlers demand that the control of the river be almost immediate.

The radical difference between the high-water and the low-water channels of the Colorado furnish another obstacle to the foregoing form of bank protection. An examination of the diagram (Fig. 72) shows, that while protection of the upper bank by the rip-rap could be readily accomplished, it would be impossible to place the fascine mattress in the proper position. At low water, when conditions are favorable for mattress work, the channel is so silted up that a mattress sunk in position would not even approximate the place it should occupy to protect the flood channel from erosion. At high water, when the channel is scoured out and the bank to be protected is exposed, the depth of water and the velocity of the current are too great to accomplish work of this class successfully.

From the foregoing it appears that mattress revetment below low water, combined with rock revetment above, should not be applied along the Lower Colorado, for the following reasons: Mr. Sellew.

(1) The high first cost and excessive cost of maintenance (10%);
(2) The time required (17 years) for the natural growth to produce the willows necessary for this form of protection;
(3) The impossibility of placing the mattress in its proper position, due to the silted condition of the stream at those seasons when depth and velocity are favorable for such work; and
(4) That in great floods a concentrated attack might destroy a portion of the mattress at a time when its repair or the protection of the bank thus exposed would be impossible.

Rock Revetment.—Another method of protecting the bank would be to make the revetment entirely of rock. At low water the exposed slope would be graded, properly rip-rapped, and at the foot of this slope a large quantity of loose rock would be placed (Fig. 82). As the high-water channel was created by the scour of the current, this loose rock would be undermined and gradually slide into position, making a revetment along the bank thus exposed which would be practically a permanent protection. In approximating the cost of such work, let it be assumed that the average depth along the levee during high water will be about 20 ft. It is known that at exposed points where severe cutting has been in progress it has been as much as 32 ft., but, for a general average depth to which revetment should extend, 20 ft. appears to be safe. Suppose that the rock will stand at a slope of 2 to 1; then the length of the revetted slope in contact with the water will be 45 ft., and, if the revetment is 2 ft. thick, the area of the section will be 90 ft. Assuming that, owing to wasteful methods by which this is applied, one-half is lost, then the sectional area of rock per linear foot which has to be placed along the levee is 135 sq. ft., or 5 cu. yd., or 25 000 cu. yd. per mile of bank, equal to 50 000 cu. yd. per mile of river. For 30 miles this would mean the placing of about 1 500 000 cu. yd. of material.

Should such a course be adopted, quarries would be opened on each side of the river at Laguna Dam, which, by connecting railroads, would supply the levees within economic reach. Another quarry at Indian Hill, opposite Yuma, would serve for the portions above and below for proper distances, while quarries at Pilot Knob would control the remainder on the California side. From this latter point, a temporary trestle, which appears to be the best arrangement, would connect with the Yuma Valley levee, on the Arizona side of the Colorado. Later, if it was decided to extend similar treatment to the Gila levees, the Arizona quarry at Laguna Dam would control the levee on the north side of the stream, and the south levee could be reached from

Mr. Sellew.

Penitentiary Hill. Considering now only the embankments along the Colorado, it appears that the suggested treatment will require a railroad over their entire length, which is about 60 miles. These levees are already in existence, and the cost of equipping them with track (52-lb. rails) is estimated as follows:

Cost per mile of railroad on existing levee:

Steel, 52-lb. = 90 tons, at $30	$2 700
Fastenings	600
Ties, 2 600, at $1.25	3 250
Track laying	400
Train service	125
(Say, $7 000 per mile)	$7 075

There is a railroad on the Reservation levee between Yuma and Laguna Dam, and deducting this length of 13 miles from the 60 miles required leaves 47 miles to be built. At $7 000 per mile this cost would be $329 000, to which may be added about $10 000 for the Pilot Knob trestle, giving a total for railroad construction of, say, $340 000. The average length of haul from these quarries will approximate 15 miles, and it should be done for not more than 1½ cents per ton-mile. The 1 500 000 cu. yd. will equal about 3 000 000 tons, and with an average haul of 15 miles, gives 45 000 000 ton-miles, which at 1½ cents equals $675 000. Using large steam shovels, quarries with long and high faces, mined with small tunnels in which heavy charges are used, it would appear that the material could be placed on the cars at an outside price of 30 cents per cu. yd.; to this should be added, say, 25 cents per cu. yd. for spreading and placing the rock on the slope, giving 55 cents per cu. yd. as the cost above that of hauling. At 55 cents, 1 500 000 cu. yd. would cost $825 000, which, added to the expense of hauling, makes a total charge of $1 500 000, which is increased to $1 840 000 when the cost of building the railroad is included. Adding 10% for contingencies and repairs gives a round sum of $2 000 000 for protecting 30 miles of river, or about $66 000 per mile, equivalent to $33 000 per mile of bank.

Although these estimates must be considered as approximations, it appears that permanent rock revetment can be had for not more than one in which mattresses are used, and probably for less. The permanence of the rock, its slight maintenance cost, the ample quantity available, and the fact that it can be placed as well during attack at high water as at low, makes it the best and most economic protection for the banks of the river between Laguna Dam and the Mexican boundary. Once the tracks were on the levee, exposed points could be quickly protected, and the remainder of the work could proceed as desired.

Mr. Sellew.

By Deflecting Currents.—Bank protection by deflecting the currents away from the shore so that erosion cannot occur may be done by spur-dikes or by opening channels across sand-bars which are the cause of the impingement. The deflection of currents by brush dikes has been tried in many localities and with varying degrees of success. They are subject to destruction by the natural course of deterioration, by deep scour which occurs around their outer ends, and by the undercutting of eddies below them which they have created. They have been tried sufficiently along the Lower Colorado under the writer's direction to demonstrate that at best they are only a temporary expedient. If built of cottonwood piling, which grows along the banks of the stream, their life would not exceed 2½ or 3 years as the maximum; probably the average is not more than 2 years. Constructed of fir piling, they could be depended on for 6 or 7 years. If, at the end of that time, the new banks which had been created by silting between them were not protected by revetment, it is probable that the dikes would need renewal, in order to hold the work. One other disadvantage of spur-dikes is that the proper location for them is demonstrated only by the varying attack of the river, and, when this attack comes on, the water is generally so deep and the currents so swift that the dikes cannot be built. It is then necessary to defend them as best one can until lower water, and perhaps, on the falling stage, the river changes its point of attack, so that dikes are needed in other places. In the writer's judgment, protection by spurs should be used only in an emergency; they have no place in any permanent form of bank protection on this river.

Dredging.—There remains the method of diverting the current by opening up channels across sand-bars. Wherever the banks have been attacked, the impingement has been caused directly by the formation of deposits on the opposite side of the stream. As these deposits build out toward the opposite bank, the flowing prism of the river is narrowed, the concentration of the water increases the velocity, the channel is correspondingly deepened, and, as a result, there is deep water and high velocity against a caving bank. Under such conditions, if it were possible to open up a channel of sufficient dimensions across this bar, and if the current could be induced to follow this new channel, the attack on the bank would be immediately relieved. In some instances, where the encroaching bar is short and other conditions are favorable, channels have been opened up and relief secured by a liberal use of dynamite. Such a method is impracticable in most cases along the river. It is seldom that a condition occurs that can be relieved by explosives.

The following is taken from *Occasional Papers No. 41*, page 44:

"The experience with the revetment work previously done had shown it to be inadequate for the purpose, and rapid changes of type

Mr. Sellew.

were not made until there was developed the standard of the present day: A fascine subaqueous mattress with upper bank paving of stone. But as the revetment work had gradually been increased in strength, it had also increased in cost, until in the new standard type the cost had reached about $30 per linear foot of bank, or approximately $150 000 per mile.

"As the large cost of a systematic improvement of the whole river became evident, the Commission was led to investigate means for temporarily improving navigation during the low-water season. The principal obstructions met with are the sand bars built up during high stages, through which the river slowly cuts a channel as the flood recedes. If this process could be assisted and hastened, navigation would be improved thereby, and to this end experiments were made with dredges. These experiments, started in 1894, were successful and as a result the Commission was led to reconsider the whole subject of the river improvement, and as a result of this study the Commission decided to adopt a new plan for future operations, namely, to depend for the relief of the immediate needs of navigation upon dredging, and to restrict the improvement by bank revetment to special localities, where local interests or necessities demanded it."

(From page 46): "From all these facts together it became apparent several years ago—not all at once, but gradually, as facts accumulated and the deduction of experience was unfolded—that it was not possible by any or all of the methods which had been employed to accomplish such permanent improvement of the river from Cairo down as was necessary to meet the urgent demands of commerce within any reasonable time to come. It was this disagreeable but unavoidable conclusion from the work of preceding years, together with the recent and wonderful development of the hydraulic dredge, that led the Commission to undertake the experiments of dredging the bars of the river with the view to the temporary improvement of its low-water channel which has been detailed in recent reports of the Commission and to which more extended reference is made elsewhere in this report. Those experiments have proceeded favorably so far as to hold out a reasonable probability of entire success."

A suction dredge of large capacity and light draft which could be maneuvered in the Colorado during flood stages would be of value in opening channels across sand-bars. During low water the dredge could be used in creating a channel about midway between the levees at those points where attack from caving banks was imminent. The excavated material could be deposited in the vicinity of the levee through pipes carried on pontoons, thereby building the banks and making their alignment more regular.

It might appear at first thought that the quantity of material to be moved would require a dredge of unheard-of proportions, and that the expense would be prohibitive, but such work appears to be well within the range of the hydraulic dredges as developed for work on the Mississippi River, the largest of which have a capacity of 2 000 cu. yd. per hour. About one-third of their time is lost in tie-ups for

repairs during high water, maneuvering for position on bars, and in change of position, so that throughout the year the dredge would operate not more than 240 days, or 5 760 hours. Such operation of the dredge would result in removing about 11 000 000 cu. yd. of material. Mr. Sellew.

Assuming a low-water discharge of 4 500 sec-ft., passing Yuma with a velocity of 3 ft. per sec., the area of the flowing prism would be 1 500 sq. ft. If this was excavated, with a depth of 5 ft. and a width of 300 ft., the 45 miles of such channel between Laguna Dam and the Sonora line would contain about 12 400 000 cu. yd. It is clear that no such quantity of excavation will ever be required along the lower river in any one season, therefore the dredge under discussion has ample capacity. The questions to be examined are: (1) its cost; (2) whether it can be designed of dimensions which will allow it to navigate the shallow and tortuous channels of the Colorado; and (3) whether it can be operated during floods for opening channels across the bars.

Referring to Document 50, 61st Congress, page 55, where is shown a memorandum of a project for maintaining by hydraulic dredging alone a navigable channel, 14 ft. deep and 500 ft. wide, between St. Louis and the mouth of the Ohio River: The estimates provide for 20 dredges, each with a capacity of 2 000 cu. yd. per hour, to cost, with all attendant floating plant, tools, auxiliaries, etc., $6 000 000, or $300 000 per dredge. The annual maintenance is stated as $100 000 per dredge. In estimating the cost of a dredge, its life is here assumed as 20 years, and a sinking fund is provided for its renewal at the end of that time.

Estimated Annual Cost of Dredges.

Interest at 3% on $300 000	$9 000
Annual maintenance	100 000
Sinking fund	11 166
	$120 166

The maintenance of the channel by dredging would require continuous work, year after year, no permanent results being obtained. In about 16 years the sum of the annual maintenance would equal the estimated cost of the rock revetment, and the maintenance, capitalized at 3%, gives an amount double that for which it appears a safe and permanent bank protection may be obtained. Whether or not a dredge can be built to satisfy the local conditions cannot be stated from the data at hand, but as such operations will cost double those necessary for permanent bank protection, further examination in this direction appears to be needless.

Mr. Sellew.

Conclusions.

The purpose of this discussion is to indicate in a general way the present conditions along the Lower Colorado, and to point out, from an analysis of the data here assembled, the future course which will probably be productive of the best results. It appears:

(1) That in their present state, the levees are at the mercy of the meanders of the stream, except throughout those portions where a railroad occupies the levee top;

(2) That checking the meanders of the stream by permeable dikes during low water and brush defences during high water are simply emergency works which accomplish no permanent good;

(3) That owing to the large amount of scour during freshets and the fill-back on the falling stage, bank protection by means of willow mattresses as constructed in other places is impractical, if not impossible;

(4) That bank revetment, permanent in character and reasonable in cost, when compared with other methods, can be readily and quickly accomplished with rock placed from railroad trains operated on the levee tops and connecting with existing quarries which are within a reasonable distance;

(5) That further investigation is needed before it can be predicted, with any degree of accuracy, what effect the possible storage of flood water on the upper reaches will have on the flood discharge and the meandering tendency of the lower river;

(6) That it is doubtful if the amount of control obtained in this manner will eliminate the necessity of bank protection, and, even if such control could be obtained, a number of years must elapse before it can be made effective;

(7) In the meantime, existing works will continue to be menaced, therefore protective measures of greater or lesser magnitude must continue. In view of this fact, and the probability that some caving banks will always exist, the money spent for their protection should be for permanent revetment.

Nothing in the foregoing should be construed as opposing in any degree the creation of storage works at the head-waters of the Colorado. All feasible sites should be carefully examined, their probable influence estimated, and a well-determined construction plan matured. Such preliminary action is necessary before the advantages to come from the complete development of this river can be realized.

The destiny of this stream should be controlled by engineers rather than by statesmen, as the author suggests.

Mr. Mead.

Elwood Mead, M. Am. Soc. C. E. (by letter).—The author's able review of the irrigation development in the Imperial Valley and the measures taken to control the Colorado River, describes the most

unique achievement in American engineering since Eads deepened the mouth of the Mississippi. The Society is indebted to Mr. Cory for having given such a complete history. Mr. Mead.

If the gap in the Colorado had not been closed, Imperial and a score of other towns would have been buried deep under the waters of an inland sea; the grain fields and orchards of thousands of farmers, and representing the savings of lifetimes, would have been blotted out; one-twelfth of the irrigated area of California would have disappeared; the Laguna Dam would to-day have probably been only a memory; and the greatest change in the earth's geography which has taken place within recorded time would have been an established fact.

Only those who heard the turbulent torrent that roared through the break in the bank of the Colorado and saw the forest-covered lands along the new channel melt and disappear in its depths, could understand the appalling nature of the disaster which impended and the tremendous odds which had to be faced to restore the river to its original channel.

In this attempt an expenditure of more than $1 000 000 had to be risked, with the chances on the side of failure. The courage with which Mr. Randolph and Mr. Cory assumed their trying responsibility, and the generalship which they showed in handling their immense equipment, are not made clear in Mr. Cory's paper. Only those who knew the conditions faced can fully appreciate the superb merit of their achievement.

The chief value of this paper, however, is not found in its description of the engineering methods used, but in the social and political conditions, attending irrigation development in the West, which it reveals. This history shows that, so far as this enterprise was concerned, there was an utter lack of public direction and supervision, or either State or National aid; and, as these are fundamental features of irrigation development, it is that portion of the paper which the writer proposes to discuss.

If it is the duty of the Government to conserve the public resources and to give any regard to the general welfare of the people developing them, this should be shown by the enactment of intelligent land and water laws and adequate administrative control of streams, as this is the only means of ensuring the full development of these resources and the right conditions of life in the arid West. This part of the country embraces two-fifths of the Nation's area. It was almost worthless without irrigation, it is immensely valuable now, but the change has been accompanied by a waste of effort, a loss of money, and the infliction of hardships and injustice which could have been easily prevented if the State and National law-makers had done their duty.

Mr. Mead.

When Western settlement reached the arid region, Congress should have provided for the diversion of rivers under public control, and in accordance with a general plan. This would have secured the irrigation of the best land, prevented the duplication of canals, or the building of canals where there was no water to fill them. It should either have built the large and costly irrigation works as Government projects, or safeguarded the private investments in these works, by making land and water security for the cost. Instead of this, there has never been any satisfactory title to water, and the public land has almost invariably passed into a control hostile to or independent of the irrigation works. Instead of adequate security, there was never, prior to the passage of the Carey Act and the Wyoming State law accepting this Act, any security for the money spent in irrigation works to water public lands, and at least three-fourths of these enterprises were financial disasters.

If all important irrigation works had been built by the Government, money could have been obtained at one-fourth the interest charge the majority of private projects had to pay, and without the ruinous discounts on loans which the flotation of these enterprises entailed. Low interest rates would have made much lower water charges possible and thus removed from American irrigation its most serious handicap.

If there had been any attempt to frame a land law suited to requirements in the arid region, it would have at once been manifest that the homestead should have been reduced in acreage instead of increased, because it requires more labor to cultivate 80 irrigated acres than it does 160 acres watered by rain, and the returns are larger. Instead of reducing the homestead and restricting settlement to homesteads, however, the Desert and Land Act was passed, which gave 640 acres to the individual, conferring title without residence, without cultivation, and too often with the mere pretence of watering. The Desert Land Act was promoted by the rich range stock owner. It was the worst handicap irrigation ever had, and, instead of aiding the deserving settler, it took away his best opportunities. Instead of public control of streams, men fought for their possessions with shotguns and shovels along the banks, or with more costly weapons in the Courts, where litigation, instead of settling issues, as a rule, created new fields for controversy. The water-right litigation of the arid States has not only been a continuing source of ill-feeling, injustice, waste, and loss, but its existence is a reflection on the capacity of the law-makers who are responsible for it. An understanding of these matters is necessary rightly to interpret what occurred in the Imperial Valley.

The irrigation and settlement of the desert of Southern California should never have been left to private enterprise. This was a case calling for direct Governmental control and responsibility. The desert

Mr. Mead.

was below sea level. It was worthless to the State, dangerous to travelers, and ugly to look upon. It was known that the Colorado River was a stream subject to torrential floods, and that the banks were alluvial; and it required only the slightest consideration to realize the danger which would menace settlers if they were allowed to make homes in this valley without the diversion works being made safe beyond question. The benefits which would come from irrigation and settlement made it a matter of direct concern to every resident of California, gave the project a National importance, and justified its construction as a public work.

If, however, the State did not build the works, it was its duty to supervise them and protect the private enterprise which did. Before investors were allowed to risk their capital or settlers risk their lives and comfort, some public authority should have seen to it that the land was fit to cultivate, and that there was a legal title to water; and there should have been an inspection of engineering plans and an investigation of financial arrangements.

Instead of this, an irresponsible company without capital employs an engineer, whom it fails to pay. A right to 10 000 cu. ft. per sec. of a navigable international stream is established by the engineer posting a notice in an uninhabited jungle of weeds and brush. Of course, this was a farce, but it was the manner of establishing water titles prescribed by the law of California. That the title was worthless was shown later, but the early investors did not know this, they trusted the State to uphold and defend its statutes, and were betrayed. Any one who reviews this record must be amazed at the exhibit of imperfect laws and the incompetence or indifference of the public authorities. The surveys of public lands were shown to have been fraudulent, which was bad enough, but the delay of six years in correcting them was infinitely worse. The examination of the soil should have been made before settlement instead of afterward, and should never have been made except by experts having practical knowledge of irrigation. Instead of a proper land law, much of the land was acquired by non-resident speculators.

When the water title was attacked by the Interior Department, it was the duty of the State to defend its authority to grant titles and to protect this struggling project and the unfortunate settlers. For this protection, however, they had to look to a foreign country, and one wonders what would have been the result if Mexico had been as indifferent as the United States. This attack on the water title by the United States seems to have been morally wrong even if legally defensible.

Finally, when it was known that the river was beyond control, and the most appalling calamity that ever menaced the State of California was impending, it should not have been left to a bankrupt company and impoverished settlers to cope unaided with this disaster.

Mr. Mead. It was the duty of the State or Nation to take charge, and provide the money and men needed to restore the river to its former channel. Apparently, no one in authority was interested, the State Government only considered the matter long enough to write a letter to the President, and the President, having Congress on his hands, shifted the responsibility to the head of a railroad company; and it was not until this railroad company took charge that we have the first refreshing example of generosity and public spirit. Nothing could have been finer than the action of Mr. Harriman. The loan of $250 000 when his time and resources were overtaxed by the earthquake at San Francisco, providing more than $1 000 000 for the last hazardous attempt to save the valley, furnishes an inspiring contrast to the supine indifference and irresponsibility shown by both the State and Federal authorities.

The Imperial Valley produced last year crops worth $10 000 000. The most desolate part of California has become attractive, productive, and profitable; but, when one contemplates the hardship, anxiety, and suffering of settlers, and the waste and loss to the investors in the enterprise, one cannot help feeling that the conditions which imposed such burdens on development ought to be removed.

The National and State benefits which have resulted ought to have brought both wealth and public recognition to the pioneers of the enterprise; instead, its engineer and organizer was in the end cast on the scrap heap, his life work wasted; and a large percentage of the pioneer settlers, after untold hardships, had to give up and leave. Many of those now in the valley have had to pay high prices for their land as the result of early acquirement by speculators. The Southern Pacific Company, although requested by the President of the United States to save this valley from destruction, has not been paid for doing so. The speculators in the company, who were astute enough to get two dollars for one, have in many instances become rich; the lawyers who have had charge of the unending litigation have reaped a fruitful harvest; but those who worked for the real success of the enterprise, the men who risked their own comfort and that of their families to create homes, have paid penalties which are entirely unnecessary where irrigation development is carried out under a proper system of public control.

Mr. Cory's paper needs to be read in connection with that recently submitted by Mr. Lewis,* the State Engineer of Oregon; both papers show the need for a change in the public conception of the duties and responsibilities of the Government in conserving and developing public resources, and a general appreciation of the need of more effective laws for safeguarding investments and making the settlement of arid lands easier, cheaper, and safer than this has been in the past.

* *Transactions*, Am. Soc. C. E., Vol. LXXVI, p. 637.

Mr. Follett.

W. W. FOLLETT, M. AM. SOC. C. E. (by letter).—Mr. Cory's paper is valuable and interesting for several reasons. It gives in chronological order the history of irrigation in the Imperial Valley, culminating in the terrible battles with the gigantic and treacherous Colorado; it records the impressions and beliefs, after sober second thought, of one who was there in responsible charge during the months and years of greatest stress, and, above all, it is especially pleasing to the writer because the author takes occasion to show how uncalled for was the hysteria which accused Mr. Rockwood of having made a criminal blunder in opening the cut through which the river made the crevasse.*

In March, 1903, the writer made a trip down the Colorado River by rowboat, starting at Yuma and going to a place known locally as "Mike's Landing," which was about 80 or 90 miles by river below Yuma and near the head of tide-water. The return trip was made by wagon, through the delta lands west of the river, along the west bank of Volcano Lake, and to Calexico.

On this trip, which was made on a Yuma gauge of 18.3, or about 1.5 ft. above low water for that season, it was noted that the height of the river banks varied from 5 to 8 ft. above the surface of the water. The maximum flood of 1902 was 24.5 on the Yuma gauge, and, judging from the high-water marks on the trees, filled the river a trifle more than bank-full, whether the banks were 5 or 8 ft. high. Apparently, so much water escaped as soon as the banks were topped that the rise ceased. After passing a point about where the crevasse of 1905 afterward occurred, where the width of the channel was 800 ft. or more, the latter narrowed, as water was spilled over the banks, until it was only 410 ft. between the overflow banks at Mike's Landing. These apparently did not overflow deeply—although at that time there had not been for many years such enormous discharges as have come during the last 8 or 9 years.

On leaving the landing, the wagon road led directly away from the river for about 10 miles and then veered to the northward, toward Volcano Lake. The high-water marks showed that there was a rapid fall in the ground as the river was left behind. Of course, these marks were not level, but fell away from the river, as drift showed that the current had been in that direction. The fall mentioned by the author —from 5 to 8 ft. in the first 3 000 ft.—was found, being nearer the latter figure. After that, the fall was more gradual.

In going north it was noted that each flood-water channel crossed was running on a ridge similar to, but much smaller than, that on which the main river ran.

As a result of that trip, the writer was impressed with the idea that the Colorado was nearing an epochal change in its course across its delta. It is well known that an alluvial stream builds up its banks

* *Transactions*, Am. Soc. C. E., Vol. LXII, p. 24.

Mr. Follett.

and beds across its delta until it lies on a ridge; and that finally the time comes when the river breaks away from this ridge, takes a new course to the sea across the lower portion of the delta, and proceeds to build another ridge. When the stream reaches this condition of instability it is impossible, except at great expense, to keep it on the high ground. The writer had no idea, however, that the river would break into the Imperial Valley, but believed that the ridge north of Volcano Lake and the embankment along the canal of the California Development Company, would prevent such a diversion.

Subsequent events have confirmed this idea, and the writer is now of the opinion that any money which may be spent in attempting to close the Abejas Crevasse will be wasted, because, even if it is closed and held, the river will break out again somewhere else.

The author has shown quite clearly* that no serious grade recession has resulted from the Abejas Crevasse. As the river has been running through this opening for 4 years, during which time there have come the two largest floods ever known, it is fair to assume that no further grade recession will occur, but that a new delta is forming, pointing toward Volcano Lake, and that the tendency henceforward will be for the bed of the river to rise. Therefore, no danger to the water supply of the California Development Company nor to Laguna Dam is to be expected. It is best, therefore, to recognize this as an epochal change, allow the river to take its own course to the Gulf, and protect the Imperial Valley by raising and strengthening periodically the levee which lies north of Volcano Lake and extends back to the river. For the valley this will be a sure protection, which the closing of the Abejas Crevasse would not afford for any length of time.

Attention is called to the narrow gorge between levees, which begins opposite Andrade and extends for 2 miles down stream. The levees average about 1 500 ft. apart, with a width of river channel of 1 000 ft.; that is, the average berm on each side between the river and the levee is only 250 ft., and, in some places, it is probably narrower. This condition is shown on Plate L.

If, during some flood, the current of the river should be deflected so as to strike the right bank, and scouring began, it is the writer's belief that the levee and canal bank would be eaten away like sugar, and the river would be diverted into the canal and down the Alamo, again reaching the Salton Sea.

To prevent this diversion, a safety gate can be built about 2 miles below the Hind Dam (see Plate L). At this point, the Rockwood Crevasse channel touches the sand hills on the north, and a cross-levee could be built from the gate to the main levee on the south. As there is much fall, a drop would probably be needed. In this might be

* Pages 1214–1215, and Fig. 3.

placed gates, if thought best, which could be used for sluicing sand from the canal above. Mr. Follett.

The writer was on the ground several times prior to the closure of the crevasse by the Hind Dam, and was strongly impressed with the danger of the river "side-wiping" the canal in this narrow stretch. If it starts to shift, the efforts of man to stop it will seem puny in comparison with the immense destructive force of the current. It is stated that, in the Edinger Dam, piles, 64 ft. long, were driven more than 50 ft. into the bed of the river, and that, when the flood struck them, they scoured out and floated away; they were not broken, but came out bodily. Attention is called to the author's statement (page 1214) that, in 1907 and again in 1909, it was found that for an increase of 10 ft. in the gauge height at Yuma there was a lowering of the bed of about 30 ft. This was where the river was flowing in a straight and unimpeded channel. It is not possible to say how deep it would scour in a sharp bend. It would be deep enough, however, to undermine and destroy the levee, regardless of any rip-rapping which might be on its face, or any rock which might be hastily dumped into the river. It is the writer's belief that this is a serious menace to the Imperial Valley. The fact that the river channel is now practically straight for about 4 miles is almost proof positive—bearing in mind the idiosyncrasies of an alluvial stream—that it will not remain in that condition very long. Whichever way the bend may start, the current will soon be attacking both sides, as it will rebound from one bank to the other.

R. H. Forbes, Esq.* (by letter).—To those who know the Colorado River, and who in a measure realize its eccentric and unmanageable character, Mr. Cory's account of control work in the Delta is rendered doubly interesting by that which the reader may find between the lines. For, in proportion as the work was difficult, original in methods adopted, and spectacular in its accomplishment, Mr. Cory's account is unassuming, matter of fact, and quietly scientific. Of the errors made by various agencies that in some way touched the reclamation of the Delta, he is most uncritical. Mr. Forbes.

An observer of events along the Colorado from 1905 to 1912 could not but be impressed by the efficiency of the Southern Pacific Railroad organization, with its ready and varied resources, its personnel, and its *esprit de corps*, in dealing with the situation. Not the least factors in a successful outcome were the democratic and friendly relations that existed between Mr. Epes Randolph, Mr. Cory, and others of the management, and the motley crew of Americans, Mexicans, and Indians whose confidence and loyal support they commanded to a remarkable degree.

Of the colossal and urgent nature of the task, the adverse weather

* Director, Agricultural Experiment Station, Univ. of Arizona, Tucson, Ariz.

Mr. Forbes.

conditions, the experimental character of the work, the conflicting advice received from influential sources, the diplomatic complications with Mexico, and the financial entanglements incident to the undertaking, Mr. Cory's own account is sufficient evidence.

In Dr. William P. Blake's account of the region, written shortly before his death, he relates the discovery in 1853 of San Gorgoño Pass, through which the Southern Pacific Railroad was built about twenty-five years later, and describes the descent of his party into the old lake bed, below the level of the sea.

He also outlines the topography and geology of the region, describing the lacustrine deposits, the fossils, the salt beds, the mud volcanoes, and to some extent the vegetation of the basin. He points out the manner in which the sediments of the Colorado, the tides, and rising land levels finally cut off a portion of the ancient Gulf of California, and describes the old lake Cahuilla thus formed, with its beach lines and its fluctuations in level as the river flowed to one or the other side of its delta. He even relates the Indian traditions of the former existence of this lake.

Most interesting, however, are Dr. Blake's quotations from his reports to the War Department in 1855, in which he points out the fertility of the soil, and the possibility of irrigating the region by a canal from the Colorado. He even states the danger of overflow through such a canal and the refilling of the ancient lake. The following words, quoted from the old report, have prophetic value:

"From the preceding facts [relating to soils and vegetation] it becomes evident that the alluvial soil of the Desert is capable of sustaining a vigorous vegetation." * * * "If a supply of water could be obtained for irrigation, it is probable that the greater part of the Desert could be made to yield crops of almost any kind. During the seasons of high water, or the overflows of the Colorado, there would be little difficulty in irrigating large areas in the vicinity of New River and the lagoons. By deepening the channel of New River, or cutting a canal so low that the water of the Colorado would enter at all seasons of the year, a constant supply could be furnished to the interior portions of the Desert. It is, indeed, a serious question whether a canal would not cause the overflow of a vast surface and refill, to a certain extent, the dry valley of the Ancient Lake."

Nothing is wanting here but a suggestion for the control of the river, as detailed in Mr. Cory's paper.

It is remarkable that a man in his early twenties, inexperienced in irrigation, and traveling for the first time through desert country, should have estimated so accurately the possibilities and liabilities of Salton Basin, fifty years before the development of the region. It seems that, until recently, Professor Blake's was not only the first, but the clearest, general conception of conditions in the Delta. Others

have promoted the irrigation of the Basin, and some have realized the possibility of a break-away; but, until 1905, additions to knowledge of the region were mostly supplementary to Professor Blake's descriptions. Mr. Forbes.

If one may look for useful suggestions in this connection, attention may be called to the necessity for a co-ordinated study, by the proper agencies, of our great physical problems, such as the utilization of a great river, and the proper control at all times of operations affecting the final solution of such a problem. The "pork-barrel" method of handling river improvements from the governmental side, is admittedly desultory and wasteful; and it is to be feared that scientific agencies engaged in the study of these same problems, as a rule, are not well co-ordinated. It may be that the Colorado has drawn attention to these facts, with corresponding advantages to come. The Newlands River Regulation Bill, now before Congress, will make possible a comprehensive study and development of the Colorado River as a whole, for storage, power, and irrigation; and the Carnegie Institution, on the purely scientific side, is soon to publish a collection of scientific papers relating to the Delta region, among which will appear Professor Blake's complete paper.

R. S. Buck, M. Am. Soc. C. E. (by letter).—The writer has read Mr. Cory's paper, as well as several of the discussions thereon, with great interest, but is forced to a view radically different from that of Mr. Sellew regarding the propriety or advisability of incorporating in such an engineering paper so much collateral matter of legal, financial, and (he might have added) political character. Mr. Buck.

Mr. Sellew says:

"The record of the operations incident to the return of the river to its former channel is extremely complete, although partly obscured by a mass of legal and financial entanglements which properly have no place in a purely engineering article."

Though it may have necessarily taken a longer time in the relating than the casual reader, in quest of purely technical knowledge, may have desired, one of the principal features of interest and value to the writer in Mr. Cory's paper is the graphic portrayal of the desperate odds which engineering talent and effort are often forced to meet, as a result of long-range financial management, clogging legal complications, and the blind, selfish play of the political game.

Engineering work is now controlled by forces far beyond the laws of physics, and, if he would occupy a position to which his technical talents properly entitle him, the engineer must learn something of these forces.

Mr. Buck.

In the writer's opinion, Mr. Cory is to be commended rather than criticized for devoting so much attention to the conditions in question, for he has certainly thrown light on some dark places, and has shown how vital it is for engineers to consider, in their planning, the laws and habits of men and money, as well as the laws of Nature.

The Lower Colorado is not merely a problem of yesterday, presenting a vague general moral. It is a vital problem of to-day and to-morrow and of years to come. It will probably take a place alongside the Lower Mississippi River as another engineering problem, dragging out a long, weary, and costly existence as a result of Government incompetence and political selfishness.

Of course, Mr. Cory's paper can affect but little the thus far meager results of mighty efforts to control the Colorado, but it should have a marked effect on future efforts, if a reasonable amount of intelligence is to direct these efforts.

If Mr. Sellew's apparent views were shared by the Publication Committee, we would have no papers such as those on water laws and valuation of public utilities. The importance of these and similar collateral subjects, the writer feels, is growing to be more and more appreciated from the engineering point of view.

Mr. Robson.

F. T. Robson, Assoc. M. Am. Soc. C. E. (by letter).—Under the heading, "Salton Sea", the author makes two statements which are quite noteworthy, and not to have been expected. The first is that the land uncovered as the sea recedes is being cultivated with entire success, and presumably with no preliminary treatment to remove soil alkalinity. This is the more significant because, before the formation of the sea, this land had an alkalinity so great that it was condemned by the soil surveys of the United States Department of Agriculture, mentioned elsewhere by the author. The soil alkalinity of this part of the desert is in general greater than throughout the portion first cultivated and for which the Imperial Area Soil Survey was made. Since then it has been covered for from 1 to 6 years by water which, according to Tables 20 and 21, was in 1907 more than one-tenth as high in soluble solids as ocean water (and generally similar in the proportion of the various elements), and is undoubtedly growing constantly stronger because of the submerged salt beds. Nevertheless, independent inquiry confirms the statement as to the successful cultivation of the land which is being exposed.

The other interesting and surprising statement is that the gross evaporation from the sea is only 6 ft. per annum. The writer has also taken the trouble to check this figure—and has found that it should be only 67 in.—and in doing so he has collected some information bearing on this point which it is thought will be of interest.

Mr. Robson.

The opportunity offered at the Salton Sea for careful determination of gross evaporation from large areas of water surface, and the relation of this evaporation to that from small pans and evaporators, was recognized by the officials of the United States Weather Bureau, and from October, 1907, to the end of 1910, a large amount of work was done there.

Special studies of evaporation loss from the surfaces of lakes and reservoirs were begun by the Weather Bureau, under the direction of Professors Bigelow and Marvin, at Reno, Nev., about August 1st,

FIG. 83.

1907, the main headquarters being transferred to the Salton Basin near Salton in the following October. Observations were also made simultaneously at the near-by points, Indio, Mecca, Mammoth, and Brawley, and at the following distant points: Phœnix, Ariz.; Eagle and Carlsbad, N. Mex., these being at low elevations in these States; Mitchell, Nebr.; Howell, Wyo.; Rupert and Boise, Idaho; Hermiston and Klamath Falls, Ore.; North Yakima, Wash.; Fallon, Nev.; Lake Tahoe, Cal.; on the Rocky Mountain Plateau up to an elevation of

Mr. Robson.

6 000 ft.; Birmingham, Ala.; Cincinnati, Ohio; Tupper Lake, N. Y.; and Lockport, Ill., in the districts east of the Mississippi River. Most of the western points selected were stations of the U. S. Reclamation Service, and at most of them evaporation observations were taken at 2, 6, and 10 A. M. and at 2, 6, and 10 P. M., though in a few cases observations were taken only at 6 A. M. and 2 P. M., which were found to be about the time of minimum and maximum evaporation, respectively, and from which, it has been shown, very accurate results can be obtained by taking the mean values.

The final bulletin on the data collected and the conclusions derived therefrom, though promised to be issued in 1911, has not yet appeared. It is hoped that it will not be much longer delayed. However, Professor Bigelow has given a summary of results and deductions in a preliminary report.* This preliminary statement does not contain the observed data, which, however, are abstracted by Professor Bigelow in the "Abstract of Data, No. 4", issued by the Weather Bureau, being "A Provisional Statement Regarding the Total Evaporation by Months at 23 Stations in the United States, 1909-10".

The preliminary experiments at Reno indicated that a large body of water loses only about seven-tenths as much as a small pan set in a dry place outside its vapor sheet. The further experiments indicated the loss to be near 65%, in the opinion of Professor Bigelow; and the results at the Salton Sea, properly corrected, in the writer's opinion, indicate the proper coefficient to be still lower, namely 60 per cent. This relation, from the practical point of view, is the most important fact brought out in the work at these various stations, particularly in that at Salton. At this point four towers were built: No. 1 about 1 500 ft. from the water's edge, No. 2 near the Southern Pacific trestle over Salton Creek about 500 ft. from the shore, No. 3 ¾ mile west, in 40 ft. of water, and No. 4, which is 120 ft. high, 1½ miles west, in 55 ft. of water (depths in 1909). These towers, though made as stiff as possible, were found to have a slight vibratory motion, even in quiet weather, and hence the water in the evaporation pans required to be damped in oscillation by submerged partitions.

The important results, as given by Professor Bigelow in the preliminary report referred to, are:

1.—That the wind velocity was so different at various heights, 0, 10, 20, 30, and 40 ft. above the ground—amounting often to 30% less at the ground than 10 ft. above—that every evaporation pan must be supplied with its own anemometer wherever evaporation observations are made, whether on land or on large bodies of water.

2.—That pans of different sizes evaporate at different rates, and

* *Monthly Weather Review*, February and July, 1910, pp. 307 and 1133, "Studies on the Phenomena of the Evaporation of Water over Lakes and Reservoirs."

these rates were found to vary approximately as the expression, 0.023 $(1.23)^n$, where n has the following values: Mr. Robson.

$n = 0$ for large open-water surfaces,
$n = 1$ for 6-ft. pans,
$n = 2$ for 4-ft. pans,
$n = 3$ for 2-ft. pans,
$n = 4$ for ordinary dry air.

This variation seems to be due to the banking up of the vapor on the leeward side under the action of the wind, and because the small pan clears much more completely of vapor, and evaporation takes place into a mixture of air of different contents according to the size of the pans and the force of the wind.

3.—The formula finally suggested by Professor Bigelow is (c. g. s. units):

$$E_d = C_2 \frac{e_s}{e_d} \frac{de}{ds} (1 + 0.070\ W),$$

where E_d = Evaporation in 24 hours (one day), in centimeters;
C_2 = Coefficient, found to be 0.138 $(1.23)^n$;
e_s = Saturation vapor pressure at temperature of the water surface, designated by s;
e_d = Saturation vapor pressure at temperature of the dew point in the air near the water;
e = General symbol representing vapor pressure;
E = General symbol representing depth of evaporation;
$\frac{e_s}{e_d}$ = Expression for the gradient (use Crelle's tables);
$\frac{de}{ds}$ = Expression representing the change of vapor pressure with temperature, s, taken. This quantity is merely the tabular difference in ordinary vapor pressure tables at the temperature under consideration (use Manual Table V).
W = Wind velocity, in kilometers per hour.

It is proposed to substitute this formula for that now in general use, which was proposed by Dalton in 1803 and may be written as follows (same notation):

$$\frac{dE}{dt} = C (e_s - e_d) (1 + aw),$$

where t = time, and C and a supposed by constant terms.

or $E_d = 0.036\ (1.23)^n\ (es - ed)\ (1 + 0.070\ W)$ using the values of the constants deduced from these experiments at Salton.

Mr. Robson.

4.—That water in pans of the same size evaporates at the same rates at 4 000 ft. elevation as at sea level, and hence the formula does not contain any barometer pressure term.

5.—The recommended formula has no annual period in the C_2 coefficient; the diurnal period is very small.

6.—A pan of very fresh water was allowed to evaporate alongside a pan filled with brackish Salton Sea water, which was gradually concentrated by adding water from the sea from November to May without emptying the old water. The brackish water evaporated a little slower than the fresh water, to the amount of 2% in April and May.

7.—The actual fall of the Salton Sea level from June 1st, 1909, to June 1st, 1910, was 51 in., and Professor Bigelow estimated that the rise was 12 in. due to inflow from the Alamo and New Rivers, and there were 6 in. of accretions from annual precipitation, making a total gross evaporation of 69.0 in. This total checked with results computed by formula from observed data necessary.

8.—Practically, it was the conclusion that engineers would necessarily have to adopt a standard pan and reduce the observed readings to the open-water surface, as explained above. Thus, the evaporation from a 4-ft. standard pan, when corrected for temperature and wind, and multiplied by 0.66, is very close to what observation suggests. If a water thermometer on a small raft in the lake measures s_0, and e_s and e_d are determined by using a sling psychrometer, through t and t_s, and the wind velocity by an anemometer as near the water surface as possible is W, then $C = 0.138$ for a 24-hour interval. In the formula, the mean values taken at readings made about 6 A. M. and 2 P. M. should be used.

The writer has checked the estimates of Professor Bigelow as to the inflow from the Alamo and New Rivers, and the increase due to the rainfall and run-off from the water-shed, from all the available data (of which considerably more exist now than when Professor Bigelow did his work). It is known that there are no springs or underground sources of supply discharging into the basin, because, until very recent years, the sea contained no water, and salt beds in the bottom were regularly mined. The rainfall is very light, consequently the run-off is small. From the time when the Colorado River was finally rediverted (the middle of February, 1907) to date is 6 years, and it seemed to the writer that the results should be checked to obtain an average for this entire period, rather than for the year from June 1st, 1909, to June 1st, 1910, which was taken by Professor Bigelow.

In determining the inflow, it is possible to utilize the sea itself as a large measuring tank in which to measure the combined rainfall on the water surface and the run-off from the drainage area due to rainfall—proper correction being made for the regular inflow from the

Alamo and New Rivers—by using the daily gauge heights or elevations of the water surface. Mr. Robson.

As a first step in obtaining the average evaporation for the entire 6-year period, the difference in elevation of the water surface on April 1st, 1907, and April 1st, 1913, was found to be 26.10 ft.

If, then, (1) the total precipitation on the sea itself, plus (2) the total run-off into the sea, plus (3) the total discharge of the Alamo and New Rivers into the sea for the same period, be added to this 26.10 ft., the result will be the total loss due to evaporation—percolation being considered as of no consequence.

a.—The writer prepared a table of the rainfall for each month of each year, as observed at Brawley, Calexico, Heber, Imperial, Mammoth, Mecca, and Salton, all these points being within the drainage area and fairly well distributed. It was then assumed that the total rainfall at all these stations, divided by the number of stations, would give a fair average of the precipitation on the sea itself. The total thus found for the 6-year period was 16.59 in. or 1.38 ft.

b.—A table was then made showing the decrease in elevation of the water surface for each month of the period, and the decrease for each month was compared with that for the corresponding month of the other years. It was found that the decrease in one month compared very closely with that for a corresponding month in another year, except in cases of unusual rains or other known causes. Eliminating these months, a total was then made of those remaining, and the result was divided by the number of months comprising the sum. The average thus found was assumed to be the normal average decrease for that month. Sufficient amounts, corrected for excessive rainfalls on the sea itself, were added to bring the eliminated months up to the average, and these additions were considered as the run-off or inflow due to precipitation. This total was 15.00 in., or 1.25 ft., for the 6-year period. The results obtained by this method were checked by examination of the daily precipitation records for these various Weather Bureau Stations. In such desert country, where the rainfall is scant, that which does occur is frequently in intense storms or in local cloudbursts. Monthly records, therefore, are of little value as indicating the probable run-off, and each storm at each observation station must be considered, instead of the monthly totals. Only two or three heavy precipitations extending over the entire water-shed occurred during the 6 years, the heavy rainfalls usually being rather local in character and in the nature of cloudbursts. The total number of such heavy precipitations throughout the period at all these stations, however, was surprisingly small, and the daily gauge heights of the sea surface for several days was carefully examined in connection with each of these heavy rains. In this way a very good check was obtained on the foregoing method of deter-

Mr. Robson.

mining the total inflow into the basin from its water-shed—exclusive of the New and Alamo Rivers.

c.—The discharge of the Alamo and New Rivers has been observed, and a rating curve has been applied only for a period from June, 1909, to October, 1910. Based on the records published in Water Supply Paper No. 300, and from information kindly given to the writer by Mr. Cory from his personal records, the following rises in the elevation of the lake surface have been determined, and are believed to be very close to the truth.

To January 1st, 1908		0.62 ft.
From January 1st, 1908, to January 1st,	1909	0.65 "
" " " 1909 " " "	1910	0.68 "
" " " 1910 " " "	1911	0.71 "
" " " 1911 " " "	1912	0.75 "
" " " 1912 " " "	1913	0.78 "
Total		4.19 ft.

To sum up, then, the evaporation has been as follows:

Loss in elevation of lake, as shown by gauge heights	26.10 ft.
(1) Total rainfall on lake surface	1.38 "
(2) Total run-off from rainfall	1.25 "
(3) Total discharge from Alamo and New Rivers	4.19 "
Total evaporation, April 1st, 1907, to April 1st, 1913	32.92 ft.
or a yearly average of	5.58 ft.
or	67.02 in.

as compared with 69.0 in., the total gross evaporation found and estimated by Professor Bigelow for the 1-year period, June 1st, 1909, to June 1st, 1910.

Table 31, containing observed data at Salton Sea, is taken from "Abstract of Data, No. 4," by Professor Bigelow, referred to previously. The figures for Nos. 1, 2, 3, and 4, for March, April, May, and June, were interpolated from curves plotted from records of previous years, and found by experience to give close results.

At the stations outside of the vapor sheet, at which observations were taken, for a 6-ft. pan on the ground, the total evaporation observed was:

Indio	119.33 in.
Mecca	107.81 "
Brawley	103.55 "
Mammoth	125.53 "
Total	456.22 in.
Average	114.055 "

Mr. Robson.

Mr. Robson. The total evaporation, as determined by the writer, was 67.02 in. Hence the coefficient to be used in converting the observations from a 6-ft. pan on the ground outside the vapor sheet, and in a desert country, to the total loss from a large water surface, seems to be $\frac{67.02}{114.055}$, or 0.59, or, say, 0.6.

Mr. Chaffey. ANDREW M. CHAFFEY, ESQ. (by letter).—Careful reading of Mr. Cory's paper leaves the agreeable impression that he has sought to be fair and unprejudiced in handling a very complicated subject. Two other publications dealing with the Imperial Valley project have appeared, one mentioned by the author*, and another† consisting of short monographs by settlers, promoters, etc., gotten out by E. F. Howe, editor of the *Imperial Valley Press*. Both are rambling sketches, rather than histories, unsystematic, full of inaccuracies, and partisan and misleading statements, and hence untrustworthy and unsatisfactory. Mr. Cory's paper, therefore, is to be regarded as the first serious history of Imperial Valley, and will unquestionably be heavily drawn on by future writers. It is most fortunate, therefore, that it is being fully discussed, its inaccuracies pointed out, its engineering and historical matter supplemented by those qualified to do so, and, more particularly even, that several of the facts brought out by the author may be gathered together so that the reader interested in details may not fail to catch their true significance.

The writer was associated with his father, Mr. George Chaffey, in the management of the project from April, 1900, to February, 1902, and, for more than twelve years, has been collecting original documents and data relating to Imperial Valley. To these, doubtless much the most complete in existence, the author, unfortunately, did not have access, due to the fact that, curiously enough, he and the writer did not become acquainted until after the appearance of this paper.

On page 1251 the author states that the first practical step toward the irrigation of the Colorado Desert was the incorporation of the California Development Company in 1896. The writer feels that this is exceedingly misleading. Incorporating a company with large capital stock, appropriating vast quantities of water, by posting notices and recording the same, all at most nominal cost, acquiring options for small cash payments, getting out reports setting forth the merits of a project, and hawking the scheme about in financial centers, cannot rightly be considered as "practical steps" toward carrying out any enterprise. It is just this sort of "shoe string" promotion which Mr. Mead doubtless had in mind when writing his discussion on this paper (page 1509) and pointing out the folly of letting irresponsible

* "Born of the Desert," by C. R. Rockwood, 1909–10.

† "The First Decade," Imperial, 1910–11.

companies go ahead without any public supervision whatsoever. On the contrary, the first "practical step" was taken when Mr. George Chaffey signed the contract (April 3d, 1900) to build canals into Imperial Valley. Many readers of the paper will undoubtedly get the impression from it that the California Development Company was at such time a going concern, and that its promoters had already produced tangible results. As a matter of fact, though it had been in existence nearly four years, it had as assets the two options on land—one in Mexico and one in California—mentioned by the author, as to each of which the Company was in default, and an idea, a project of large and attractive proportions on which not one shovelful of earth had been turned, and toward the consummation of which not one single practical step had been taken. Its obligations, aside from its capital stock, were various debts, aggregating a considerable sum, and $350 000 worth of what was called land scrip—issued prior to 1900 at 10 cents on the dollar and dissipated in promotion expenses—which was retired at face value in cash or in exchange for water stock of the various Mutual Water Companies at market price at the most inopportune time, namely, just before the water distributing system was completed in the valley. Mr. Chaffey.

The contract recited that the California Development Company owned, through a subsidiary Mexican Company, 100 000 acres of land in Mexico through which the canal must run. But for this representation (which turned out to be untrue) the contract would assuredly not have been made. The idea in reality was free to Mr. Chaffey, or to any one else for that matter. Indeed, Mr. Chaffey, at the request of Dr. Wozencraft, had considered the proposition in the early Eighties, before the later promoters had even heard of it.

To say, therefore, that at this date (April, 1900) there was a "practical change of management," that the engineering policy changed, or that "original plans were not carried out," is to create an absolutely erroneous impression. To quote Mr. Chaffey himself:

"I saw a way to accomplish the object with the means at my command by disregarding the Rockwood Survey altogether, adopting another line by which the bank of the canal would be made to serve as a levee to prevent the flood waters of the Colorado from finding their way into the Alamo, and utilizing many miles of that natural channel for the main canal."

This contract of April 3d, 1900, provided that Mr. Chaffey was to construct such canals as were necessary for the purpose of taking water from the Colorado River just above the Mexican boundary line to where the central main canal intersects the same boundary line in Imperial Valley, "said canals to have a capacity sufficient to deliver four hundred thousand acre-feet of water per annum at said last-named point"; that no more money should be expended "than is neces-

Mr. Chaffey.

sary in such construction"; that the construction cost of such canals should not exceed $150 000; that such construction was to be "at actual cost to first party"; that Mr. Chaffey was to receive $12 000 per annum salary for five years, payable when the Company was able to pay it, and one-quarter of the Company's capital stock; and that he should have charge of the Company's finances as well as its engineering works during that period.

It is felt that the foregoing abstract of this contract will suffice to indicate clearly its fairness, to say the least, to the Company.

From this date until the contract was terminated—April 3d, 1900, to February, 1902—Mr. George Chaffey and associates furnished the necessary money, and, dividing the engineering responsibility with no other person, designed and built the diversion works and located and constructed the main canal—including the Central Main west of Sharps Heading and in the United States—as it exists to-day. During this period he was assisted in the business management, in planning the system of Mutual Water Companies—which system, by the way, the author to the contrary notwithstanding, the California Supreme Court, in the case of Thayer *vs.* California Development Company, has recently not only held to be legal, but has highly commended—and in making the tri-party contracts, by the writer and by Messrs. L. M. Holt (who with Mr. Chaffey evolved in 1881 the first Mutual Water Company ever incorporated, at Etiwanda, Cal.), N. W. Stowell (who was the first to introduce concrete water conduits to irrigation construction in California in 1878, and who had large experience with irrigation works), and J. W. Swanwick, who was largely responsible for the tri-party contracts.

A great deal has been stated in the public press and in governmental reports—and Mr. Mead in his discussion (p. 1509) might easily be understood by the careless reader as coinciding therewith—condemning the California Development Company as an irresponsible corporation at all times prior to the Southern Pacific Company's taking over the management in June, 1905. This was far from being true during the period when Mr. Chaffey was directing its affairs—April, 1900, to February, 1902. The men just mentioned were those he associated with him; all except the writer were unusually experienced in the different phases of irrigation work and development, and financially able to build the canal. Mr. Chaffey himself was a man of wide experience gained in the practice of his profession of Civil and Mechanical Engineer. Best known as the founder of Ontario, Cal. (1883), he had founded Etiwanda, Cal. (1881), and had developed the irrigation systems in both places to such a state that the visit of a Royal Commission from Australia in 1885, resulted in his proceeding with his brother to that country and establishing the irrigation dis-

tricts of Mildura and Renmark, both at this time populous and prosperous communities, conceded by all public men to be "the great object lesson in irrigation for the rest of Australia." In 1882 Mr. Chaffey produced the first electric current (generated by water-power) in Southern California, and in 1884 lighted the City of Los Angeles with electricity. A large number of the first settlers in the Imperial Valley were actually from Etiwanda and Ontario; all were experienced irrigationists, and it is safe to say that 90% of them made their purchases because they personally knew of Mr. Chaffey's previous successes. Mr. Chaffey.

The writer, of course, agrees with Mr. Mead that the State or Nation should protect settlers on and investors in irrigation projects, examine and approve engineering plans, etc., etc., and especially he agrees with his comments regarding water right laws, the unfortunate condition of which is responsible for most of the financial disasters which have overtaken irrigation enterprises in the West, and of which the California Development Company is, perhaps, the most notable example. At the same time, it must be admitted that the greatest and most rapid irrigation development the world has known is that responsible for what is known as Southern California, and the Government—State and National—in no wise helped and not seldom added severe handicaps. It is sometimes said that Southern California has been built on "shoe strings"—certainly, many of its most successful enterprises have been started with inadequate capital, on confidence in the proponent's resourcefulness. Under such conditions, people are "live wires" to a degree beyond the comprehension of officials and employees of powerful corporations and of the State and National Governments. Much of the resentment toward, and often unfair criticism of, the U. S. Reclamation Service, by owners and officials of, and settlers under, private irrigation undertakings had its beginnings in the attitude of those who never need to consider for an instant financial arrangements, discounting securities, etc., toward "flimsy" work and the twists and turns of men driven to their wits' end when doing things with insufficient capital. It is well enough to say "Don't try them if you cannot get enough money to insure success." Such a policy would undoubtedly prevent not a few failures; but, on the other hand, by it the Southern California of to-day would not have been for decades to come.

The Imperial Valley is possibly the most striking example of this. In the first place, if the soil had been first examined by Government experts instead of by practical farmers, the project would have been condemned *in toto* and the region still original desert. Next, work was begun with small capital in hand, and in 10 months' time, and at the cost of less than $100 000, Mr. Chaffey put water into the burning desert 60 miles away from the Colorado River, and along lines, engineering, legal, and financial, which experience shows would have meant large success to all (had the Government only kept its hands

Mr. Chaffey.

off), and by doing so realized the visions of the dreamers and the hopes of the promoters who for half a century had dreamed and promoted, and accomplished nothing. In less than 2 years, the Imperial Main Canal, essentially as it is to-day—except the $75 000 head-gate at Andrade—and more than 400 miles of distributing ditches, were completed and the water was ready to turn on to 100 000 acres of land, at a cost to the settlers averaging less than $10 an acre; and the capital at hand was less than the promoters had expended in the hitherto vain effort to get started.

In contrast is the Government Yuma Project, with unlimited capital: $3 000 000 initial appropriation and more than $3 000 000 later; time, 8 years; acreage, 100 000; cost, $70 per acre; bitter disappointment and heavy loss to settlers relying on Government estimates as to money, and, more particularly, time required to complete the work. As a part of the Yuma Project, Imperial Valley would now be in exactly the state it actually was in 1902—eleven years ago—as far as development is concerned. In the meantime, in 1905, it was sending out $5 000 000 worth of products, and at present more than $10 000 000 worth. The gain in time has more than paid all the real damage *per se* done by the runaway river.

As the author has pointed out, this misfortune would never have occurred had it not been for numerous unnecessary and inexcusable obstacles. For some of these there is possibly some excuse, or at least explanation, but the soil survey and report was the most disastrous and inexcusable of all. The space devoted to it by the author in his paper is out of all proportion small compared to its significance, and the facts about it should be elaborated somewhat.

As stated by the author, a few samples of soil from this region were analyzed in 1893 by the Director of the California Experiment Station, University of California, Professor Hilgard, and again in 1896-97, and also in 1900, when the Imperial Land Company began active work. In the summer of 1901, the Bureau of Soils, U. S. Department of Agriculture, requested the co-operation of the promotion companies in making a study of and report on the soils of the Imperial Valley. This was gladly given, and, on October 17th, Mr. J. Garnett Holmes, of the Bureau staff, arrived and began work. Later, his immediate superior, Thomas H. Means, M. Am. Soc. C. E., and others of the Bureau, joined him, and on December 20th (in 63 days) the field work was completed. It took only 3 weeks (January 10th, 1902) to issue a preliminary report, "Circular No. 9," covering the 169 sq. miles of territory which had been examined. Before this circular reached California, an Associated Press dispatch from Washington advised that:

"The condition of soils in the Colorado Desert in San Diego County, as disclosed by a survey just completed by the Agricultural

Mr. Chaffey.

Department in the vicinity of the new irrigation plant at Imperial, is reported to be 'much more serious than was anticipated.' This is the expression used by Milton Whitney, Chief of the Bureau of Soils, in a preliminary bulletin which he has deemed best to issue by way of warning." * * * *

This refers to the report which the author says was "unfavorable, * * * and calculated to deter sensible people from settling in the region." This is a more than conservative way to put this matter, as is shown by the single extract—by no means the strongest of many—which the author quotes on page 1271.

In 1903 the U. S. Department of Agriculture, Bureau of Soils, issued the "Soil Survey of the Imperial Area, California (Extending the Survey of 1901), Advance Sheets of Field Operations of the Bureau of Soils, 1903." This document, under the head of "Present and Prospective Development," on page 31, makes the statement:

"The sole dependence of the people of the Imperial Area must always be agriculture. * * * The source of wealth, therefore, is limited to the soil, and to a greater extent than in almost any other part of the country. Thus the problem confronting at least a part of the farmers in most arid regions is here—where alkali is so generally distributed in the soils and the conditions so unfavorable to reclamation—about as serious as it could well be.

* * * * * * *

"The people of the Imperial country should recognize the fact that aside from the general problem of securing water for irrigation they have to solve perhaps the most serious agricultural problem of the arid West. Here is found a most refractory soil, much of it impregnated with alkali. The only way to benefit the land is to carry away the salts. The application of gypsum cannot be of the slightest benefit. Little or no benefit will be derived from running water across the land with the expectation of flushing the alkali off the surface. * * * The water must pass through the soil and find ready egress through natural or artificial drainage ways.

"The quantity of salt taken out of the soil by alkali-resistant crops, such as sorghum and sugar beets, is not appreciable, the benefit to the soil in such cases resulting mainly from the prevention of evaporation at the surface through cultivation and from the leaching of the salts into the subsoil by irrigation water. If the subsoil be practically free from salt, as is often the case in arid regions, this vertical distribution of the salts alone is often all that is necessary so to reclaim the soil that sensitive crops can be grown. But it has been shown that in the Colorado desert the subsoil is the greatest source of danger, so that every bit of salt removed should be permanently removed. * * * By far the greater extent of the soil of the valley is a sticky, plastic loam or clay, through which water passes very slowly. The natural drainage in the soil itself is very poor, and to be anything like adequate it must be supplemented by artificial drains to carry off the ground

Mr. Chaffey.

water as the salts are washed down from the surface. * * * Tile drains are the best and in the end the most economical for draining the land. They are, however, expensive, and the question is, will it pay?

* * * * * * *

"That it will eventually pay to drain these lands there can be little doubt, but in the present state of the country concerted action will be difficult and individual effort futile."

In February, 1902, the University of California, College of Agriculture Experiment Station, issued Bulletin No. 140, entitled "Lands of the Colorado Delta in the Salton Basin." This bulletin gave essentially the same results of soil analyses, but was much more careful in its comments, and on pages 50 and 51 gave crop reports from actual settlers which were excellent. It also stated, after giving a list of native plants from the Salton Basin, on page 44, as follows:

"The list of plants here given is notable for the absence of most of the species considered elsewhere as prominent alkali indicators. We miss at once the salt—or alkali—grass (*Distichlis*); the 'Greasewood' of Nevada (*Sarcobatus*) and that of the San Joaquin Valley (*Allenrolfea*); the samphire (*Saliscornea*); and the tussock-grass (*Sporobolus airoids*) * * *. But as a whole the collection made does not speak of 'irreclaimable' alkali land so far as we know their habits. * * * Taken as a whole, the native vegetation does not altogether confirm the unfavorable impression derived from the leaching of the soil samples."

In addition to these soil reports, in January, 1902, several interviews, written up in a sensational manner, appeared in the daily papers in California, practically condemning the Valley and virtually warning investors and settlers from the field. These were the most disastrous of all in their effect on the enterprise.

Experience has proved that these reports were fundamentally wrong in their conclusions, as less than one-half of 1% of the lands brought under cultivation has failed to produce most satisfactory, indeed, phenomenal crops. Nevertheless, the Government's publications were such that the author's statement: "It seems certain that, had the territory not been already settled in very large measure when these reports were sent out, Imperial Valley would yet be unreclaimed" (page 1271), is undoubtedly absolutely true.

The author is in error on page 1264 in referring to the elevation of the bottom of the Chaffey head-gate. This structure was started in March, 1901, and work was rushed as rapidly as possible. When completed, its floor was 3 ft. below the river bottom, and, to make the gate more secure, three 2 by 12-in. sand-boards were put on the toe of the A-frame, to be removed when the sand and silt became settled

around the structure; there was no necessity for removing them while Mr. Chaffey was directing affairs, and, later everybody apparently forgot about them and they were never taken out, the idea thus obtaining that the floor of the gate was at the top of the sand-boards when in reality it was much lower, and as low as it was possible to place it that season. Working at high pressure against a rapidly rising river, the head-gate was finished, and Mr. Chaffey himself turned the water through it on May 14th, 1901. Mr. Chaffey.

Before leaving this subject, and in view of the controversy that has raged regarding the necessity of the fatal cut in Mexico (made more than 2 years after Mr. Chaffey had severed his connection with the Company), it is interesting to note, from Government records, that the old Imperial Canal, from the old intake, carried throughout the Summer of 1904 and until October, 1904, when the Mexican Intake was cut, more water than ever before, and quite enough to supply the users in Imperial Valley.*

The author's statement (p. 1255) that the initial price charged for water stock was $5.75 is misleading. Those who purchased during the construction period were given bonds of the California Development Company equal in amounts to their initial payments, bearing 5% interest and acceptable at their face value for the last installments on their notes. Hence, those paying $3.00 cash on their water stock purchases got water rights at $5.75 per acre. Only $80 000, par value, of the bonds were thus given out to water stock purchasers on total sales of 50 000 shares in Imperial Water Companies Nos. 1 and 4, the settlers coming in having so little cash and speculators so little faith that they could not or would not take full advantage of the opportunity offered.

The author is again in error as to the reasons for the termination of the five-year construction contract between Mr. Chaffey and the California Development Company. It was not because the former was frightened out by the soil reports, but because it was found that the power of attorney to vote, for five years, stock, which, with his own, constituted a majority and control, was found ineffective on account of the certificates not having been actually turned over. Success had been achieved and these shares of stock began coming in for transfer. It became a matter of buy or sell, and the original promoter's idea of value was deemed to be too inflated, so Mr. Chaffey made the best terms possible for his holdings and withdrew in February, 1902.

The author's outline of the Delta Investment Company and its activities is also misleading, and in some respects entirely erroneous.

* See "Progress Report of Stream Measurements for the Calendar Year 1904," by the late W. B. Clapp, M. Am. Soc. C. E., Water Supply and Irrigation Paper No. 134, p. 27, and compare with measurements in previous years.

Mr. Chaffey.

The facts are that in the fall of 1901 it became apparent that the sales of water stock would not produce sufficient money for the work that must be done, and Mr. Heber organized the Delta Investment Company in the hope that by giving it a favorable contract to purchase the bonds and mortgage notes of the California Development Company, outside capital could be attracted to the new company. The Delta Investment Company was launched with the consent and approval of those owning or representing all the stock of the California Development Company. By the terms of this contract, the Delta Investment Company agreed to purchase bonds and notes from the California Development Company to the amount of $21 000 in cash per month for twelve months, thus guaranteeing the California Development Company $252 000 in cash, the amount estimated as absolutely necessary to spend during the coming year in a permanent intake head-gate, canals, and other necessary works. In consideration of this guaranty the Delta Investment Company had the right for 12 months to purchase any or all of the bonds and mortgage notes of the California Development Company at 50% of their face value.

As the whole enterprise was still considered by outsiders as an experiment, and the banks of Los Angeles refused to concede any value whatever to the Company's "securities" for loaning purposes, or to purchase them outright at any figure at all, and the soil experts had commenced giving out their unfavorable opinions, the only reasonable criticism of this contract is that it was unfair to the Delta Investment Company and, consequently, unfair to those stockholders of the California Development Company who were large stockholders in the Delta Investment Company, in that it indirectly threw on them the burden of financing the California Development Company without adequate remuneration.

That the privilege of buying the bonds and mortgages at 50 cents on the dollar did not prove especially attractive is best shown by the fact that only a small fraction of the holdings of the California Development Company changed hands under it during the 4 months it was in operation. Mr. Cory, therefore, is correct in stating (p. 1260): "It must be admitted that the Delta Investment Company took over such securities at a larger price than could have been obtained from any other source," but quite incorrect in stating either that there were "many" or "large" or "apparently dishonest" transactions between the two corporations, or in giving the impression that it was a hardship on the California Development Company to part with $2 in its so-called "securities" for $1 in hard cash. As a matter of fact, the California Development Company could well have afforded to be much more liberal, and the writer knows that if any one had come into the

office at that time with $252 000 in gold coin and offered it in exchange for $1 000 000, face value, of the so-called "securities," there would not have been a voice raised against taking the money, it was so urgently needed. Mr. Chaffey.

Finally, the author is entirely mistaken in saying that March 1st of that year found the California Development Company "with all its bonds gone, its collateral notes and mortgages largely depleted, no money in the treasury, and deeply in debt." The facts are that at that date it had $47 000 of its bonds on hand, $525 000 of mortgage notes, $235 000 of accounts receivable, besides lands, canals, machinery, equipment, etc., and unsold water stock estimated (at the selling price at that time) to be worth $2 235 000, and its liabilities, including $453 000 of bonds and deferred payments to Hanlon and Andrade, were less than $500 000; in truth, from a few months after Mr. Chaffey started work, the California Development Company never was without an ample supply of mortgage notes and bonds in the treasury, but outsiders had not sufficient faith in them to buy them for cash.

In view of what was accomplished in the 22 months ending February, 1902, and the fact that some of the best men in Los Angeles would have joined him and furnished large amounts of capital, provided he had secured full control, it is doubtless safe to say that had he taken control, instead of retiring from the company, there never would have been any runaway Colorado River and the development of the Valley would have been even much more rapid than it has been.

C. E. Grunsky, M. Am. Soc. C. E. (by letter).—The problems of the Lower Colorado River have a wonderful charm. They are presented by Mr. Cory in a most comprehensive and attractive way, and he has done the Profession valuable service in putting on record and making available for convenient reference the results of an experience on river work which is unique in character and magnitude. Mr. Grunsky.

So long as there was a fighting chance, in 1906 and 1907, the engineers under Mr. Cory's guidance and upon the wise determination of Mr. Harriman were to keep up the fight. How the fight was won has been well told by Mr. Cory. The writer takes pleasure in again expressing his admiration of the able way in which the work was handled.

At the outset, every one, so far as the writer knows, believed that the work of making a closure in the fall of 1906 would be greatly facilitated by the use of brush mattresses on which to dump the rock. What the work done on the Colorado in 1906 and 1907 has clearly demonstrated is that, with adequate transportation facilities, a brush mattress on which to drop the rock is not essential. It is only necessary to place the rock more rapidly than the water can undermine and bury it.

Mr. Grunsky.

Without the spur track from the Southern Pacific main line down to the Lower Mexican Heading, the first attempt to close the break would have been a failure, and yet the writer recollects distinctly that plans were under discussion for the beginning of this work, under which reliance was to be placed on water transportation. The outcome has demonstrated clearly that, when such work is to be done, every possible contingency should be foreseen so that every emergency can be met properly. It was a wise precaution, too, to keep an equipment and a force on hand and available for repairs during the high water of 1907, even though, as it turned out, they were not needed.

At that time the levees were new, and the river brought down an unprecedented volume of water—a maximum of about 100 000 sec-ft.* Naturally, it would be expected, therefore, that the levees had at once been subjected to a severe test. This might have been the case if the conditions on the lower river had remained as in years past; but they had been undergoing a rapid change, with the result that the new levee was only wet here and there, and there was no opportunity to observe what might have happened if the water had been 3 or 4 ft. up on the levee.

The writer made a special study of the problem of the Lower Colorado River for the Secretary of the Interior in the early summer of 1907, and his observations at that time and in the two preceding years as Consulting Engineer in the U. S. Reclamation Service, together with many years of familiarity with certain features of the river, are the basis of the comments which are now prompted by Mr. Cory's paper.

As early as 1883, or thereabouts, Gen. G. W. Shanklin, at one time State Surveyor General of California, and Mr. Duncan Beaumont called the writer's attention to the New River country, as a part of the Imperial Valley was then called, and the desirability of making an instrumental survey to see what could be done toward accomplishing the irrigation of that valley was discussed. It was known at that time that the only practicable route for a canal would be across Mexican territory. The situation appeared to be too complicated, and nothing was done; but the writer, from that day to this, has never lost interest in the problem.

In 1896 the writer explored a portion of the Colorado River below the Grand Canyon and confirmed the selection of a dam site at the lower end of Iceberg Canyon, as the best available, in a long stretch of river, for a low dam to be used in creating a fall for power. He reported at that time that it would be feasible to construct a dam of loose rock on a sand foundation by blanketing the bed of the river for a considerable distance up and down stream with broken rock, using large blocks for the down-stream portions of the work, allowing

* Erroneously estimated at 115 000 sec-ft. by the U. S. Geological Survey in Water Supply Paper No. 249.

the water to bury these as deep as it would, and using finer material in the up-stream face, which would ultimately be made impervious or nearly so by the river silt. The plan of that day involved the complete turning of the Colorado over a low spur of the mountains. Mr. Cory's experience at the Lower Mexican Heading confirms the feasibility of carrying out work of this character. Mr. Grunsky.

Several years later the writer was stationed for three months on the Colorado a few miles above the mouth of the Virgin River, and had additional opportunity for observation. At that time boilers were to be set for mining operations; and brick was wanted. No clay deposit could be found. The most promising mud-bar in the river was sampled. The mud could be balled up and would crack somewhat in drying. It was submitted to a chemist at San Francisco and reported to be composed almost entirely of very fine silicious sand entirely unfit for brick-making.

Above the Virgin River the water of the Colorado, at low and high stages, carried a large quantity of this silt in suspension. This would settle quickly when the water was dipped from the river in a glass, and within a few seconds the water was clear enough to drink. There was certainly comparatively little clay in the silt carried by the river water at this point. This observation leads the writer to assume that the main Colorado must be the principal source of the fine, light sediment, other than clay, which the river carries to the delta, and accounts, too, for the preponderance of material of this character in the river delta; it also makes it appear probable that the clays, bedded as the author describes, probably have originated in other parts of the river's water-shed.

During the low stage of the river, above the Virgin, the writer had occasion to erect a mast or pole on a gravel bar for the support of a cable. The gravel was unusually firm. It consisted of all sizes from cobble-stones down to sand, and in its dry condition appeared to be almost cemented. The mast was erected and large boulders were piled around it. When the river rose the gravel around the mast became wet, softened, lost its cohesion, and acted very much like a quicksand; the mast required additional support or it would have fallen.

A heavy crankshaft lying above the water on another portion of the gravel bar commenced to sink into the gravel when this was wet by the rising water, and was with difficulty supported until it could be transferred to safer ground.

These facts are alluded to as a warning against placing too much reliance on gravel for the facing of bank or levee slopes. The gravel, in the case of the Colorado River levee, serves a most excellent purpose, and its use is not criticized, but gravel has no particular virtue as a material for resisting the attack of a current, and will have but little resisting power when used in spur dikes. It is an excellent

Mr. Grunsky.

material, however, as in the case of the levees on the Mexican side of the Colorado, for blanketing the levee, serving as a protection for the earth slope against wind erosion, and checking to a large extent the activities of burrowing animals.

The Colorado below Yuma, as explained by Mr. Cory and as noted by the writer in a paper presented to this Society in 1907, is flowing down the slope of a delta cone. While undisturbed by human agency its floods annually watered broad areas, and the rank vegetation which sprang up on these areas was an effective barrier opposed by Nature to the concentration of the river's flow along new channels, even though some of the water going over-bank should long ago, if topography alone is considered, have cut out a new course for the river. The river has been compelled by these restraining forces to hold for more than 500 years to the course as geographers first knew it from Yuma to the Gulf.* However, though the river, unaided, could not break away from this general alignment, it swung back and forth, within restricted limits, on an ever-changing serpentine course. The river along the thread of the stream has a fall of about 1 ft. per mile, and the average fall along the air line from Pilot Knob to the Gulf is about 1½ ft. per mile.

When attempts are made to confine a river of this character between levees there is trouble. Under the attack of the river, the banks will continue to break away, first at one point and then at another, and no amount of care in the location and construction of levees can insure them against destruction from this cause. To check the caving bank is difficult and expensive, even when adequate facilities are at command, as has been well set forth by Mr. Sellew. In ordinary cases, it is out of the question to eliminate entirely this source of danger to levees located comparatively near the river bank.

It is natural, then, that the levees in the case of such a river should be set far back from the banks. In this location on the Colorado the levee cuts off the river bends and, therefore, follows a line of greater slope than the river. This is actually the case below Yuma, except for the first long stretch below Pilot Knob, where the river is straight for some 8 miles and the levees on each side are parallel with the stream and comparatively near the banks. Below this straight reach, the river channel, down to the Arizona boundary, is about 30 or 40% longer than the levees on their present location (Plate LVI).

If the river rises above banks and water stands against these levees, some barrier must be interposed to its flow if erosion at the base of the levee is to be prevented.

Even when constructed as was the original levee at the Lower Mexican Heading, with borrow-pits on the land side, the work of levee

* *Transactions*, Am. Soc. C. E., Vol. LIX, p. 6.

Mr. Grunsky.

building gives more or less open space for the water on the river side along the levee, and there will be concentration of flow there which will rapidly cut channels in the light silt soil of the delta. The spur dikes, as built by Mr. Cory, offer some obstruction to this flow, and are of value under certain conditions; they have been of use during such moderate bank submersions as have occurred since the levee was built, but under a real test, with water 4 or 5 ft. on the bank, they would serve to concentrate fall and would start local cutting which might prove quite as dangerous as the general erosion due to uniform flow along the levee. It may be stated in a general way that the efficiency of such spurs for the same aggregate quantity of material in them will ordinarily increase as distance between them is decreased.

While Consulting Engineer in the U. S. Reclamation Service and adviser to the Secretary of the Interior, the writer reached the conclusion that it would be hopeless to endeavor to carry out the proposed scheme of building levees along the Gila River just above Yuma. Levees along the banks of the Gila cannot be maintained short of an expenditure for bank revetment which the value of all the land to be there protected would not justify. The situation is somewhat more favorable on the Colorado, which, owing to a lighter gradient, is less erratic than the Gila, but there, also, the fact should be recognized that it presents no ordinary problem.

The land to be protected on the Lower Colorado is of such extent and of such fertility and potential value that there should be no hesitancy in taking every step that may be necessary to bring the Colorado under permanent control.

The Secretary of the Interior was advised by the writer in 1907 that the Colorado should be given permanent banks from Pilot Knob about as far down as the Arizona boundary. He was advised that this work might cost from $50 000 to $150 000 per mile of bank, involving, as it would, permanent loose rock revetment of banks; and that the United States should be prepared for an expenditure of from $4 000 000 to $5 000 000, of which a portion should be contributed by Mexico because the benefits of the work would accrue to Mexico as well as to the United States. He was also advised that there should be created at once an International Engineering Commission, with full power to undertake the work of giving the river a permanent direct channel, as indicated, and to give consideration to all other problems arising on this stream. At the same time, the irrigation problems were reviewed, and the need of an early action for the protection of the Imperial Valley was pointed out.

At that time the Imperial Valley had to depend on a foreign corporation, *La Sociedad de Yrrigacion y Terrenos de la Baja California*, for protection against overflow and against complete and permanent submersion of the valley by the Colorado. It had to depend on

Mr. Grunsky.

this company, and it is still dependent thereon, for its irrigation water, which, after being diverted from the river in the United States, is turned over to the Mexican Company by which it is re-delivered into California. Such an arrangement needs the sanction and protection of higher authority. The arrangement cannot be regarded as entirely satisfactory until, under some treaty or other convention with Mexico, the right of a diversion of Colorado River water through Mexico is permanently assured to the people of the United States, and the two countries acting in harmony adopt adequate measures for keeping the Colorado out of Salton Basin.

Circumstances have favored the maintenance of the work done on both sides of the Colorado prior to 1907 below Pilot Knob. In that year the river carried more than the ordinary quantity of water; but the delta had been dry for two seasons, the river banks were free of grass and weeds, which had been largely burned off, and the over-bank flow, therefore, was far in excess of what would have occurred if the river had not been out of its natural course from 1905 to 1907, and if well-watered banks had been covered with dense vegetation. Due to its bare banks and to the consequent large over-bank flow at low elevation, the river did not rise as high and there was not as much water against the levees as there might otherwise have been. Then, too, in the spring of 1907, the cutting off of Nigger Bend and the shortening of the channel at that point by 2 or 3 miles had some effect in lowering the high water as far up stream as Yuma, and then—in 1909—came the relief at the Abejas. It may be assumed, therefore, that the behavior of the levees on both sides of the river, in 1907 and in the following seasons, is not a conclusive test of similar structures.

The writer inspected the levees on both sides of the river at high water in 1907. On the west side the levee below the dams at the Lower Mexican Heading had not been wet. At and near these two dams, completed a few months before by Mr. Cory, where the borrow-pits were on the land side, there was some seepage under the levees. Miniature, pin-head, under-water volcanoes made this apparent to the eye. The water in the borrow-pits was but little lower than in the river, consequently this seepage was caused by a pressure head of only a few feet. No doubt, it would have increased somewhat with a rise in the river. It was the result of the slow movement of the soil-water inland from the river.

On the Arizona side the borrow-pits were carrying a small quantity of water; they were not bank full. The abatis work across the borrow-pits appeared to be catching considerable trash, and each barrier of this kind checked in some measure the velocity of flow for a short distance up stream, but gave the impression that under ordinary conditions of bank submersion such structures would have been quickly cut out by the water passing around their ends. The writer was not

impressed with their efficiency, although they undoubtedly did some good under the conditions which prevailed in 1907. Mr. Grunsky.

In 1910 the writer again had an opportunity to inspect the levee on the west side of the Colorado, and noted that where the checkerboard arrangement of borrow-pits had been adopted the spill from one into the next, even with very slight river bank submersion, had caused some channel cutting, making clearly apparent an inherent weakness of this arrangement.

After a number of favorable seasons these outside borrow-pits will to a large extent be refilled with sediment from the river. If located close to the bank and on no greater slope than the river, the refilling of such pits along such a river as the Colorado may occur quite rapidly. Until thus refilled and overgrown with vegetation, they are, to almost the same extent as a continuous borrow-pit, a menace to the integrity of the levee whenever the latter follows an alignment along which there is an excessive fall, as is the case on the Colorado with the Paredones levee and with those above and below the Abejas.

In reporting to the Secretary of the Interior on the matter of river treatment, the desirability of using hydraulic dredges in the construction of the levees was referred to by the writer, and he still believes that, wherever the location will permit, the bulk of the levee work on the Colorado should be done by this method. The first work would then be the excavation of an ample trench, the material from which would form the river side restraining embankment for the hydraulic fill. The hydraulic fill would then be deposited in the rear of this, refilling the trench and bringing up to the desired height an embankment so wide of base that underflow through cracked soil and through burrows would be made impossible.

The writer is of the opinion that the control of the Colorado between permanently fixed banks should not be projected beyond some agreed point near the Arizona boundary line. If the river is kept on a proper alignment down to that point, it can wander about over a large lower portion of the delta without menace to the Imperial Valley. It will then, as it does to-day, send its waters, at least in large part, into the Volcano Lake region, and will warp up first one and then another section of its lower delta region. In the far future, then, the time may come when complete control to the Gulf can be economically justified.

If controlled mainly by giving the river a direct alignment between permanent, well-protected banks, supplemented with levees, as far down stream as here indicated, the protection of the Imperial Valley and the whole Alamo and New River country will be complete, if the cross-levee to the northward of Volcano Lake from the base of the Cocopah Mountains to the Colorado at the Lower Mexican Heading

Mr. Grunsky.

and up the river to Pilot Knob be brought up to proper height and be protected adequately, particularly against wave action.

The writer desires to note that the various estimates of flow of the Colorado, even those based on gaugings, are to be accepted with caution. Some additional information relating to methods of gauging should be given before these estimates are accepted as conclusive. This applies particularly to the measurements made at the river's high stages. It is understood that some special precautions are now being taken to insure accuracy of soundings and the correct placing of the current meter at the intended depth; but in 1907 the writer knows that this was not done, and that the maxima then recorded are too great by from 15 to 20 per cent.

The two-point method of gauging was at that time used. The gauging was made from a car supported by a cable. In mid-stream the car was from 5 to 8 ft. above the water surface. A sounding was made immediately before the velocity was measured. The heavy sounding lead was lowered from the car to the water surface and a reading of the paid-out line was taken. Then it was lowered to the bottom of the river and another reading was taken, the difference between the two being recorded as the depth. No allowance was made for the line swinging out of the vertical, due to the force of the current, which was about 7 ft. per sec. in mid-stream. By observation from shore on June 24th, 1907, the correction to be applied to the recorded mid-stream depth of 45 ft. was found to be about 6 ft. The recorded depth determined the required immersion of the current meter. When the meter was supposed to be at one-fifth depth, or 9 ft. below the surface, it was in reality barely below the surface; and when it was supposed to be at four-fifths depth, it was but little deeper. The only value of the velocity measurements as made lies in the fact that they can be used to determine surface velocity. They were recorded, however, as applying to the two-fifths and four-fifths points, with a resulting over-estimate of mean velocity. In this particular case the recorded discharge should be reduced 15% to give approximately the flow of the river on that day.

The errors of observation as above noted were, of course, called to the attention of the Reclamation Service and the United States Geological Survey, but no correction has been applied, and the writer does not know how long such methods of gauging were maintained at that station.

In Water Supply Paper No. 249 of the U. S. Geological Survey, page 45, the discharge is noted for June 24th, 1907, at 112 000 sec-ft. Of this quantity 11 000 sec-ft. were flowing in the north channel of the river and 101 000 sec-ft. were recorded for the main stream. According to a proper interpretation of the measurements on that day, the main stream carried only 86 000 sec-ft., and probably somewhat

less. The aggregate discharge for that day should have been noted at 97 000 sec-ft., instead of 112 000 sec-ft. The error in the main stream gauging was about 17%, or the recorded main stream flow should be reduced 15 per cent. The same correction should undoubtedly apply to the entire period in 1907 during which the river was at or near its highest stage. The writer has no information as to whether the same method of gauging was still in use in 1909. If it was, there can be no doubt that in that year, also, there must have been a considerable over-estimate of discharge. Mr. Grunsky

Mr. Cory is right in his conclusion that the construction of reservoirs within the water-shed of the Colorado will have some beneficial effect in equalizing the stream flow and in reducing the maximum discharge. It is immaterial whether or not the storage possibilities have been over-estimated. This can only affect the extent of the reservoir influence; and yet, whatever this may be, it will not change the river problem, except as to its magnitude. The river will still have its varying volume of flow. Its channel will adjust itself to the new conditions. The same lack of channel capacity will be felt at high stages on the lower river as is felt to-day, and the same problem of keeping the delta channels of the river on the Gulf slope will confront the river engineers of the future as confronts those of to-day, except only that there will be somewhat less water and correspondingly less silt to be reckoned with.

Perhaps a word should be said about the Laguna Weir. The change in the original design from a paving with large blocks of rock to a paving with concrete was due to the fact that the granite which had to be removed at each end for the sluice-ways was not of a character which could be used for this paving work. It was anticipated by the engineers who designed and approved the structure that the granite at the "Lagunas" which appeared to be disintegrated and rotten at the exposed surface would be of good quality when cut into; but, as the work progressed, it was found that the hills afforded very little sound rock within the limits of the prescribed excavation, and that at the best quarry sites near the weir only a small proportion of the rock was suitable for paving. This situation was carefully considered before a modification of plans was recommended by the Board of Consulting Engineers which had this matter under consideration in 1906.

The writer, though not desiring to criticize unfavorably the works which have been carried out at Laguna for the diversion of water into two canals, one on each side of the river, has never been in full accord with the general arrangement of the structures at that point. The plans for these structures were approved before he had anything to do with the Reclamation Service, and no one is more pleased to learn that they are rendering satisfactory service. Nevertheless, he

Mr. Grunsky. would call attention to the fact that the decrease of depth of overflow over such a structure, resulting from its great crest length, 4 700 ft., is not necessarily of sufficient importance to outweigh the disadvantages that will result from the use of a dam with so long an overfall crest. The storage of silt in the reservoir space above the dam, in the case of such a river as the Colorado, is of no importance. This space, except for a channel of ordinary width leading to the sluice-gates, is soon filled with silt and overgrown with willows and cottonwoods. There is a strong tendency for drift to lodge, and, within a few years, there may be such obstruction to a concentrated flow in lines parallel to the original course of the river that it may be difficult to keep the waterways open to the two ends of the weir without permitting one or the other to parallel and endanger the structure. The conditions at the weir, in a few years, may be such that water will go over it at uneven depth, and, in that event, the great length will fail to accomplish fully the desired purpose. At any rate, there will be trouble from time to time in keeping the water on a proper course to the two ends of the dam. The removal of silt which the sluice-gates will permit is dependent on the depth of the sluice-ways below the sills of the canals. The silt which the river will deposit in the large channel leading to a sluice-way, while the water is forced to rise to the crest of the dam, can of course be sluiced out from time to time by opening the gates, but this will be restricted to the deposit in a channel. It is not the accumulation in a reservoir, and this fact should not be lost sight of in planning such structures. Even this, however, may be worth while. The writer believes that the river should have been forced into a definite position above the weir by making a section thereof, probably 800 ft., a few feet lower than the rest of the structure and then arranging flanking walls to be overtopped at highest stages of the river and to serve as training walls of the large-capacity channels leading to the sluice-gates, which would, as at present, serve to keep the channel open to the head-gates. One great advantage of such an arrangement would be the concentration and depth of flow necessary to carry drift of whatever size over the dam.

Mr. Clarke. CLARENCE K. CLARKE, ESQ.* (by letter).—Although this paper and Mr. Sellew's discussion of some phases of the subject seem to have covered the ground quite thoroughly, it appears to the writer that room remains for a few statements of fact concerning the "rough and ready methods" of dealing with the river which Mr. Sellew does not accept as a solution of the engineering problems pertaining to the subject.

Being one of the men referred to by Mr. Sellew as "red-blooded fighters, who did not know when they were whipped, but * * *

* Chf. Engr., Palo Verde Mutual Water Co.

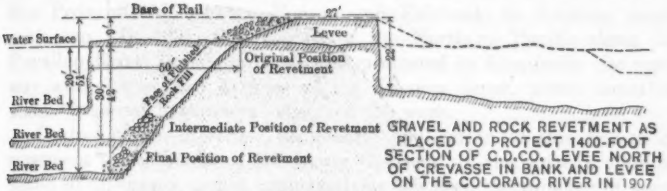
fought on to victory unmindful of its cost," the writer desires to correct an erroneous impression. The crevasse in the river bank and levee in 1907 was closed by railroad men, who used methods with which they were familiar; they tried no experiments and devised no new engineering practice. They knew they were not whipped at any stage of the game, and they kept at the job because they had done the same thing on a smaller scale many times and were confident of ultimate success. Mr. Clarke.

The use of the water of the Colorado for the irrigation of land creates the problem of control. There is no other reason for subjecting that river to control. The problem, so-called, as the writer sees it, presents three phases: 1, direction of the flow of the river and control of its meanders, involving bank protection; 2, exclusion of overflow water, by levees, from land susceptible of reclamation and irrigation; 3, safe and certain diversion of water from the river into irrigation canals.

The Lower Colorado has no fixed channel, because of the character of the soil, which is a deposit of silt, readily eroded. The current swings back and forth, cutting the banks and changing the meander line, and an apparently insignificant obstruction sometimes causes shifting of the channel for miles. A sudden shift of the channel from one bank to the other may leave a canal intake dry and put an irrigation system out of business. It may cut across a tongue of land, changing a wide bend into a tangent and forming a new bend lower down. Therefore, one factor of the problem is the maintenance of a defined course of the river between permanent banks. That may be accomplished by adequate protection of the banks and control of the meanders. It is advisable and feasible to straighten the course of the river at some points, and by increasing its velocity, to check its tendency to swing from side to side. The shortening of the river, resulting from the elimination of many horse-shoe bends, would increase the scouring action of floods and their silt-carrying capacity, and greater volumes of sand and silt would be transported to the lower delta and deposited there, building up large areas of land and accelerating the work that the river has been doing for ages. By the control of the lower river, the floods could be diverted into the basin of the Laguna Salada, and that shallow basin could be converted by silt deposit into an arable and fertile valley. In time, of course, the deposition of silt would work back, and the normal grade of the river would be re-established, necessitating the adaptation of levees to the new condition.

It is the writer's purpose to point out that this is not a problem calling for the invention of new methods of river control.

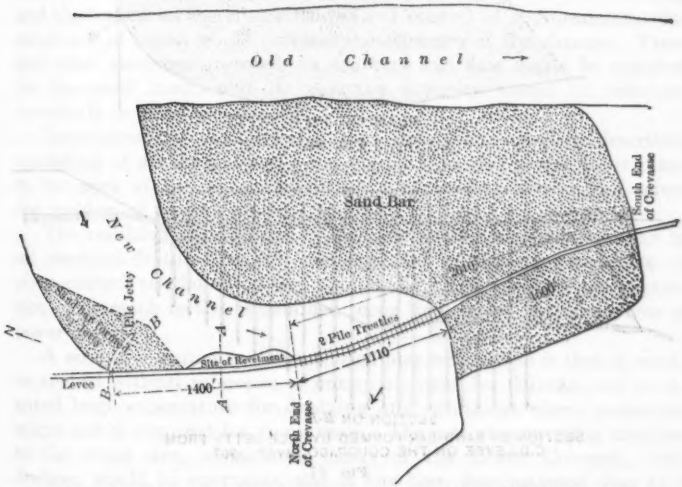
Bank Revetment.—Effective bank protection can be provided most readily and economically by laying a railroad track on the top of a



Mr. Clarke.

levee; and, as other writers have suggested, it may be applied in sections as needed. That tracks on the levees along the Lower Colorado are indispensable to their maintenance and the defence of the banks against undercutting attacks by the river, has been the writer's fixed conviction since his first experience with the river, and he notes with gratification that Mr. Sellew has revised his former opinion on the subject and concluded that the railroad track facilitates the work of levee protection to a degree that more than offsets the cheapness of the methods heretofore used by the Reclamation Service on the Colorado.

Having the "firing line" established by the track on the levee, it is important to provide an abundant supply of "ammunition" and means of rushing it to "the front." Quarries and gravel pits are opened, and are equipped with derricks to handle large rock, and steam shovels to handle small rock and gravel. When the river begins bank cutting and threatents to undercut the levee, train loads of gravel and rock are taken to the point of attack and dumped at the toe of the levee. Gravel is dumped first in order that it may underlie the heavy rock and prevent the sluicing out of silt and sand where the rock lies on the bottom. When the bank caves, the rock on the berm falls into the trench dredged for it by the river, and if the scouring continues and the trench is deepened, more rock is dumped to reinforce the revetment and raise it to the crest of the levee. Small rock and steam-shovel material serve to fill and face the revetment. When such revetment has dropped to the river's lower scour plane and has been completed by proper reinforcement, the work of bank protection at that point is done permanently, and the levee thenceforth is safe from undercutting.

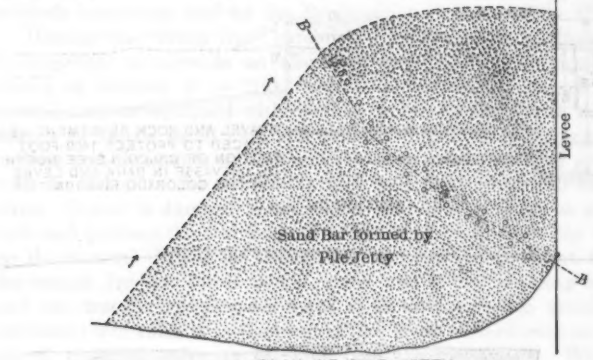


An illustration of this method of bank revetment was the saving of a section of the C. D. Co. levee, as a part of the work of closing the break with what Mr. Cory calls the Clarke Dam, in January, 1907. The river swung in against the levee north of the break and threatened to destroy 1 400 ft. of the embankment and widen the crevasse from 2 600 to 4 000 ft. The width of the berm between the toe of the levee and the bank varied from 30 to 50 ft. for the greater part of the 1 400 ft., but near the north end of the section the current had washed away most of the berm, and in the bight the water was close to the toe of the levee. To divert the current from this bight, a jetty 90 ft. long was built out from the upper side. The jetty consisted of two rows of piling, 5 ft. between rows and 8 ft. between piles in the row, the piles being "staggered" or alternated. The piles were 40 ft. long, and were driven in 26 ft. of water. Before the completion of the jetty, the discharge of the river was increased to 40 000 sec-ft. by a freshet in the Gila. Gila freshets carry great volumes of heavy silt in suspension, and this material drops readily when the velocity of the current is checked. It was not necessary to oppose any other barrier or baffle

than the piles to this heavily laden flood, and no brush was placed in the jetty. Eight days after the completion of the jetty, the river discharge fell to 15 000 sec-ft., and a bar was exposed on each side of the jetty and extending 13½ ft. beyond its outer end, where the water had been 26 ft. deep. The rapid formation of the bar was due to the Gila silt. To accomplish similar results with Colorado River water alone, more obstruction, in the form of fascines or wire entanglements, would be required, and the process of bar formation would be slower. Mr. Clarke.

SECTION ON *A-A*

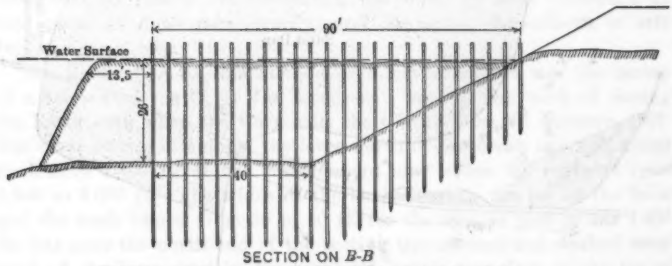
FIG. 84.



PLAN SHOWING METHOD OF DEFENDING LEVEE AGAINST ATTACK BY RIVER DURING CLOSURE OF COLORADO RIVER CREVASSE BY S.P.R.R. ENGINEERS IN 1907

FIG. 85.

When the jetty was built, the levee embankment was widened toward the river with gravel and rock, the track was moved to the extended fill, and large quantities of gravel and rock were unloaded, covering the berm to a width of from 8 to 10 ft. from the toe of the



Mr. Clarke.

levee. As the river cut away the bank and deposited the gravel and rock at the bottom, where the material was needed, more rock was unloaded. The depth of water at the bank, when the cutting began, was from 20 to 25 ft. This depth increased to 42 ft. as the river dredged a trench, and at that depth the scouring action ceased. When the revetment was completed and the 1 400-ft. section of levee had been protected, the height from river bottom to base of rail on the levee was 51 ft.

PLAN OF PILE JETTY

FIG. 86.

SECTION ON *B-B*

SECTION OF SAND-BAR FORMED BY PILE JETTY FROM C.D.LEVEE ON THE COLORADO RIVER, 1907

FIG. 87.

Gravel is a factor of vital importance in this method of placing rock on a sand or silt bottom, a detail which appears to have escaped the notice of some of the "innocent bystanders," who watched the closure of the crevasse and predicted utter failure of the work. The plan of providing revetment material at a threatened point and leaving to the river the work of dredging a trench and placing the rock, has been approved recently in a practical way by so eminent a river engi-

neer as Mr. Sellew, who used the method last year in defending one of his levees from attack. As he does not refer to the use of gravel as a bed for rock revetment, presumably that essential detail of the method was omitted. Mr. Clarke.

This method of bank protection, however, is no innovation, and, in his application to the closure of the Colorado crevasse of practice that is old to "firing-line" railroad engineers in the West, the writer cannot lay claim to originality. He used the same method on the San Pedro River, between Benson and Fairbank, in Arizona, many years ago. In 1891, the roadbed of the Northern Pacific along the Puyallup River, in Washington, was protected in identically the same way within less than 4 miles of the Tacoma depot, where doubtless many "innocent bystanders" observed the work.

Control of the River.—The general application of this system of revetment to the banks of the Lower Colorado, in the writer's opinion, would solve, simply and at comparatively low cost, the problem of keeping the river within defined bounds and protecting levees against undercutting between flood seasons. Combined with the straightening and shortening of the river's course and control of the meanders, this revetment of banks would increase the efficiency of the channel. Trees and other obstructive growth on the bars and flats would be removed by the river itself, and its carrying capacity would be sufficient eventually to take care of floods.

Experience has demonstrated that the revetment here described, consisting of gravel and rock, and placed from the lowest scour plane to the crest of the levee, constitutes a permanent barrier and solves the problem of control of the Colorado.

The resulting rock-reveted permanent barrier would be similar in all essential features to that contemplated in the suggested plan of river control attributed to Gen. Marshall, which involves the excavation of a trench to the ascertained scour line by the use of dredges or power shovels.

A serious objection to the suggested plan referred to is that it would be applied without reference to immediate need for defense, and would entail large expenditure for dredging and revetment where protection might not be required for many years. The cost of excavating trenches to the scour line, along both banks of the Lower Colorado, with dredges, would be enormous, and it has been demonstrated that such expenditure is quite unnecessary. The river can be depended on to do all the dredging and to place the gravel and rock at the bottom of the trench.

Only the National Government could or should undertake the task of controlling the Colorado, as it has prosecuted the work of protecting lands along the Mississippi against inundation. The first step in the project obviously would be to construct levees along both banks

Mr. Clarke.

and lay tracks thereon. During the progress of this work, gravel and rock quarries should be opened and equipped with the requisite loading appliances, and cars should be provided to carry the material to the front. In case of attack on the levees by the river, material would be sent to the threatened points, and the work of permanent revetment would be done at those points. After the completion of the levees, the means and material for revetment would be kept in readiness; during each flood season the river would be observed vigilantly; and every attack on the levees would be met promptly.

This method would distribute the work over many years. Conceivably, 50 years or more might pass before the banks would be reveted throughout the course of the lower river, but during that time the stream would be virtually under control. The cost also would be distributed, and no very great expenditure probably would be called for in any one season. The ultimate result would be absolute control of the river between permanent barriers defining its course.

Control of Meanders.—Emergency methods of control of meanders and of the direction of the channel, used on the Colorado, are simple and comparatively inexpensive, and may be applied by settlers to the temporary protection of their riparian lands. The writer had occasion to resort to these methods in January, 1913, for preservation of the flow of water through the intake of the Palo Verde Valley irrigation system.

The Palo Verde intake is cut through a rock projection into the lower part of a wide bend in the river. The river developed a tendency to cut across the bend by the chord of the meander arc, and, if unchecked, the channel would shift toward the Arizona shore, and leave a wide bar in front of the intake. This tendency was shown in the cutting away of the nose of a bar that extended from the Arizona or eastern shore to about the middle of the bend, and it was necessary that the bar should be maintained. This was accomplished by driving posts and placing fascines and sand bags on the point of the bar. A fascine jetty was built out from the Arizona bank, 1½ miles above the bar, and pointing down stream at an angle which would direct the current into the bend above the intake. The cost of this work was small, and the effect was all that was required. The channel was kept in the bend close to shore, and the supply of water through the intake was assured for the season.

By similar means, when the river begins cutting the bank and threatening destruction to lands or levees, a bank-caving current may be converted readily into a silt-depositing eddy. Fascine jetties—rows of driven posts with bundles of brush placed between them and anchored with sand bags—may be built quickly by the farmers, and danger may be averted if detected early and if the remedy be applied at the first indication of trouble. Such temporary defences are avail-

able in advance of the permanent system of protection, consisting of levees, railroad tracks, and rock revetment, and may be built by intelligent farmers without the aid of engineers. Mr. Clarke.

Levee Construction.—The writer did not participate in the exhaustive discussion of the relative merits of river-side and land-side borrow-pits in levee construction on the Colorado, which followed the failure of Col. Ockerson's levees and was carried on recently by many engineers in the technical press. The subject having been reopened by Mr. Cory and Mr. Sellew, however, it seems pertinent to call attention to a few facts which have been overlooked or ignored by both.

Mr. Cory explains clearly and correctly the failure of the levee below the Hind Dam in December, 1906, which was due solely to the absence of a muck-ditch under the levee. He gives reasons for the omission of the muck-ditch, chief of which was the supposed necessity for confining expenditure, as closely as possible, to the repair of the break. Mr. Cory says the desirability of muck-ditching was fully realized, and it was a part of the original design, but because levees had been built without muck-ditches on the Colorado, and some one advanced the theory that a cracked adobe foundation would be made tight by pressure when wet, the vital necessity of muck-ditching was not recognized, and the builders of the levee decided to "take a chance." The theory of the closing of adobe cracks proved unsound. Water followed the cracks under the levee and caused the break.

Mr. Sellew admits that water did go under the levee because of the absence of a muck-ditch, but he contends that "the damage caused by a head of 15 in. against the levee was due primarily to the presence of land-side borrow-pits."

The borrow-pits, 3 ft. deep, were separated from the levee by a berm 40 ft. wide, and it is manifestly absurd to assert that there could be any relation between the pits and a 15-in. head against the levee. The pressure angle of the greatest head against any levee on the river would not reach the pit. According to Mr. Sellew's theory, an inside borrow-pit ½ mile back of the levee would increase the static head and cause failure of the work. Mr. Cory left an opening for attack when he said the increased total head was "the only pertinent objection to land-side borrow-pits." Experience has demonstrated, however, that the objection is impertinent, irrelevant, and immaterial. No land-side borrow-pit levee, properly muck-ditched, on the Colorado, has been broken or even damaged by the river, but every river-side borrow-pit levee has been breached or destroyed, and every flood season since levees were first built on the river has seen a strenuous fight to maintain them. The river-side borrow-pits are invitations to the river to side-wipe the levees with currents of eroding velocity, and a levee not blanketed heavily with gravel, or rip-rapped with rock or mattresses, melts away like a bank of salt. Every levee breach has been

Mr. Clarke.

caused by current erosion, not by static head or pressure. No levee has been pushed over by the river.

"Last Word" on Borrow-Pits.—Quoting from Mr. Sellew's discussion, page 1482:

"Regarding the advantages and disadvantages of land-side and river-side borrow-pits, the writer has fully expressed himself, so that it is not necessary to comment further. Particularly is this so when the author [Mr. Cory] states that he 'realized that this [land-side borrow-pits] was not in accordance with the usual practice.'"

The implication that Mr. Cory confessed judgment against the land-side borrow-pit and yielded every point to Mr. Sellew in the argument, seems to the writer no more than a verbal quibble. A practice may be "usual" and still not the best possible under all conditions.

Doubtless there is satisfaction in the belief that one has routed all opponents in argument and said the last word on a debated subject, but it does not appear to the writer that any one of the eminent engineers engaged in the borrow-pit discussion has warrant for "laying that flattering unction to his soul."

It might be inferred from Mr. Cory's statement, that the land-side borrow-pit method of constructing the C. D. Co. levees in 1906-07 was "decided on after careful consideration of the advantages and disadvantages," that there was doubt on the subject in the minds of the men on the job. The matter may have been—in fact was—debated persistently by the "innocent bystanders," but there never was any question of methods in the minds of the railroad "firing-line" engineers having direct charge of construction. It is and has been for years, not only the usual practice, but the invariable rule of railroad engineers in the West, that nothing between an embankment and a river shall be disturbed. The protection afforded by earth in place and by trees and brush must be maintained intact. That was why the land-side borrow-pit system of construction was adopted as a matter of course. It was followed until the bystanders, tired perhaps of being innocent, got themselves appointed as a "consulting board" and after two attempts succeeded in getting an imperative order from financial headquarters to the engineers on the job to conform to the usual practice of the levee builders on the Yuma Project. Had they succeeded earlier, the levee could not have been built at all during the flood period. From the moment the water came over the river bank, work of any sort on the river side of the levees was impossible.

Experience in railroad construction and maintenance in regions subject to floods, in the building of dams and levees in the Delta of the Colorado and in the Palo Verde Valley, and in the control and maintenance of irrigation canals of large capacity, has left the writer in no doubt concerning the essential principles of levee construction on the Lower Colorado River.

Mr. Clarke.

The first requisite pertaining to the location of a levee in this region is a careful underground survey to determine the sort of material to be encountered in excavation for muck-ditches. Large deposits of unfit material, such as adobe, heavily alkaline soil, and certain kinds of sand, must be avoided by detours. Seepage is the only factor detrimental to the land-side borrow-pit plan, and that is to be eliminated by the muck-ditch. The theoretical additional head against the levee, due to a borrow-pit 40 ft. in the rear of the levee, is a negligible factor. Under conditions actually encountered on the Colorado, there is not any additional head, either in fact or in theory. That objection to the land-side borrow-pit is not even theoretically plausible.

Essential Features.—The essential features of efficient levee construction on the Lower Colorado are: location avoiding bad ground and careful muck-ditching to exclude seepage; land-side borrow-pits, leaving all natural protection on the river side undisturbed; gravel blanket to resist erosion and to minimize attacks by burrowing animals; railroad tracks on top of the levee to facilitate maintenance and to make possible the protection of banks and levees by permanent rock revetment.

Mr. Sellew is unquestionably right in his conclusions:

"That in their present state, the levees are at the mercy of the meanders of the stream, except throughout those portions where a railroad occupies the levee top"; and, "That bank revetment, permanent in character and reasonable in cost, when compared with other methods, can be readily and quickly accomplished with rock placed from railroad trains operated on the levee tops and connecting with existing quarries which are within a reasonable distance."

The first conclusion is sustained by the history of all the Colorado levees, and the correctness of the second was demonstrated clearly in 1907 by the holding of the 1 400-ft. section of levee against the attack by a flood of 40 000 sec-ft. at the time of the last closure. The permanency of rock revetment thus constructed, however, depends on the placing of gravel as a bed for the rock. That is a vital detail of the method.

In rip-rapping levees and reveting the banks at the toes, in the opinion of the writer, grading to uniform slope is not only unnecessary, but inadvisable. It is better to place the gravel and rock on the natural ground. Setting rip-rap by hand on the face of a levee makes a neat looking job, but it is needlessly expensive, and the protection is less effective than that secured by the gravel and rock method.

Before leaving, finally, the subject of closure of the crevasses and the preservation of Imperial Valley in 1906-07, the writer desires to put on record the fact that the accomplishment of the work was due primarily and exclusively to the independent judgment and courage

Mr. Clarke,

of Mr. Harriman, who persisted in his belief that the breaks could be closed, and his determination to close them in the face of opposition, and regardless of the positive assertions of a host of eminent engineers that closure was a physical impossibility.

Submerged Weir.—Mr. Cory has described briefly the submerged rock weir placed across the river at the intake of the Imperial Valley Canal in the summer of 1910, and has mentioned its unexpected stability and durability. Mr. Sellew does not discuss the weir or its effects directly, possibly because he did not view its construction with favor, but his comment on Mr. Cory's statement concerning the permanency and efficacy of rock fill in the crevasses has bearing on the subject. Of the rock fill Mr. Sellew says:

"How it would act as an overflow weir, carrying 150 000 sec-ft., even if covered with concrete, is problematical. In addition to a concrete top, crest and foot-walls appear to be necessary to prevent the top from being undermined, and, if these are provided, the resulting structure will not differ materially from Laguna Dam either in design or cost."

This is a case in which accomplished facts fail to justify speculative theory, and it appears to be in order for the writer, as the builder of the weir, to state the facts and show the actual effects of the installation.

Construction of the weir was necessary because of the recession of the bed of the river, following the diversion of all its flow into the Abejas channel, and because of the lack of a powerful dredge to keep the floor of the 1 900-ft. intake from the river to Hanlon gate as low as the sill of the gate. The discharge of the river was diminishing, and danger of complete diversion of the channel from the intake was imminent. The placing of a weir to check recession and direct the current was the only practicable rapid method of returning the water to the canal and saving a $6 000 000 crop in Imperial Valley.

A trestle, 960 ft. long, composed of four-pile bents, 15 ft. between centers, was built across the river, below the intake, to the Arizona shore, at an angle of approximately 70°, the Arizona end being the farther up stream. Caps, stringers, ties, and rails were placed on the structure, and steam-shovel rock from the adjoining quarry was dumped from the trestle and spread to a width of 50 ft. No brush at all was used, and no derrick rock was dumped. As the weir was designed to be temporary, no gravel was placed either before or with the rock. The discharge of the river during the progress of the work was about 9 000 sec-ft.

The weir was constructed in 21 days, at a cost of $22,500, of which amount $4 000 was recovered in salvage of rails, ties, stringers, and caps. The quantity of rock used was 12 800 cu. yd., of which 9 600 cu. yd. were placed in the weir, the rest being used to revet the banks

and raise a spur track above the high-water mark of 1909. The angle of the weir to the current served to point the channel to the California shore, and also served other purposes familiar to "firing-line" railroad engineers. Mr. Clarke.

The weir arrested the recession of the river bed, turned the water into the intake, averted a water shortage in the Imperial irrigation system, and saved to the farmers of Imperial Valley crops worth $6 000 000 or $7 000 000. Also, the successful construction and operation of the weir demonstrated that the farms of Yuma Valley, dried out and virtually abandoned for 5 or 6 years, could have been watered at small expense, and could have produced and marketed crops to the value of $1 000 000 a year while awaiting the completion of those great engineering monuments, the Laguna Dam and the Colorado River Siphon. It is evident that the lands of Yuma, Cibola, and Parker Valleys can be provided with water by the construction of weirs, and brought under cultivation at nominal expense.

Although the piling of the trestle was cut off above the rock fill and removed in the spring of 1911, the rock weir remained in place. How such a fill would stand an overpour of 150 000 sec-ft., even without a concrete top, is not problematical in any sense. The weir at the intake has endured two freshets, one of 150 000 sec-ft. and the largest on record, and it still remains. It has neither crest, core, nor footwall of concrete, and it is not covered with concrete, but its top has not been undermined. It differs radically and widely from Laguna Dam in design and cost, but its function is the same. A permanent rock-fill weir, built with gravel, large rock, and steam-shovel rock, and having a cross-section width of 200 ft. on the bottom, certainly would stand any overpour that the Colorado could muster, and its cost would be comparatively small.

Useless Dredging.—Although the work of a dredge in the intake above the concrete gate was of material aid in getting an adequate supply of water to the canal, the writer cannot concur in the opinion that the operation of the dredge *Imperial* below the gate was of the slightest efficacy or value at any time. The dredge has dug a hole below the gate; the hole has been filled with sand; the dredge has dug it again, and so on in one continuous round of costly futility, like the labor of Sisyphus. Had the *Imperial* been placed above the gate, it would have been useful. When the banks of the Alamo channel, constituting the main canal, had been raised and strengthened to carry safely a large flow, the discharge of from 2 500 to 3 000 sec-ft. through the gate solved the problem of water supply for the valley canal system. In an hour and a half 2 500 ft. of water sluiced sand from the canal below the gate to the depth of 1 ft. The Alamo Canal is an efficient channel for 5 miles below the gate, when carrying 2 000 sec-ft. or more, and dredging is wholly useless.

Mr. Clarke.

When the writer took charge of work on the C. D. Co. system, he found two large dredges, the *Delta* and *Gamma*, at work in the main canal at an operating cost of $9 000 a month. The dredges were useful in straightening the course of the Alamo, cutting across bends and building up banks, but when they operated in the canal to remove silt and sand, they only moved a hole up and down stream. Careful instrumental observations and cross-section surveys showed that the floor of the canal behind a dredge was at the same level as before the dredge reached it.

The writer put the dredges out of commission and tied them up, thereby saving $9 000 a month. It is doubtful if a dredging barge, occupying more than one-third of the width of a canal carrying Colorado River water (laden heavily with silt and sand), can be operated efficiently to remove deposits.

The removal of quicksand from the Imperial canals is a problem to be solved by the managers of the main supply system. Sand in the canals of the Mutual Companies constitutes a menace, and is a cause of great increase in maintenance expense. The deposit of sand in these canals and in farmers' laterals is avoidable. Doubtless a small percentage of sand brought through the head-gate is removed by the *Imperial*, but all of it could be removed more economically by other means at the lower end of the Alamo main, and it is obviously the business of the C. D. Co.'s Receiver to take care of that sand instead of sluicing it out upon the valley farms.

Summary.—The writer has endeavored to make clear, by statement of fact and description of work accomplished, that there is no abstruse problem involved in placing the Lower Colorado under control and confining its floods to a determined course.

The meanders of the river are subject to direction by simple and inexpensive means, the current at the early stage of its wandering tendency responding as readily to the guiding hand as does a bridle-wise horse to the touch of rein upon the neck.

The permanent revetment of the banks has been demonstrated to be comparatively easy of accomplishment by methods familiar to, and applied by, railroad engineers in the West for many years.

That a railroad on the top of a levee is indispensable to maintenance and to application of the rock-fill method of bank revetment has been shown conclusively by experience. Costly experience has proved the unwisdom of removing any natural protection from the berm on the river-side of a levee, and has established the correctness of the railroad "firing-line" practice in the construction of embankments along streams, particularly those flowing through regions of alluvial formation.

Submerged weirs, to raise the bed of the river, arrest the recession of scour planes, and divert water with certainty and safety into canal

intakes, may be built as permanent structures by the simple and inexpensive method of dumping gravel and rock from trestles, without placing any crest or core-walls, or using a pound of cement. Mr. Clarke.

The operation of dredges for the removal of sand from main irrigation canals is ineffective and a waste of money where water can be carried in large volume at sluicing velocities.

U. S. MARSHALL, ASSOC. M. AM. SOC. C. E. (by letter).—The author's statements regarding the very unfavorable soil report on the Imperial Valley, issued by the U. S. Department of Agriculture (which actual results have proven to be unjustified), and the belief expressed that, had this soil report been issued before the reclamation of the valley was well under way, the effect would have been a complete condemnation of the project, are serious matters and worthy of most attentive consideration. The writer has had similar experience, and has no doubt that many others interested in reclamation work have encountered this same bugaboo of an adverse Government soil report. It is certainly the duty of the U. S. Bureau of Soils to rectify some of the wrongs done to different parts of the country through adverse reports on various soil types. The writer knows of no case where this has been done in a way which has had any practical effect. Mr. Marshall.

The object of a soil survey should be to determine what the land is adapted to and what methods of cultivation are indicated and required. The findings of a survey should be, by all means, of a constructive and not of a destructive nature, and the chief purpose should be to find some beneficent use for the soil surveyed. Any report that condemns a soil type as worthless, unless based on the most thorough investigation, necessarily does a most serious and inestimable injury to the area reported on.

It should be the office of the Government to encourage the development of waste land, but certainly some of the soil reports would discourage even a preliminary investigation of the areas in question. Because of the usual high respect for Government experts and their disinterested attitude in such matters, their statements, official and otherwise, are generally taken as expressions of ultimate facts, and unimpeachable as to the conditions of the soils reported on. However, in the West, to-day, there are notable cases of great districts, with proven agricultural value, which were condemned by the Government Bureau of Soils.

The writer's experience with an adverse soil report will serve as another example, supporting these statements. While one of the engineers was making a report on a proposed 60 000-acre levee reclamation project in the Sacramento Valley, California, on which it was estimated $2 000 000 would be spent for levees and drainage works, the following developed:

Mr. Marshall.

The project had advanced to the point where the parties who were to finance it had paid for 26 000 acres of the land involved, and plans were being hurried for the reclamation works, when the U. S. Department of Agriculture's "Soil Survey of the Marysville Area, California," was called to the attention of one of the several representatives of the purchaser. This report, issued in 1911, was the work of Messrs. A. T. Strahorn, W. W. Mackie, H. L. Westover, L. C. Holmes, and Cornelius Van Duyne, and on page 30 contained the following comment regarding that part of the area in which this project was located:

"When protected from overflow by levees, this soil will be saturated for some portion of each year on account of the high water level outside the levees. Extensive drainage ditches and pumping plants would remedy this to a considerable extent, but to keep down the level of the water table for such extensive areas would be very expensive, and only the most profitable crops would justify the expense. The physical condition of the soil is about as unfavorable as it possibly could be, owing to water-logged condition and consequent nonaeration. Should the type ever be thoroughly protected from inundation, the agricultural value of the section will probably depend upon the introduction of crops suitable only to low, moist land that will yield a considerable return for the labor and money invested.

"The following table gives the results of a mechanical analysis of a sample of the soil of this type [amounts given in percentage by weight]:

Fine gravel.	Coarse sand.	Medium sand.	Fine sand.	Very fine sand.	Silt.	Clay.
0.0	0.5	0.7	3.4	1.8	41.0	52.7"

This report, coming from the Government, and obviously unbiased, seemed to this representative to be a solar plexus blow to the project, and he felt that the purchaser had been misled. The parties effecting the sale felt that their reputation was in jeopardy. They had never seen the soil report, but were positive, because of actual results, that the soil was very productive. The engineers were censured for failing to bring the report to the attention of the parties interested, and it seemed certain that the whole project would fall through.

In an effort to re-establish confidence, a large number of representative farmers, experienced in handling bottom lands, were taken over the area and asked to pass judgment on the soil. All agreed that any land supporting a heavy tule growth was valuable when reclaimed, as much of this identical soil which had been reclaimed in the Sacramento Valley produces great crops. Much of the land in this area, however, is not covered with tules, and these bottomland farmers would not vouch for it because they could see no native tule growth, which was the basis for their conclusions. In this diffi-

Mr. Marshall.

culty the writer had recourse to the United States Government surveys made in 1854 and 1864. In these notes frequent reference was made to tule growth encountered. On platting these, a map was obtained showing that the tule growth in 1864 covered nearly the whole of the area in question. This was accepted as convincing proof of the continuity of soil type, and the purchaser was reassured to the extent that reclamation is now going on.

There will thus be created for the community a vast acreage of exceptionally productive ground which, had it been impossible to offset the adverse report of the soil experts, would have continued a worthless expanse of duck marsh, and the reputation of many men of high standing would have been shattered and confidence in their integrity and judgment lost. Further to re-establish the reputation of the land and prove the mistaken character of the soil report in question, comparisons were made with the "Soil Survey of The Woodland Area, California," by the U. S. Department of Agriculture. This area adjoins that of Marysville, and was reported on by Messrs. C. W. Mann, J. F. Warner, H. L. Westover, and James E. Ferguson. The soil type commented on so adversely in the Marysville Area is reported on as follows in the survey of the Woodland Area, page 25:

"Where this soil type is protected from overflow and is free from alkali it is adapted to grain, sorghum, Egyptian corn, hay, and other forage crops.

"The texture of the soil * * * is shown in the following table [by percentages]:

Fine gravel.	Coarse sand.	Medium sand.	Fine sand.	Very fine sand.	Silt.	Clay.
0.1	0.7	0.9	3.3	1.4	41.2	52.3"

The survey of the Woodland Area was made prior to that of the Marysville Area. The mechanical analyses of the two soil types are identical. In reporting on the Woodland Area there could have been no mistake in advising on its adaptability for the crops mentioned, for, at the time the survey was made, the land was producing a very heavy alfalfa crop.

It should be remembered that all information, used in showing the original Marysville Area report of this soil type to be grossly in error, was as available to the Government soil experts as to the writer, and that for their most adverse report on the soil in question there is no real excuse. Nevertheless, as it was obvious that an error had been made, a supplementary report revising the survey of certain soils in the Marysville Area has been issued by the Government, in which the former report was corrected and the mistakes excused on the ground that at the time the survey was made the soil in question was covered

Mr. Marshall.

with water, thereby making thorough investigation difficult! Certainly this was reason enough for failure to get good first-hand data; but why should a report be made condemning many thousands of acres of land on such flimsy investigation?

The writer dissents from Mr. Sellew's comments as to the propriety of including the discharge records at Yuma prior to 1903, in Table 3. All available data should always be given, with explanations, and thus permit the reader to draw his own conclusions according to his own experience and judgment. Furthermore, the result of taking the yearly rainfall for the entire 265 000 sq. miles of water-shed of the Colorado River as the combination of yearly rainfalls at eight different stations scattered over the water-sheds, which it was assumed gave a fair average, does not seem to be justifiable. This is shown by platting the average rainfalls and yearly run-offs, as given by Mr. Sellew for 1903 to 1912, as in Fig. 88. This proves that there is no law that can be deduced connecting yearly rainfall and run-off totals on a water-shed as large as that of the Colorado River, and that one cannot tell with any more certainty than a guess what the run-off of the Colorado River was by using the rainfall data of the eight rain-gauge stations selected.

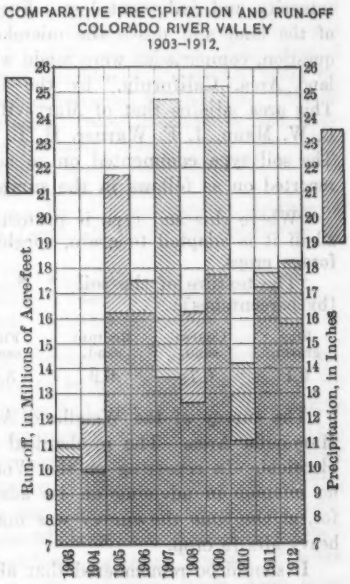


FIG. 88.

Therefore, to condemn the discharge records at Yuma prior to the establishment of permanent gauging stations there, as being too low, because they do not conform closely to what one might expect from the rainfall records given, in the writer's opinion, is wrong. The early data are not precise, but they are valuable and should have weight in the consideration of the problem.

That there may be long cycles of high and low yearly discharge of rivers is well established. The writer calls to mind some investigations which he made into the past levels of the Great Salt Lake. By inquiry from old settlers and by searching records it was found that in the last century Great Salt Lake had two cycles, and probably three, of extreme high and extreme low water, and, according to such

experience, the lake should be high at this time, and such is the case. The lake is now some 8 ft. higher than it was at the time of the construction of the Lucin Cut-off in 1902, and this rise has taken place in spite of the fact that, for irrigation purposes, much more water than formerly is now being diverted from the rivers emptying into the lake. Mr. Marshall

H. T. Cory, M. Am. Soc. C. E. (by letter).—The writer has been surprised and greatly interested at the reception of this paper by those connected with the several interests involved. Though especial effort was made to be fair and dispassionate in the presentation of the various features of the work and situation, yet so much bitterness has been engendered between many of the various agencies in the development of the region that it was felt impossible to write anything worth while and avoid causing, in many quarters, a feeling of unfairness. The discussions by Mr. Sellew and Mr. Chaffey contain all matters of that kind of which the writer has been able to learn, and Mr. Chaffey's discussion deals primarily with matters concerning which the writer at no time had any personal knowledge. The other discussions, numerous conversations, letters from officials of the Southern Pacific Company, of the United States Reclamation Service, of the Interior and State Departments of the National Government, of the California Railroad (Public Utilities) Commission, of the California Development Company and most of the Mutual Water Companies in Imperial Valley, of the Imperial Irrigation District, and from Mr. Rockwood and several of his associates in the project, have all expressed appreciation for the fairness of the presentation. In several cases minor changes in wording have been suggested, but it is a source of much pleasure that all these seemed to be not only fair but an improvement, and every one of these changes has been made. Mr. Cory

The writer must confess that he has often felt very pessimistic and impatient about the unreasonable attitude and stubbornness of a prejudiced man, and therefore such a result is most interesting and encouraging. Possibly, after all, misunderstanding is responsible for much of the failure to appreciate the work and real motives of others. At any rate, this is a striking illustration of men of affairs taking a common ground, or at least a tolerant appreciation of others' actions and opinions, when all the facts of a complex situation are systematically set forth in an apparently fair and comprehensive way, even with the handicap of strong feelings in the matter based on partial or misleading information. If such better understanding will result in less misapplied energy in completing the work thus started, the writer's efforts will be very well repaid.

The next most interesting things brought out by the discussions are the opinions as to the contents of the paper. Mr. Sellew regrets

Mr. Cory.

that the record of engineering operations was "partly obscured by a mass of legal and financial entanglements which properly have no place in a purely engineering article." Mr. Elwood Mead, on the other hand, finds that this same obscuring "mass of legal and financial entanglements" is the most valuable part of the paper, saying:

"The chief value of this paper, however, is not found in its description of the engineering methods used, but in the social and political conditions, attending irrigation development in the West, which it reveals. * * * as these are fundamental features of irrigation development, it is that portion of the paper which the writer proposes to discuss."

Mr. Buck confines his discussion largely to criticizing sharply Mr. Sellew's view. President Swain, in his annual address recently delivered before the Society, urges engineers to feel that their duty is to study and deal with financial, legal, and even social entanglements, and not those only of physics and applied mechanics. The views of various individuals in this regard are no doubt characteristic of their respective holders and the result of their life experiences.

Mr. Robson has added a more detailed study of the evaporation at the Salton Sea and shows that the figures given in the paper were somewhat too large, surprisingly small though they seemed. It might be well to point out that the coefficient, 0.6, derived by Mr. Robson for 6-ft. pans becomes, by Professor Bigelow's formula, 0.49 for 4-ft. pans and 0.4 for 2-ft. pans, in estimating the evaporation from large water surfaces from experimental small-pan data.

Mr. Knowles expresses the feeling, shared by many engineers as well as laymen, that reservoirs on the head-waters and along the tributaries of streams subject to disastrous floods offer the best means of flood control in theory, and oft-times in practice. It is probable, as a matter of fact, that Messrs. Knowles, Sellew, Grunsky, and the writer are not far apart in this matter, and that all agree that the extent to which such methods may be feasible differs with each stream. Mr. Knowles asks for data relative to this question, but it is believed that those presented by Mr. Sellew and the writer are all there are.

Concerning these data, however, it is important to remember that neither Mr. Sellew nor the writer has any personal knowledge of the storage possibilities in the water-shed, and both agree that the available published facts are not sufficient to determine the feasibility of complete, or the extent of practicable, reservoir control of the Colorado River. Consequently, the conclusion reached by Mr. Sellew, as a result of his analysis, that there is but one available reservoir site—Browns Park with a capacity of 2 200 000 acre-ft.—on the entire Colorado River water-shed, is not only startling but quite unwarranted. Furthermore, the statement that "storage on the Gila is out of the question, as this stream carries more silt during its flowing season

than the Colorado," is quite out of accord with the opinions of his superiors in the U. S. Reclamation Service, as the Roosevelt Dam has just been completed, creating a reservoir behind it having a capacity of 1 284 000 acre-ft. at a cost of $3 697 000, according to the first item of Table 23. This reservoir is on the Salt River, one of the main branches of the Gila, and has all the latter's essential characteristics. Mr. Cory.

As a matter of fact, many reservoirs will no doubt be constructed on the Colorado River water-shed, including probably the Kremmling site, in spite of the fact that at present it "is in the hands of interests foreign to irrigation or storage development," and these reservoirs will have considerable beneficial effect in reducing flood flows; it is immaterial whether or not the storage possibilities have been overestimated, as this can only affect the extent of such an influence; but, as Mr. Grunsky says:

"Whatever this may be, it will not change the river problem, except as to its magnitude. * * * The same lack of channel capacity will be felt at high stages on the lower river as is felt to-day, and the same problem of keeping the delta channels of the river on the Gulf slope will confront the river engineers of the future as confronts those of to-day, except only that there will be somewhat less water and correspondingly less silt to be reckoned with."

This is especially true because below Yuma the river is practically a "joint track" for the Colorado and the Gila, which are very different types of streams, but each at times alone causes approximately equal maximum flood heights from Yuma to the Gulf. Of course, the floods on the Gila are flashy and those on the Colorado are long sustained, but that does not signify as much as might be thought, so far as river control is concerned. Fortunately, severe Gila and Colorado floods never occur simultaneously.

As to the quantity of water—the discharge of the Colorado at Yuma—the writer believes that the first half of Table 3 should be given, agreeing with Mr. Marshall that it is always best to set forth all available data, with explanations—as was done in this case—and let the reader decide what to use and what to discard. The recorded discharges prior to November, 1902, are by no means as reliable as those after that date, but that does not mean that they are worthless, though it does mean that they must be used with care and discretion. In this matter the comments of Mr. Grunsky on the reliability of the measurements taken since that time, especially at high stages, are very pertinent.

In any event, it seems clear that, beginning with 1905, the discharge of the river has been markedly greater than normal, and that long periods will occur when the discharge will be markedly less than normal—as is pointed out very well by Mr. Marshall. In the case

Mr. Cory. he mentions the water is within 4½ ft. of the rail base on miles of the very expensive Lucin Cut-off crossing the Great Salt Lake, and the water is still rising. The relationship between yearly rainfall and run-off, even on very large water-sheds, and especially if few widely scattered points be taken, is by no means constant, as Mr. Marshall says, and as the writer and doubtless many others have learned from time to time to their discomfiture. With the existing data it is not safe to decide in more than a tentative way as to either maximum or minimum quantities. Mr. Sellew's maximum figures as regards river control are probably fairly close to the truth, but, with respect to the minimum for estimating safe irrigable acreage, caution must be used. Fortunately, it will be at least another decade before all the lands easily covered by canals in these regions can be brought under complete cultivation, and the dry cycle of years will probably be well under way, so that the safe limit of land which can be served by the natural flow of the river will be determined in time to avoid excessive development.

With respect to the rise of the river bed at Yuma, Mr. Sellew is correct in the opinion that much more information is necessary before definite relations can be established regarding it. The Southern Pacific Company, however, has kept gauge heights at Yuma since 1878, and these records show a steady rise of the river bed (taking averages), or a steady increase of the river discharge. The reader can judge which is more probably occurring. Also, the old maps on record in the British Museum, in archives at Madrid and Mexico City, and in the Bancroft Library in the University of California, have been carefully studied by Mr. Godfrey Sykes, of the Carnegie Institution, in connection with this very matter, and the final figures he has adopted (which will appear in a volume on the Colorado Desert by the Carnegie Institution, now in press) check well with the "memory of a steamboat captain," Capt. Mellon, of Yuma, quoted by the writer in the paper.

Undoubtedly the difference in elevation at any two points on the river will change as the length of the river between these points is modified by meanderings of the stream; and, also, the two points, Laguna Weir and the conglomerate hills at Yuma, are the only ones on the lower river which may be regarded as definitely fixed—as was pointed out in the paper and again by Mr. Sellew. The latter, however, has mistaken effect for cause when he concludes that the increase of 4 ft. in difference of gauge height of the river at Yuma and Laguna Weir "is plainly caused by the meanders of the river" between these two points. This stretch of river had a normal length of nearly 14 miles, from 1856 to 1909, and this had increased to 17 miles in

1912, because the stream had lowered at Yuma more than 3 ft. as shown by the diagram Fig. 3 (for reasons set forth in the paper), though no change is possible at Laguna Weir. The stream has re-established its normal grade per mile by lengthening itself, and, as the bed at Yuma rises again, a corresponding shortening will follow. Mr. Cory.

It would seem that the comments in the paper as to the design and methods of construction of the Laguna Weir were not clear, either to Mr. Sellew or Mr. Grunsky. Fig. 89 shows diagrammatically a cross-section of the weir as built, and as the writer proposes. The resulting structures would not differ in function, concrete top, crest or foot walls, appearance when completed, or general design in the sense of cross-section above ground.

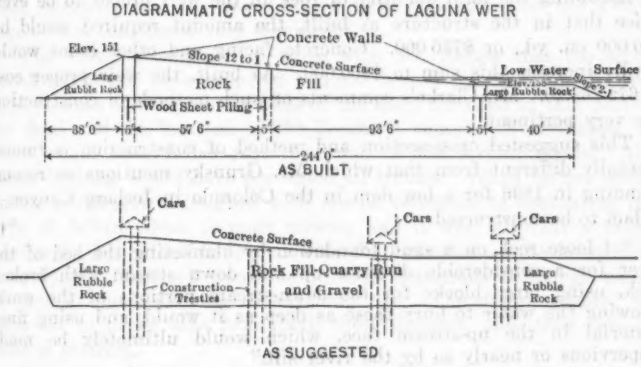

FIG. 89.

The difference is in the omission of the concrete cross-walls (which were very expensive in time and money) in the second design, and changes in method of construction by driving the river sideways ahead of rock and gravel filling from trestles, and thus making it do all the excavation. The result would be a greater yardage of rock in the structure, but the total cost of it in place, including excavation and everything, would certainly not have been any more than the costs given for the material placed in closing the central section of the weir—undoubtedly it would be materially less on account of the much more favorable conditions and the larger quantities. The figures given by E. D. Vincent, M. Am. Soc. C. E., Resident Engineer on the work, and quoted in the paper, are, in round numbers, $1 per yard, made up of the following items*:

* *Engineering News*, June 10th, 1909.

Mr. Cory.

Labor, dumping cars	$0.020
Labor, general	0.020
Sundry supplies and implements	0.008
Railroad hauling	0.217
Depreciation, rolling stock and track	0.062
Excavation, rock-quarrying	0.468
Trestling	0.149
Proportion of storage of apron rock	0.014
Light and water	0.011
Depreciation, special derricks	0.001
Proportion of superintendence	0.032
Overhead charges, Yuma and Washington offices	0.038
	$1.040

Assuming the total quantity of rock in the weir proper to be even twice that in the structure as built, the amount required would be 750 000 cu. yd., or $750 000. Concrete facing and other items would hardly increase this sum to $900,000. As built, the weir proper cost $1 672 168.20. Mr. Clarke's comments on such methods of construction are very pertinent.

This suggested cross-section and method of construction is fundamentally different from that which Mr. Grunsky mentions as recommending in 1896 for a low dam in the Colorado in Iceberg Canyon—a dam to be constructed

"of loose rock on a sand foundation by blanketing the bed of the river for a considerable distance up and down stream with broken rock, using large blocks for the down-stream portions of the work, allowing the water to bury these as deep as it would, and using finer material in the up-stream face, which would ultimately be made impervious or nearly so by the river silt."

Such cross-section design and method of construction is of course entirely independent of Mr. Grunsky's suggestion that the weir top should not have been uniformly high but have had a section, say 800 ft. long, a few feet lower than the rest, to hold the river in a definite position above the weir and to insure sweeping drift of whatsoever size over the structure.

Mr. Clarke's comments on "useless dredging" are most interesting—they differ materially from reports made by those who recommended, built, and are operating the dredge *Imperial* immediately below the Concrete Head-gate. It seems probable that this dredge has not entirely solved the silt problem in the Imperial canal system, as its advocates have enthusiastically proclaimed. Future results will be watched most carefully.

The writer regrets that he did not make clear that no levee failures were caused by the flood of December 7th, 1906, on that portion of the Yuma Project built under Mr. Sellew's direction, for, on taking

charge of the Project, in October, 1906, Mr. Sellew at once ordered muck-ditching under all new levees. This had not been done before, and there were two failures from this cause opposite the Lower Heading on the Project levees, as stated in the paper and illustrated with a photograph, Mr. Sellew to the contrary notwithstanding. The writer remembers this most vividly, because his original design of levees included thorough muck-ditching, which was peremptorily ordered cut out as an avoidable expense, because, up to that time, none had been done in building the levees of the Yuma Project. After the disaster due to the flood of December 7th, 1906, careful examination of the damage to levees on both sides of the river was made and data were collected to show convincingly those not on the "firing line" that, with thorough muck-ditching, all completed levees on the river would have been effective, and the two failures from this cause on the Project levees were considered very significant. Mr. Cory

The writer is inclined to agree with Mr. Sellew that the second break might not have occurred had the borrow-pits been on the river side, because of the peculiar facts of the short duration of that particular flood and the location of the breaks it caused. Nevertheless, the levee would have failed just the same in the several places. Also, muck-ditching would have prevented all trouble. When failure occurs, future construction designed with special reference to preventing that type of failure alone is most unwise, and it was felt that a failure similar to that which happened with the extension of the levees built later by Mr. Ockerson would be quite as disastrous as though caused by lack of muck-ditching or anything else. The design adopted was expected to prove safe from both these dangers, and, thus far, has done so entirely.

It is true that the recommendations of the first and second consulting boards as to levee construction and reconstruction were not followed—a careful reading of these recommendations and of the paper will, it is believed, convince the reader that this was wise. Especial attention is called, for example, to the recommendation on page 1394 to comply with which would have cost $12 000 per mile, though the total cost of the levees, exclusive of gravel blanketing, was considerably less.

As to the efficiency of the interrupted or checkerboard system of borrow-pits, Mr. Grunsky's observations coincide with the writer's, as set forth in the paper. There is no doubt that some—even though slight—additional security is obtained. The question in any case to be decided is whether it is great enough to justify the additional cost. The writer's opinion is that, as the materials grade more and more into those easily eroded, the available precautionary measures are, in their order of effectiveness: river-side borrow-pits with occasional short traverses; river-side continuous borrow-pits; river-side checkerboard

Mr. Cory. borrow-pits; land-side borrow-pits; hydraulic-dredge-built levees, as described by Mr. Grunsky; and, lastly, blanketing with cementing gravel, concrete, etc.

The effectiveness and cost of checkerboard borrow-pits, and consequently whether or not to use them, must be determined for each individual case. With those soils and conditions of vegetation, grade, etc., where they will afford all the needed added security, considerable additional cost is justified; and, where this is not the case, little or no additional expenditures for them is wise. Similarly, as to the cost, with small levees, narrow berms, and easily handled soil—so that the haul is of maximum importance—the additional cost as a percentage will be greater, and *vice versa*. This difference, as set forth in the paper, was actually determined carefully by building adjoining sections of levee with continuous and with checkerboard borrow-pits, using half of one camp on each section and interchanging men and teams daily. Every effort was made to secure otherwise identical conditions, and it is believed with unusual success. The levee was uniformly 8 ft. high, 10 ft. wide on top, slopes, 3 to 1, berms 40 ft., borrow-pits with 50-ft. traverses each 400 ft. in one case, and 100 ft. alternately borrow-pits and undisturbed in the other, depth of pits in both cases, 2½ ft. at levee end and 4 ft. at far end. The material was the Colorado Delta silt described at length in the paper. The costs, excluding contractor's profits, were found to be 19 and 25¾ cents, respectively, per yard of embankment in place on completion; the settlement was very slight. This is in the ratio of 100 to 135.5. Mr. Sellew, with essentially similar work, done under normal instead of rush conditions, reports the costs as 11 and 13 cents, respectively—shop costs only—or in the ratio of 100 to 118. If the reader is interested as to the consistency of these two results, he can compute the average haul in the two classes of borrow-pits and check them up.

The method of constructing levees by hydraulic dredges, as suggested by Mr. Grunsky, has been used to a considerable extent on the Sacramento River, although the material from the muck-ditch is there usually deposited on both the river and land sides of the trench, and the hydraulic fill made in the excavation and space between the two banks. The soil in that locality is such that it does not erode easily, and, more often than not, the levees are located on the river banks. With levees set well back and with the shallow, muddy Colorado, it is very doubtful whether such methods could be used successfully for levee building on that river. Furthermore, the amount of work done, especially during any one year, will probably be so small, and the deterioration and cost of handling a dredge on the lower river so great, that the total levee cost would probably be much higher than by the present methods.

Mr. Grunsky points out that the levees along the river have not yet been subjected to a conclusive test, and suggests two points: seepage under the levees with land-side borrow-pits, and reasons why the levees have not yet needed to be as high as were built. As to the former; miniature, pin-head, under-water volcanoes did appear, but their number and size did not seem to be large, when the effective head was greater, and after a time they stopped entirely. In not a single case did any of these become in any way menacing. Furthermore, last year the water-table rose above the ground surface behind the Reservation Levee of the Yuma Project with river-side borrow-pits, covering a considerable area, and seriously interfering with crops. The action is a rise of the underground water, and not seepage under levee structures. Mr. Cory.

The top grade line of the levees built under the writer's direction has proven to be higher than as yet required because of the abnormal overbank flow and cutting off of Nigger Bend in 1907 (as pointed out by Mr. Grunsky), and later by the Abejas Division, which did lower the river at Yuma, as shown by Fig. 3, and at all points below as far as the diversion, Mr. Sellew to the contrary notwithstanding. Indeed, it was this lowering at the Concrete Head-gate, which, with silting up in the Imperial intake, caused the building of the rock weir across the river at that point in 1910, as commented on by Mr. Clarke. Nevertheless, to have built lower levees would have been taking an unjustifiable risk. This is shown most strikingly by what happened with the levees near the Abejas Dam. In this case the levee grade was fixed by reference to the fresh high-water marks of the 1909 flood which had its outlet down the Abejas, but after that closing was to be held in the old river channel. This latter did not scour down as was expected* and, had the levees held, they would have been overtopped in the vicinity of the dam by a 100 000-sec-ft. river that summer. Fig 90† shows the situation there.

Mr. Grunsky believes the control of the Colorado between permanently fixed banks should not—at least for a long time—be projected beyond some agreed point near the Arizona boundary line, and in this he is joined by the Board of Review which reported on the failure of the Ockerson levees, the writer, and most of those who have been on the "firing line." The exceptions are Mr. Ockerson and Mr. Sellew. This is a matter of judgment, and all available data affecting the matter, for which a place could be made in a paper of this kind, have been given.

Mr. Follett confirms the writer's figures of land slope away from the river banks, and suggests the desirability of a secondary levee from

* See statement by Mr. Ockerson, *Engineering News*, Dec. 7th, 1911.

† Taken from House Document 504, 62d Congress, 2d Session.

Mr. Cory.

the sand hills to the C. D. Co. levee, where it is a mile away from the river, with a gate structure where the main canal is crossed. This idea has been given careful consideration; the Board of Review just mentioned has reported that the money such a secondary levee of defense would cost could be more judiciously expended on the principal levees along the river. The writer agrees with the Board of Review in this.

The writer is surprised, on re-reading the paper on receipt of the discussions, to find that so little had been said about bank protection work. This was partly the result of touching as lightly as possible on unsuccessful river control work done by others, partly because of a tacit understanding with other members of the Society as to the contents of the paper and their discussions thereof, and partly because, since holding the levee embankment on the north side of the Second Break in January, 1907, by gravel and rock revetment, as set forth in the paper and in Mr. Clarke's discussion, the proper way to do such work has seemed obvious. Messrs. Grunsky, Hind, Clarke, Herrmann, and the writer went over this matter together in June, 1907, and agreed as to the general procedure on the lower river—practically

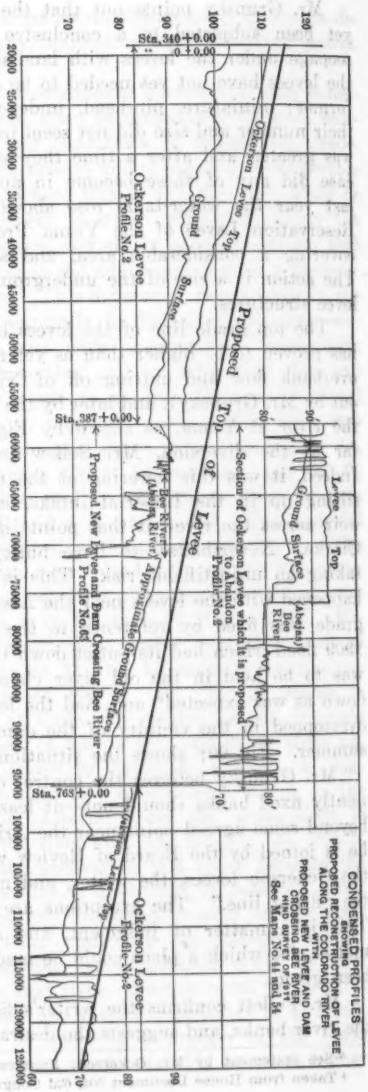

FIG. 90.

that concisely set forth by Mr. Clarke under the heading "Control of the River." Mr. Grunsky reported accordingly to the Secretary of the Interior at the time, and Mr. Sellew has now reached practically the same conclusions, except as to the important difference of reveting only at threatened points and so distributing the work over many years and letting the river do all dredging and placing gravel and rock well down to the limit of scour. In any event, the matter of funds will doubtless distribute the work over a long period, and the procedure recommended helps to arrange the "cutting of the garment according to the cloth." Mr. Cory

With a railroad track on the levees, with large quantities of rock ready in near-by quarries and gravel pits in constant operation, and a very large railway organization which, at any time, on telegraphic notice, will send, for cost plus 10%, work trains, steam shovels, and a completely organized force, the methods of bank and levee production work here seem to the writer to be self-evident. All those who have had to deal with the lower Colorado, except Mr. Ockerson, agree as to the vital importance of a railroad track on these levees.

When thus equipped, and with the foregoing plan of river control and levee revetment, there is no reason for locating levees farther from the bank than needful to provide sufficient waterway for the greatest possible floods. Location farther back means on lower land and hence higher levees and greater difficulty to revet and hold when attacked by bend erosion. Such more distant levee location can at most mean a later date for completing the entire river revetment, and, outside of reasonable limits, this becomes a disadvantage rather than advantage.

Consequently, the writer still feels that:

"Because of the various successful and unsuccessful work done in the region * * *, the Colorado River Delta now presents no unusual, unsolved engineering difficulties; its problems are chiefly matters of statecraft, in both river control and irrigation."

The writer joins with Professor Forbes in regretting that the exceedingly interesting geological sketch and historical review of the Colorado Desert, prepared as a part of this paper, by Professor Blake shortly before his death, could not be utilized in that way. Fortunately, it will appear elsewhere, and its reading is commended to those interested in this subject.

Mr. Chaffey's discussion is of especial interest, not only to the writer and those locally interested, but to many members of the Profession who never had a personal interest in the Lower Colorado. The corrections and criticisms it contains the writer can only admit to be fair; he regrets the inaccuracies in the paper which called them forth, and takes this opportunity to express his pleasure at their being

Mr. Cory. presented. Since the paper was presented, the Supreme Court of California, in Thayer *vs.* California Development Co., finally held the system of mutual water companies and triparty contracts to be legal, and, in addition, commended such plan. This is the first decision handed down squarely on this point, though in other cases the District Federal Court and the State Supreme Court had by indirection practically decided just the opposite. It is, indeed, a sad state of affairs when it takes from 1906, when the first litigation began, until 1913, for investors and settlers to know definitely whether their operations and organizations are within the law. Mr. Mead is right in saying that at least three-fourths of the irrigation enterprises have been financial disasters because the laws were such that there was no adequate security for the money expended. So it is that, in spite of the legality of the plan as finally decided and its excellent basic business principles, it would doubtless have been better had the project been carried out under the Carey Act.

The writer takes pleasure in expressing appreciation of the standing of Mr. George M. Chaffey in irrigation work in the West. The Ontario Colony he founded in 1883 was selected ten years later as a model for the irrigation exhibit at the World's Exposition, and in his work at Mildura, Australia, he designed, had built in England, and installed, the first centrifugal pumps driven by triple-expansion engines, there being four pumps on the same shaft with a total capacity of 320 cu. ft. per sec. lifted 20 ft. He is at present, among other things, head of the magnificent water system irrigating 10 000 acres of citrus lands near Whittier, Cal., including the highest priced agricultural lands in California ($5 000 per acre). Furthermore, he is a man of affairs and of large means which he acquired principally in irrigation enterprises and banking, and hence has the confidence of moneyed interests.

The comments of Mr. Chaffey and Mr. Marshall on soil examination and reports are pertinent and worthy of serious consideration. The effect of the soil reports on the Imperial region was most serious.

It is nearly a year since the paper was written, and in that time the maze of litigation over the Imperial Irrigation System has, if anything, become more complex. Arrangements have been made to supply water to additional lands by the Receivers of both the American and Mexican Companies for 50 cents per acre-foot, with a 10% free allowance for seepage and evaporation, and with no "water right" or water stock charge or requirement. Thus the later comers are getting water for their lands on better terms than the pioneers in the region, and the opportunity for bettering the financial status of both parent companies by the sale of valuable water rights—and so in the last analysis having the new-comers bear a proper share of the inevitable

burden of readjustment, however that is to be accomplished—has been lost. This resulted from an unfortunate hostility between the two Receivers. Dr. Mead is certainly justified in his comments on laws governing irrigation projects. Mr. Cory.

The development of the country is going on more rapidly than ever, and land values have increased very markedly, due to the growing confidence of the outside public. The 1913 shipment of perishable products alone is 3 880 carloads, as follows:

Cantaloupes	3 499
Watermelons	338
Tomatoes	10
Other vegetables	26
Miscellaneous	7

A new high-line east side main is nearly completed which will water an additional 150 000 acres, and surveys have been completed for a Mexican Canal following closely the Paredones delta divide, crossing New River near Volcano Lake and thence northwesterly to the International Boundary Line near where it is crossed by the West Side Canal. These canals have no especially noteworthy engineering features, however.

No progress whatever seems to have been made in international negotiations looking toward joint governmental river control or conservation and division of the Colorado's waters between the two countries.

A very interesting and complete description of the Colorado River Siphon of the Yuma Project, by George Schobinger, Jun. Am. Soc. C. E.,* has recently been presented before the Society.

Paper No. 1271

CONSTRUCTION PROBLEMS, DUMBARTON BRIDGE, CENTRAL CALIFORNIA RAILWAY.*

By E. J. Schneider, M. Am. Soc. C. E.

With Discussion by Messrs. L. J. Le Conte, R. D. Coombs, O. E. Hovey, Lewis D. Rights, Theodore Belzner, and E. J. Schneider.

It is not the object of this paper to give a complete description of all the construction features of the Dumbarton Bridge. The aim and purpose is to outline, in a general way, the field methods, and to discuss details only where exceptional problems were met.

To secure an all-rail route into the City of San Francisco from the main line tracks on the eastern shore of San Francisco Bay, thus to avoid ferrying increasing numbers of freight cars between Oakland and San Francisco, the Central California Railway, better known locally as the Dumbarton Cut-off (Fig. 1), was projected and constructed by the Southern Pacific Company during the three years ending September 30th, 1910. The cut-off connects Niles and Newark on the east side with Redwood City on the west side of the bay. Through this improvement, the all-rail distance between Oakland and San Francisco has been reduced 26.1 miles, as compared with the corresponding earlier distance *via* San José.

The bridge proper consists of a draw-span, 310 ft. in length over all, and three 180-ft., double-track, through, riveted, approach spans at each end of the draw. All structural steelwork was designed in accordance with the Harriman Lines Common Standards of 1906,

using what corresponds to a Cooper *E*-55 loading. The center to center distance of end pins is 1 474 ft.

There is also a considerable length of single-track, creosoted timber, ballasted trestle at each end of the steelwork. The length of the east approach trestle is 1 002 ft., and that of the west approach 5 366 ft. The total length of the entire structure, steel spans and timber trestles, is 7 842 ft., or approximately 1½ miles.

No unusual methods were required in building the timber trestles, which are all of standard type. The bents are 15 ft. on centers, and each bent consists of six piles. The piles are of Oregon fir, and in lengths ranging from 60 to 120 ft., the penetrations in some cases being as great as 60 ft., depending on the depth of the mud.

The specifications call for piles of 10-in. tip in the pier foundations, and for a 9-in. tip for those used in the trestles. The butt diameters were limited only by the width of the gin, which was 22 in. The trestle piles were creosoted; those for the foundation piers supporting the structural steel spans were not creosoted. Fig. 2 shows the pile-drivers used.

Test piles, driven at about 300-ft. centers along the proposed bridge axis, indicated that the depth of the mud varied from 2 to 4 ft. near the middle of the channel, and from 16 to 18 ft. toward the shores of the bay. Under the mud was found a stratum of fine black sand, mixed with gravel, averaging from 15 to 20 ft. in depth, and below this a hard clay. It is interesting to note that no trace of clay was found by the Spring Valley Water Company when making tests only about 500 ft. to the north and on a line paralleling the Dumbarton structure.

According to the original plans, it was the intention to extend the wooden trestles from each shore for the full approach lengths to the rest piers of the draw span; but when the east approach had been completed to within about 120 ft. of the draw, on August 21st, 1907, at 3 A. M., a length of about 120 ft. of trestle was undermined and washed out, precipitating the pile-driver equipment into the bay. There was no storm at the time; the accident was due entirely to the currents produced by the outgoing high tide.

These difficulties at once prompted a modification of the original trestle plans. It was first proposed to alter 200 ft. of the east approach and 600 ft. of the west approach, immediately adjoining the

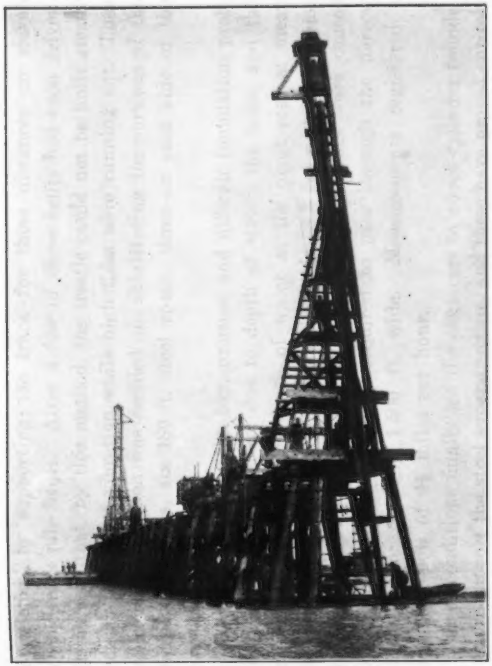

FIG. 2.—DRIVING PILES FOR DUMBARTON POINT TRESTLE.

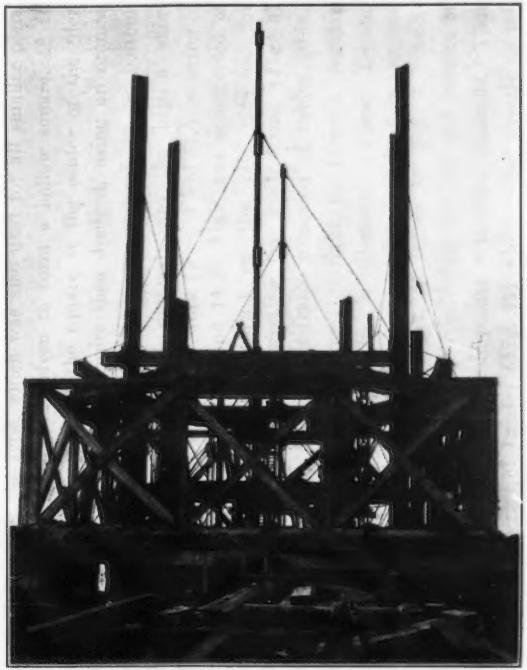

FIG. 3.—ERECTION OF GUIDE-FRAME FOR CYLINDER PIER, DUMBARTON POINT DRAW.

draw span, by supporting the track for these distances on eleven double-track pile bents. After a few of these bents had been driven, it was seen that, by this method, the trestle could not be built steady enough to prevent vibration while high tides were running out. Thus a second modification was decided on, substituting for portions of the trestle approaches, six 180-ft. steel spans, three on each side of the draw (Fig. 8).

At this location in the bay, unusual and difficult foundation problems presented themselves, due to depth of water, the tides, and the nature of the soil. The depth of water at the pivot pier at mean low tide is 51 ft.; at extreme high tide it is 58.3 ft., with an extreme range of tide levels of 11.7 ft. Very rapid currents were caused by the large prisms of water required to pass through the narrow channel, approximately 1 500 ft. wide. Measurements registered a maximum flow of 4½ miles per hour.

These conditions finally led the engineers to adopt cylinder foundations to support the steel superstructure, and these have proved entirely satisfactory. They selected for the type of pier a cylindrical steel shell, enclosing piles and concrete. A description of the 40-ft. pivot pier will illustrate the type, which was also used for all smaller piers. Eight clusters of piles were driven to form a hollow square, 48 ft. on a side, with the center of the square at the center of the pier. About 10 ft. of mud and sand were then dredged, using an orange-peel bucket. The dredged material was placed in a bottom-dropping scow, transported, and dumped into the bay a short distance from the bridge site. Falsework (Figs. 4 and 5), consisting of four wooden trusses, 44 ft. long and 14 ft. high, was constructed of 12 by 12-in. timbers and supported on the pile clusters, for the purpose of sustaining and erecting the guide-frame (Fig. 3) for the steel cylinders. The guide-frame consisted of twelve 20-in., 65-lb. I-beams, 80 ft. long, placed upright to form a regular, twelve-sided polygon about 39 ft. in diameter. These I-beam columns were braced horizontally at intervals of 12 ft. 6 in. by two 12-in. channels placed back to back, as shown by Fig. 6. Additional stiffening was obtained by reinforcing the top and bottom of these 12-in. channels at their mid-points with 8-in. channels. Thus was formed a series of trusses (Fig. 15) which added greatly to the lateral stiffness of the entire frame. In general appearance the guide-

frame resembled the framework for a gas holder (Fig. 9). As the frame was built it was lowered by tackle until it rested on the soil. Then it was weighted to refusal by loading 300 tons of steel on its top. To assist in securing an even settlement, a $\frac{3}{8}$-in. water jet was used, while the I-beam columns were tapped with a pile hammer. The guide-frame came to refusal when the first set of horizontal channel struts rested on the sand bottom. These struts were 17 ft. 4 in. above the lowest parts of the frame. The three lower courses (Fig. 7) of the steel cylinder were then assembled on the falsework, and with rope tackles were lowered as a unit into position. A clearance of $\frac{1}{2}$ in. was allowed between the outer flange of the upright I-beams and the webs of the guide-channels which were attached to the shell. A rail was fastened to the top of the section of the shell with clips at each of the twelve points adjacent to the upright I-beam columns of the guide-frame. These rails were used as level rods, being appropriately marked. The shell was driven to refusal, with an even settlement, the bottom edge resting 6 ft. below the lowest horizontal struts of the guide-frame.

The space within the cylinder shell was then further excavated, the center portion being dredged about 5 ft. deeper than at the outside, which just about offset the uplift of the ground, due to the driving of the outside row of piles first and working toward the center with succeeding piles. Two skid pile-drivers, with an overhang of 30 ft., were used (Fig. 11), working from the pier protection used to support them. Inside the steel cylinder 141 piles were driven, at about 32-in. centers, as shown by Fig. 15. Care was taken to place each pile as nearly as possible to match its position on the pile plan. A pile, in position for driving, is shown by Fig. 10. A diver cut off two-thirds of the piles at an average height of 3 ft. above the bottom of the cylinder; the remaining piles extended to within 15 ft. of the top of the pier, or about 13 ft. below the top of the guide-frame.

Before the second unit of the steel cylinder was placed, the lower section was filled with concrete to within 7 ft. of its top, this being the highest level to which the concrete could be placed without disturbance from the tidal currents passing over the top of the section. A bottom-dump bucket was used, having a capacity of 18 cu. ft. Care was taken to provide an even distribution of concrete. A diver was

employed continuously. He found that the concrete materials had very little tendency to spread, because the concrete was being deposited in still water. The second unit of the shell was then assembled and lowered to place.

To provide for a good connection between the units, a rather unique detail (Fig. 16) was evolved. The guide-frame was relied on to bring the joints to proper position and hold them there, but, to insure a more perfect bearing, continuous, flanged-steel plates, ½ in. thick, were riveted around the entire outside of the cylinder on the upper sections at Joints 5, 8, and 11. Flanged clips, of ½-in. steel plates 8 in. long, were placed around the interior of the cylinder, and were 2 ft. from center to center. Thus a butt joint was formed, with cylindrical flange plates on the outside and flange clips on the inside. This portion of the work was also watched very carefully by a diver as the unit was lowered into position, the result being that an even bearing was obtained and also a very satisfactory connection.

Concrete was placed to a level of about 7 ft. from the top of the second unit in the same manner as already described. The various operations were continued until the pier was completed to a level above the permanent water line. After this stage of the work 1 000-lb. coal buckets were used to place the concrete, as shown by Figs. 12 and 13.

The falsework trusses were dismantled and taken down when the last section of the steel cylinder had been lowered into place (Fig. 14). The piles of the falsework dolphins were pulled with the aid of two donkey engines.

The construction for the end abutment piers of the draw span, and also for the piers of the approach spans (Fig. 17), was carried on in approximately the same way as for the pivot pier, so far as work below water was concerned. As no protection was provided for the abutment piers, the foundation piles were driven with a skid driver resting on a scow. This driver (Fig. 18) was elevated on cribwork to provide the necessary clearance above the guide-frames. In the smaller piers only 5 of the 25 piles were cut off at a low level by a diver (Fig. 19); the remaining 20 piles were allowed to extend well up into the top of the shell.

With the exception of the pivot pier, all foundation cylinders were 18 ft. in diameter to an elevation 2 ft. above high water. Above

this level the diameter for the steel shells of the abutment piers for the draw span was reduced to 12 ft. (Fig. 20); for the cylinders under the fixed spans the diameter was reduced to 14 ft. These reductions in diameter permitted of an easy adjustment due to errors in alignment in placing the lower shells (Fig. 23).

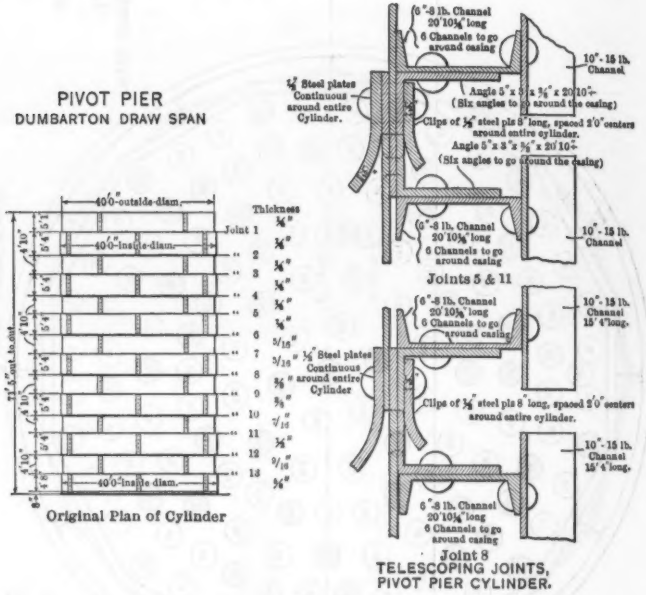

FIG. 16.

To insure a good bond in the cylinder piers at the sections where the 18-ft. diameter was reduced to 12 or 14 ft., fifteen 10-ft. lengths of old steel rail were placed vertically in each cylinder, and spaced around a circumference about 15 in. inside of the upper cylinder. These rails were lashed to the pier girders by steel cables, holes being cut through the webs of the girders where required.

Each of the two rest piers of the draw span consisted of four cylinders (Fig. 21). Above the water line the 12-ft. sections were braced and tied together by four plate girders, each 96 in. in depth. The two girders running parallel to the track line extended through and were riveted to the farther sides of the cylinders. The

FIG. 23.

two cross-girders were framed into the longitudinal ones. To provide clearance for placing the grillage beams under the bridge shoes, it was necessary to cut from each end of each girder a portion of the top flange and web.

Each pier under the approach spans consisted of two cylinders, the lower sections 18 ft. in diameter, the upper ones 14 ft. in diameter, as already explained. The 14-ft. sections were tied together by two plate girders, each 7 ft. 2 in. in depth.

The anchor-bolts for all spans were placed as the concrete was poured. The only provision made for adjustment was that provided by the slotted holes of the shoes.

The erection of the draw span required no unusual methods. The material as it arrived from the plant was unloaded along the tracks, so that it could be placed on a barge as required. The unloading derrick (Fig. 22) was somewhat out of the ordinary in that the A-frame was pin-connected, which permitted it to be raised or lowered, an important and advantageous feature in railroad work. The draw-span trusses, floor, and bracing, were assembled and erected on the draw-span protection in a position at right angles to the line of track. A double derrick or traveler (Fig. 24), running on four lines of rails, enabled the erecting crew to make rapid progress. The span was assembled complete (Fig. 25), ready for riveting, in 14 days. Figs. 26 and 27 show the draw-span.

The six approach spans were floated into position. To facilitate their erection on land, pile bents were driven in the shallow water of the bay shore on the Newark side. A sufficient number of pile bents of this character were built to permit the assembling of two spans at once (Fig. 28). When one span was thus assembled and completely riveted, the temporary trusses of the falsework were knocked out and barges were placed in position. The old steamer *Thoroughfare,* which for many years had been used to ferry freight cars across San Francisco Bay, incidentally having been condemned by the Government, was cut in two, bulkheaded, and, as though by the irony of fate, assisted in the erection of the bridge which is destined to relegate to the past the scheme of bay transportation, for which the old steamer was originally built.

Particular care was used in selecting the time to float the various approach spans into position on the cylinder piers. At the erection

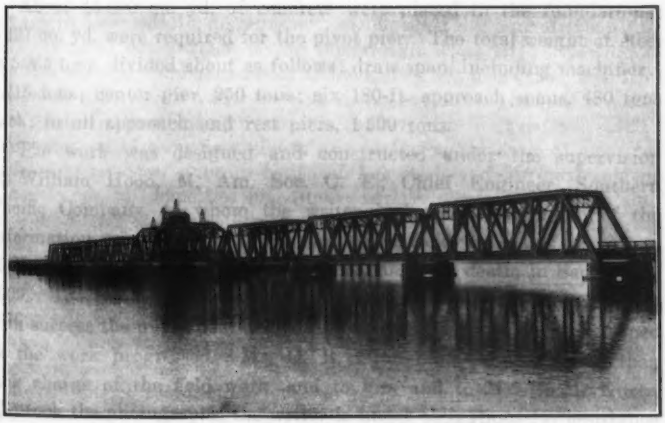

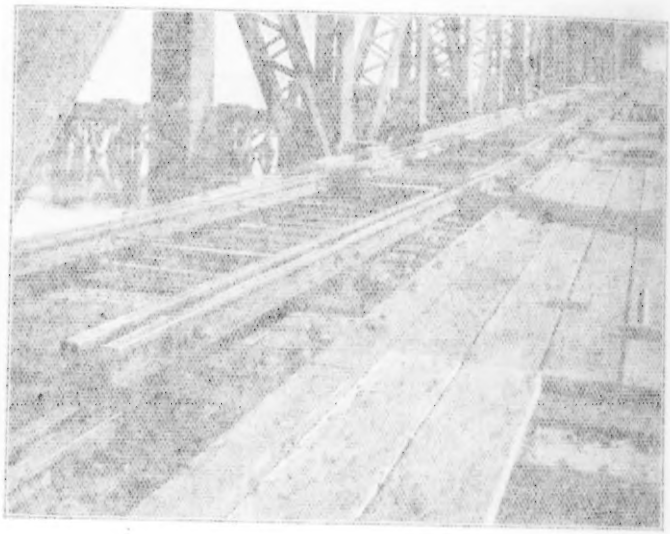

FIG. 35.—DUMBARTON POINT BRIDGE.

site the barges were placed under the spans at low water, so that the rising tide would lift the steelwork clear from the temporary pile supports. The spans were towed against the tide (Fig. 29). When a span got into position between its cylinder piers (Fig. 30) block and tackle lines were thrown out and made fast to the piers. These lines were connected with donkey engines and capstans, so that a span could be adjusted to its proper position over the grillage beams (Fig. 31) and hold it while being lowered. The lowering was accomplished by opening sea valves in the barge. When the span was in place on the grillage, the cribbing was knocked out and the barge withdrawn. The average time required to place a span, from the time it left the falsework on the shore until the removal of the barge from under it at the piers, was about 2 hours, but in each case depended somewhat on the distance the span had to be towed.

To provide for a continuous rail (Fig. 34) at the ends of the draw span, the inside flanges of the guide and traffic rails were cut off flush with the web to permit the rails to slip over a cast-steel filler block. The rails were hinged with a slotted hole at the other end, where a similar casting was placed. The engine which provides turning power for the draw also operates the end track-lifting devices. The bridge is opened or closed in 2 min. Fig. 35 is a view of the completed bridge.

About 15 000 cu. yd. of concrete were placed in the foundations; 3 137 cu. yd. were required for the pivot pier. The total weight of steel is 5 935 tons, divided about as follows: draw span, including machinery, 1 215 tons; center pier, 250 tons; six 180-ft. approach spans, 480 tons each; in all approach and rest piers, 1 590 tons.

The work was designed and constructed under the supervision of William Hood, M. Am. Soc. C. E., Chief Engineer, Southern Pacific Company, to whom the writer is indebted for much of the information contained in this paper. The field work was in charge of Mr. W. E. Marsh, Assistant Engineer, until his death, in September, 1909. Too much credit cannot be given to Mr. Marsh for devising with success the many field details and operations which were developed as the work progressed. Mr. C. R. Broughton, his assistant, then took charge of the field work, and to him and to Mr. C. M. Kurtz, who took the photographs, the writer is under obligations for assistance in collecting the facts described in this paper.

DISCUSSION

Mr. Le Conte.

L. J. Le Conte, M. Am. Soc. C. E. (by letter).—The writer is very much interested in the subject presented in this paper, inasmuch as he was officially connected with the progressive changes made in the proposed plans, and in the final acceptance of the bridge after completion. The local struggles with bad foundations make the construction of the "Dumbarton Cut-off" one of the most instructive pieces of bridgework in the State of California.

The first trouble encountered was when an attempt was made to put in ordinary trestle approaches from the shore line on each side out to the site of the draw span. These approaches, as well as the draw span, were double-track structures. After a long and expensive struggle, it was found to be impossible to maintain a trestle bridge in the deep and strong tidal currents which prevail at the bridge site. It was finally concluded to put in six 180-ft. through riveted spans, three on each side of the draw-span. This caused a great increase in the cost, which was naturally very embarrassing.

The troubles with bad foundations, however, had just begun to develop. For the land approach across the salt marsh from Newark, westward to the bay shore, the plan adopted was to build the embankment by dredging two canals (one on each side), and depositing the material in the embankment lying between. This method led to much trouble in the maintenance of way. The first tracks laid, of course, were only for construction trains, but the embankment settled so irregularly that the track lines could not be kept passable, even for them, which means a great deal to one of experience. This trouble continued during the time of the construction of the steel bridge in its entirety. The track lines could not be maintained in serviceable condition, because of the settlement of the embankment and the gradual rising of the beds of the two canals on each side. Finally, the Southern Pacific Company, in desperation, obtained two hydraulic dredges, and put them to work filling up the two canals with good heavy materials, dredged from the bay shore and deposited through two long pipe lines. This expedient had the desired result, and settlement of the embankment practically came to an end. The permanent track lines were then established and well ballasted, and the "Dumbarton Cut-off", after three years' operations, was officially opened to general traffic on September 30th, 1910.

The author's description of the method of putting in the center pier of the draw-span is most interesting and instructive. Of course, engineers differ as to the best method of laying concrete under water. The writer is decidedly in favor of the judicious use of the "tremie", as being the most rapid, and therefore the most satisfactory, method. The principle to bear constantly in mind is that, where the face of the

freshly laid concrete is being constantly washed by the ponded water, the faster the concrete is laid the less effect the water will have on it. By rushing the rate of laying, the water has not time enough to act on any one face before a new layer is right on top of it, hence, the quicker the laying is done, the better the results. Mr. Le Conte.

This principle was first called to the writer's attention in 1872, by the late Gen. B. S. Alexander, Corps of Engineers, U. S. A., who stated that he got it from the late Gen. Joseph Gilbert Totten, Corps of Engineers, U. S. A., Hon. M. Am. Soc. C. E., at Dry Tortugas, off the south end of Florida. The experience, therefore, is of long standing.

The writer wishes to express his profound regards for the late Mr. W. E. Marsh, Assistant Engineer, Southern Pacific Company, who extended many courtesies to him during his official inspections. The Dumbarton Bridge stands to-day as a lasting monument to wise judgment and good construction.

R. D. Coombs, M. Am. Soc. C. E.—The speaker is particularly impressed with the size of the piles used, the lengths being from 60 to 120 ft. and the diameter of the tips either 9 or 10 in. In the East such sizes are not obtainable for ordinary work. The question arises: Was it thought necessary to use large tips in order to increase the bearing power of the piles, a necessity not indicated, at least to the speaker's mind, if the underlying soil was sand and clay? Mr. Coombs.

A certain proportion of the foundation piles extended up into the concrete piers, presumably as an anchorage, and the speaker would inquire whether such piles were peeled. In several cases in which the concrete foundations were very shallow, the speaker has extended the piles as far as possible into the concrete, using peeled piles with spikes driven into the sides of the embedded portion. The exact anchorage value of this method is not definitely known, but it is undoubtedly considerable.

Referring to the advisability of penetrating so-called crusts, the speaker believes it is usually necessary to do so in pile work, particularly where the "crust" is a vegetable deposit underlaid by sand or clay, or both. In some sections of the New Jersey swamps there is a peat-like deposit about 10 ft. deep, which, if unbroken, might carry a highway load, but is useless for pile foundations. However, the sand and clay below will support heavy loads by skin friction very effectually.

Is it not true that the old formula for the drop-hammer is just as inaccurate as any new formula for the steam-hammer? Is not pile-driving mainly a matter of judgment? In the speaker's opinion, it is.

As an illustration, two more or less typical experiences may be cited: In one, the foreman informed the speaker that he had just driven a spliced pile 190 ft. long. Naturally, he was at once assured

Mr. Coombs. that he had not done anything of the kind. The fact was that, through a conscientious attempt to obtain the usual penetration per blow, the piles were being broken at the splices and driven horizontally. Hard bottom was not more than 40 ft. below the surface.

In the second case, piles from 65 to 75 ft. long, driven in blue clay, for a wharf, were stopped under easy driving to prevent them from going below cut-off. A few months later, stevedores unloaded 80-lb. rails on the wharf, piling them 6 ft. high, and there was no settlement.

Mr. Hovey. O. E. HOVEY, M. AM. SOC. C. E.—The speaker has been much interested in this concise and well-illustrated paper; and, though there are many interesting details in the draw-bridge superstructure which might be mentioned if any extended discussion of it was undertaken, only a few points, which were of particular interest to him during the design of the draw-span, early in 1907, will be mentioned. The Dumbarton draw-span was one of the heaviest center-bearing spans which had come to the speaker's notice at the time the design was made. The center-bearing type of draw was considered to be particularly desirable in this location on account of the difficulty in securing foundations, the simpler details of the center, the rigidity of the bridge under traffic after the wedges at its ends and center were driven home, and the ease with which final adjustments of height of center and end supports could be made during construction in case there was any settlement of the piers. The center bearing of this bridge was designed for a total load of about 2 600 000 lb. Grillages of I-beams were embedded in the concrete of the end and center piers, under the end and center wedge supports and the center pivot. The center pivot casting rested directly on the top of the center grillage, and the disks at the top of this casting consisted of two steel plano-concave and one phosphor-bronze double convex disks, 36 in. in diameter. These disks were the largest with which the speaker was familiar at the time the design was made, although much larger ones have been used more recently in the manufacture of draw-bridges, the largest with which the speaker is familiar being those supporting the Southern Pacific draw-span over the Sacramento River, at Sacramento, Cal., which are 52 in. in diameter.

The design of the power plant in the operator's house of the Dumbarton draw is of interest because, although it was expected ultimately to use electric energy for operating the draw, electric current would not be available at the time the bridge was completed, and it was necessary, therefore, to provide some other source of power temporarily, and desirable to have an alternate power available, even after the electric current was in use. For the permanent equipment a 52-h.p. motor, designed to use 440-volt alternating current, was provided. For temporary and alternative use an 80-h.p., three-cylinder, four-cycle, gaso-

line engine, running at about 300 rev. per min., was selected. In the operation of this draw-bridge it is necessary to provide, from one source of energy, means to lower and raise the center and end wedges, and also to open and close the bridge itself, four separate operations being required. The type of gasoline engine selected was not reversible, therefore special transmission mechanism was necessary to produce rotations in each direction for lowering and raising the ends of the bridge and for opening and closing the main structure. Many bridges have been built with mechanism to provide for these four motions, but, in a large number of cases, the necessary shafts, gears, clutches, levers, etc., have been located in various positions on the superstructure. In conformity with the well-established practice of the builders of this bridge, it was decided to use a type of transmission mechanism, between the gasoline engine and the main shafts of the bridge, which would be entirely within the operator's house and self-contained on a large cast-iron bed-plate, so that the transmission mechanism could be assembled and carefully aligned in the shop and then shipped to the bridge in such condition that a minimum of field work would be necessary in placing and adjusting it. This transmission mechanism included two mechanical and two friction clutches, with the necessary shafts, gears, and friction-band brake control, all actuated by the operator from a central point. Mr. Hovey

The electric motor selected was of the ordinary reversible type, and therefore required special transmission mechanism to shift the application of power to the wedge-operating shafts or bridge-turning shafts at pleasure; but it did not require special mechanical provision for reversing the direction of rotation. To keep the whole mechanism compact and rigid, it was decided to place the motor on a cast-iron base which was carefully fitted and bolted against one end of the cast-iron base of the gasoline engine transmission mechanism. The motor base also supported bearings for a countershaft, the pinion of which was arranged to mesh directly with a gear on the extended end of a countershaft of the gasoline engine transmission mechanism. The motor countershaft was also provided with a friction cut-off coupling, so that by moving a hand-lever the motor could be thrown into engagement with the gasoline engine transmission mechanism or allowed to run idle. By this construction, it will be noted, the transmission mechanism can be driven by the gasoline engine or by the electric motor, at pleasure, and in case of necessity a shift from electric power to gasoline engine power can be made simply by releasing a clutch and starting the gasoline engine.

On account of the location and weight of the bridge, the time of opening and closing was fixed at 2 min., as stated in the paper. During a visit to the Pacific Coast in July, 1912, the speaker had an oppor-

Mr. Hovey.

tunity to inspect the Dumbarton Draw-Bridge, and during this inspection the bridge was opened by the operator, who did not know that he was being timed. Beginning with the first movement to set the railroad signals—the signals were set at danger—the operator on the bridge received his signal to open, and the cold gasoline engine was started and operating speed was attained in 60 sec.; 20 sec. were required to lower the ends of the bridge; 5 sec. were used in throwing the clutches from the wedge-operating shafts to the bridge-turning shafts; and 85 sec. sufficed to open the bridge 90°; thus making the total time from the first motion of the signals to the fully open position of the bridge, 2 min. and 50 sec.

The speaker visited many draw-bridges on the Pacific Coast, but did not see an operator's house, or a set of bridge mechanism, in such perfect condition as that on the Dumbarton Bridge. The bridge operator evidently took great pride in the maintenance of the structure. The bridge machinery, after practically two years' use, was as clean as one would expect to find well-maintained machines in a shop, and the operator's house, in all its appointments, was a model of neatness.

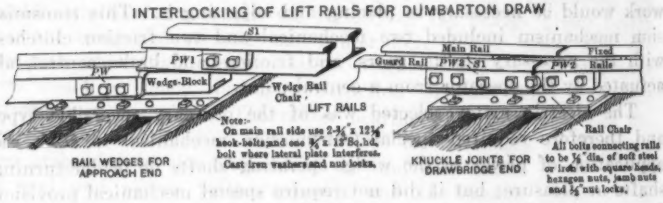

FIG. 36.

The author mentions the lifting rail joints, but does not give full details of their construction. The speaker observed that these joints were in perfect condition, after having been in service for about two years, under heavy freight traffic, and that they were of a somewhat unusual design, their construction being illustrated in Fig. 36.

The main and guard-lifting rails are bolted together with close-fitting separators, *S* 1, hinged to the fixed rails on the draw-span, and supported on the rail chair, *R C*. The lifting ends extend over on to the approach span, a distance of about 4 ft., where they seat on a wedge rail chair, *W R C*. The bottom flanges of the main and guard rails are coped off on the inside to allow them to slide up and down on the wedge-blocks which are riveted down to the base-plates of the wedge rail chair by countersunk rivets, and form a firm support, holding the rails true to gauge.

The wedge-block is of such shape as to clear the flanges of passing wheels, and its sides are extended up and finished to fit the under side of the rail heads, thus giving them good support. In a later design,

short easing rails were added outside of the main rails to support wheels with worn treads while passing over the joint, so that their flanges would not rest on the wedge-blocks. Lifting rails of many designs have proved unsatisfactory and expensive to maintain and operate, and experience with funnel rails seems to justify their use. Mr. Howey.

In reference to the large piles used on this work, the speaker would state that it is much easier and cheaper to obtain such piles on the Pacific Coast than near New York City, and their use insures a better foundation than is likely to be obtained by the small slender piles frequently found in this section of the country.

LEWIS D. RIGHTS, M. AM. SOC. C. E.—The author is to be congratulated on the concise and clear manner in which he has covered the engineering features connected with this bridge. The speaker is interested in the description of the erection of the steelwork, which seems to have proceeded in a very expeditious manner. Mr. Rights.

Mr. Schneider speaks of the novel construction of a derrick-car, which, according to the illustrations, consisted of a hinged **A**-frame placed on a standard flatcar. Such tools have become common in the East, and almost every bridge company owns one or more. Hinged **A**-frames of wood have been in use for some years, and, about ten years ago, S. P. Mitchell, M. Am. Soc. C. E., conceived the idea of building a special steel car with a hinged steel **A**-frame. A car of this kind was used successfully in connection with the erection of the Warehouse Point Bridge, where the New York, New Haven and Hartford Railroad crosses the Connecticut River, below Springfield, Mass. Mr. Mitchell then substituted heavy steel struts for back-stays, patented the invention, and has built, or authorized the construction of, a number of cars. The **A**-frame is 23 ft. high, making the total height of the car when in use about 27 ft. Such height of mast is necessary for booms of 50 and 60 ft., and cars have been built recently with masts some 7 ft. higher. The standard overhead clearance for the Middle Western roads is 22 ft. above the rail, and as this is not sufficient to clear the top of the **A**-frame, Mr. Mitchell has made arrangements to lean the frame back and shorten the back-struts by a series of pin-holes in the latter. On some of the Eastern railroads, especially the New England roads, the overhead clearance is very much less than 22 ft.; in some cases it is only about 15 ft., with a minimum of 14 ft. 6 in. This is not much more than sufficient to pass a high furniture car, and it is not always practicable to lean the **A**-frame back far enough to be able to work under such clearances. In the last few years some of the Eastern concerns have attempted to overcome this difficulty by building a heavy steel frame, the top chords of which occupy about the same position as the eaves of a box car. One company has made the front posts of this frame hollow, so that

Mr. Rights. an A-frame can telescope into them. An arrangement of pin-holes enables work to be done with an A-frame at a height very little above that of a box car, or to extend the frame so as to give a mast of about 18 ft. Several other companies have used this same type, but have hinged a short A-frame on the top of the steel truss, instead of at the car floor.

Another feature of interest in connection with the erection of the Dumbarton Bridge is the illustration of the double-headed traveler. It would seem that the single booms at each end of this traveler were designed with the idea of working alternately on the fixed spans, and that probably only one boom was worked to advantage at any one time. A single boom for the erection of a truss was not considered good practice several years ago, owing to the number of pieces which had to be held in place while a connection was being made, but the introduction of riveted joints has produced quite a change in methods. Recently, derrick-cars have been used very successfully in the erection of riveted trusses, although there are engineers and erectors who maintain that other tools are more efficient. In this matter, it is sometimes difficult to decide as to the most efficient method of erecting steelwork. Several years ago, the New York, New Haven and Hartford Railroad, in extending its six-track line into New York City, built a great number of overhead bridges for the separation of street and railroad grades. The bridges were designed for New York City paving standards and very heavy live loads, and consisted of three trusses with double roadways and sidewalks. The spans were not very long, 120 ft. probably being the average. It happened that during a period of about 18 months, four different bridge companies secured contracts for four bridges, the details of which were very similar. They were all overhead highway bridges, with the erection conditions almost exactly the same, and the interesting feature was that each of the four companies used a different method of erection.

One company used a steel gallows, or gantry traveler, reaching above the trusses, and erected the steel from fixed hoists.

The second company erected two heavy steel derricks in the street, one at each abutment, with booms long enough to meet at the middle of the span.

The third company had two derrick cars, one of which was placed on the upper falsework and was used for erecting the trusses; the other was used down on the railroad grade to supply the upper one with material.

The fourth concern built a two-boom mule traveler, that is, a low-decked traveler with two masts and booms. The booms reached out over the falsework to get material from the cars below.

Mr. Rights.

The speaker was interested in the erection of one lot of bridges, and watched carefully to see what the other companies were doing, in order to learn whether there was any marked difference in the methods. As far as he could see, each concern was guided in the choice of erection tools by what it had on hand, and there did not seem to be any very great advantage of one kind of tool over the other. The speaker is satisfied that the method in which he was interested was the best; but the representatives of the other concerns feel the same way about their methods, so that the question is still open.

Mr. Belzner.

THEODORE BELZNER, ASSOC. AM. SOC. C. E. (by letter).—The floating of the six approach spans into position, recalls to the writer operations of a similar nature on the Harlem River Ship Canal Bridge during the fall of 1905 and the summer of 1906.

The author states that the average time required to place a span was about 2 hours, depending on the distance it had to be moved. More information concerning the itinerary of the work, such as rate of motion, distance floated, etc., for each operation, would be of interest.

In reference to the floating of the approach and draw-spans of the Harlem River Ship Canal Bridge at Kingsbridge, it may be of interest to state briefly the actual times required in the six operations of moving the old and placing the new spans.

The Department of Bridges of the City of New York issued a permit closing the Ship Canal Bridge to street travel for a total time of 5 days, of which not more than 3 days were to be consecutive. It was calculated that only 1 day would be necessary for moving each of the approach spans and that the draw-span operations could be completed in 3 days.

Prior to the removal of the old approach spans, the new spans were moved to points about 115 ft. east and west of their final positions (these movements consisting of a land and water operation). The two old spans were 100 ft. long and weighed 240 tons each; the two new spans were 100 and 112 ft. long, and weighed 330 and 380 tons, respectively. The old draw-span was 272 ft. long, weighed 900 tons, exclusive of cribbing, and was floated from Kingsbridge to the University Heights site, a distance of about 1 mile. The new draw-span was also 272 ft. long, weighed 1 500 tons (and with the cribbing nearly 2 000 tons), and was floated from 216th Street, a distance of $\frac{1}{2}$ mile to its new site at Kingsbridge.

On October 19th, 1905, at 5 A. M., the south approach span operation was begun, and at 5.45 P. M. the first vehicle passed over the bridge, the time elapsed being $12\frac{3}{4}$ hours. On November 6th, at 1.30 P. M., the north approach operation was begun, and at 10.15 P. M. the bridge was opened to surface traffic, the time elapsed being $8\frac{3}{4}$ hours. These

Mr. Belzner.

operations delayed travel 21½ hours, or 26½ hours less than the calculated time.

The draw-span operations extended from 10.15 A. M. on June 14th, 1906, to 5.20 A. M. on June 17th, the time elapsed being 2 days, 19 hours, and 5 min., or 4 hours and 55 min. less than the stipulated time.

In other words, the entire operations were accomplished in 3 days, 16 hours and 35 min., or 1 day, 7 hours and 25 min. less than the 5-day limit.

Mr. Schneider.

E. J. SCHNEIDER, M. AM. SOC. C. E. (by letter).—It has been particularly gratifying to the writer to note the interest which has been taken in this paper. Certain points are raised by Mr. Rights regarding the double-ended traveler: The single booms at each end of the traveler were designed especially for facility in erection of the draw-span, which was erected as symmetrically as practicable, from the center toward each end, on top of the protection work which had been designed to act as falsework. Had the traveler not been double-ended, additional falsework would have been required at one end of the draw-span protection and at the site of the erection of the six 180-ft. spans.

Answering Mr. Coombs in regard to piles and pile-driving: The specifications called for lengths of from 60 to 120 ft., the diameter of the tips to be 9 or 10 in., the usual requirements by the Southern Pacific Company for ordinary work, and no change was made in them for this particular piece of construction. Pacific Coast piles, no doubt, are larger than those ordinarily used in the East. All piles used at Dumbarton were peeled.

TABLE 1.—RECORD FOR FLOATING SIX 180-FOOT SPANS FROM FALSEWORK TO PIERS, FOR THE DUMBARTON BRIDGE.

The Span Numbers Run from East to West, Numbering the Entire Draw-Bridge as Span No. 4.

Date.	Span No.	Hour.		Time interval.	Approximate distance floated, in feet.
		Clear of falsework.	Landed on piers.		
September 16th, 1909.....	3	12.25 P. M.	2.00 P. M.	1 hr. 35 min.	700
September 26th, 1909.....	2	9.30 A. M.	11.00 A. M.	1 " 30 "	500
October 14th, 1909.....	1	10.55 A. M.	12.15 P. M.	1 " 20 "	300
November 7th, 1909.....	5	8.25 A. M.	9.40 A. M.	1 " 15 "	1 200
December 9th, 1909.	6	7.45 A. M.	9.50 A. M.	2 " 05 "	1 400
December 11th, 1909.....	7	10.05 A. M.	11.05 A. M.	2 " 00 "	1 600

Pile-driving is mainly a matter of judgment. The lengths of the piles at Dumbarton were determined from actual test driving on the

Mr. Schneider.

line across the Bay, and from the records of the borings made by the Spring Valley Water Company on the line of its submerged pipe a short distance from, and approximately parallel to, the bridge.

The points brought up by Mr. Belzner, in reference to the average rate of motion, distance floated, etc., for each operation, can best be answered by a copy of the record for floating the six spans from the falsework to the piers, Table 1.

The average rate of motion for each operation was a little less than 1 mile per hour.

Paper No. 1272

THE ABSORPTION OF OXYGEN BY DE-AERATED WATER.

By Earle B. Phelps, Assoc. Am. Soc. C. E.

With Discussion by Messrs. W. E. Adeney and Earle B. Phelps.

The Report of the Metropolitan Sewerage Commission of New York, dated August 1st, 1912, and recently issued, contains, among other interesting material, a Report by Dr. W. E. Adeney, in which especial attention is given to the subject of re-aeration of polluted tidal waters. Dr. Adeney's views and conclusions are in many respects directly contradictory to those which William M. Black, M. Am. Soc. C. E., Colonel, Corps of Engineers, United States Army, and the writer reached after a study of this problem, in connection with New York Harbor, and fully stated in a report to the Board of Estimate and Apportionment of New York City, published March 23d, 1911. As this last-named report did not have a wide circulation, and as the matter under discussion is one of great importance, not only in the case of New York Harbor, but in all similar situations, it seems appropriate at this time to consider the facts and the conclusions that have been drawn therefrom by various workers.

Dr. Adeney made the first important contribution to this subject in his well-known experiments undertaken on behalf of the British Royal Commission on Sewage Disposal. His results are fully set forth in Appendix VI of the Fifth Report of that Commission.

He describes experiments, with glass tubes 6 ft. long and ¾ in. in internal diameter, in which he exposed de-aerated water under varying conditions, and, at the expiration of stated times, withdrew samples

from various depths and submitted them to analysis for dissolved oxygen and nitrogen. Both sea water and distilled water were used. He found that, with either kind of water, mere exposure of the upper surface to the air resulted in practically negligible re-aeration in the lower depths. He reported a tendency toward accumulation of the dissolved gases in the upper layers, which was greater in the distilled water than in the sea water, under these conditions. He next closed the top of the tube, introduced a small tube just below the surface of the water, and, by suction, caused a slight current of air to bubble through the top layer of water. This led to a slightly greater absorption on the part of the distilled water. In the case of the sea water, however, this method of procedure resulted in a fairly rapid absorption of oxygen and of nitrogen, and the quantities of these gases found at various depths at the conclusion of each experiment showed a tendency toward uniform distribution.

Dr. Adeney refers to this phenomenon as the "streaming effect", and identifies it with a similar effect obtained by Huefner under quite different circumstances. He adduces evidence, although inconclusive, that Huefner's theory of a direct streaming of the liquid, brought about by difference in specific gravity, is not tenable. He did not investigate fully the cause of the streaming effect, but believed it might be due to:

"* * * minute dust particles, or by other centres of condensation, possibly of an electrical nature, carried by the air current and being taken up by the water together with the gaseous constituents of the air, and that these bring about in some way a sufficient density of the dissolved or condensed gases to render it possible for them to be drawn gravitationally downwards through water."*

The previous passage of the air through one tube of water destroyed to a large degree its power to bring about this streaming effect in a second tube, while the power was completely lost by passing it twice through water, thence into a third tube. Dr. Adeney suggested that the ions, or dust particles, or whatever may be the exciting cause, were removed by such treatment.

Col. Black and the writer showed by experiments with dyes and by determining the amount of evaporation resulting from the passage of dry, or partly dry, air into a tube of water, following Dr. Adeney's

*British Royal Commission on Sewage Disposal, Fifth Report, Appendix VI, p. 64.

technique, that this streaming effect, so-called, was caused by a true streaming of water currents. These currents are caused by an increased specific gravity of the salt solution following evaporation of the water from the surface layer. This explains also the effect of using two or three tubes in series, and the absence of any material streaming in fresh water. In the latter case, a slight tendency toward streaming was observed, and, without further investigation, this was ascribed to a slight lowering of the temperature at the surface, due to evaporation, and the consequent increase in the density of the surface layer. Undoubtedly, also, the increased density resulting from the solution of atmospheric gases is a factor, as shown by Huefner. Although Dr. Adeney in his first report claimed to have disproven the theory of circulating currents of water, the explanation of this matter by Col. Black and the writer has been tacitly accepted by him in his report to the New York Commission, so that there need be no further discussion of the theory involved. The real point at issue is indicated in the following statements:*

"It is equally evident from these experiments that whatever may subsequently be discovered to be the true cause of the streaming, its effect in large volumes of sea or river water under natural conditions must be of great importance, and of such dimensions that the effect of ordinary diffusion may, in comparison, be entirely neglected."

Col. Black and the writer state:†

"In practice no such results would be observed, since the upper layers of an estuary are always somewhat fresher than the lower."

This latter statement, Dr. Adeney says, has no real foundation in fact. In this connection, reference to the New York Commission's report‡ will be of interest. Here is shown the condition of the water at The Narrows, as regards both dissolved oxygen and salinity or percentage of sea water, at seven different stages of the complete tidal cycle. A distinct stratification is shown in each instance. From the surface to the 20-ft. depth there is an average increase of about 6% of sea water. In the case which shows the greatest uniformity throughout the depth, there is more than 2% increase. Moreover, the condition at the Narrows is less favorable to the contention of Col. Black and the writer than the majority of the cases shown in the

* British Royal Commission on Sewage Disposal, Fifth Report, Appendix VI, p. 64.

† Report of Col. W. M. Black and Prof. Earle B. Phelps concerning The Location of Sewer Outlets and The Discharge of Sewage into New York Harbor, 1911, p. 52.

‡ Metropolitan Sewerage Commission of New York, 1912, p. 449.

diagrams which follow. At the mouth of the Hudson, the gradient ranges from 6 to 8% of sea water in 20 ft., and in the upper Hudson, at Mount St. Vincent, it is normally more than 10% in the same vertical distance.

There seems to be, therefore, sufficient "real foundation in fact" for the assertion that stratification does exist, and that there is, therefore, no such vertical circulation of water from top to bottom, as Dr. Adeney found in his tubes, which were initially at a uniform concentration. If further foundation in fact be required for this almost self-evident proposition, reference may be had to the work of Morton F. Sanborn, Assoc. M. Am. Soc. C. E., on "The Distribution of Sea Water in the Charles River Basin."* As a result of a year's study, with almost daily examination of the vertical distribution of sea water in various parts of the Charles River Basin at Boston, Mr. Sanborn found stratification to be so persistent that the most severe storms produced only a temporary uniformity, even in the upper 20 ft. of the water, and that, after the cessation of such storms, stratification was re-established. The analytical evidence is direct and positive, and rests on no theory. The streaming effect which depends on the presence of more dense layers above those of less density, is impossible in waters that show increasing concentration of salt with increasing depths. These conditions exist in the cases that have been cited; therefore, the phenomenon of streaming does not and cannot occur.

Dr. Adeney's further suggestion that the sewage matters are concentrated in the upper layers is obviously true, but beside the question. We are considering the rate of absorption of dissolved oxygen by a polluted water, under the restriction that the dissolved oxygen content shall not be reduced below a certain specified amount. This value, if properly determined, will limit the amount of sewage which may be received into the water in question, under the restrictions imposed. The most favorable assumption that can be made is that the sewage is uniformly distributed. This, in other words, will give a maximum permissible pollution. If, on the other hand, we assume a concentration of pollution in the upper layers, then either the amount of permissible pollution will be decreased in proportion to this decreased volume of water available, or the conditions at the surface will be reduced below the assumed standard. Such a concentration of

* *Engineering News*, March 10th, 1910, p. 272.

sewage near the surface would result in a greater average rate of oxidation than if there were uniform distribution of the same quantity of sewage, but it is not the condition of maximum re-aeration.

Dr. Adeney next refers to the experimental technique by which Col. Black and the writer determined the diffusion coefficient. He first points out that that coefficient bears no resemblance to the one determined by Huefner, and believes that our series of ascending values with increasing temperature are due to a streaming effect, because of failure to take extreme precaution in preserving the purity of the water used. With regard to the first point, the apparent discrepancy is merely one of units used in the formula. The exact definition of a complicated coefficient of this kind cannot be simply made, and the reader is referred to the original paper (page 89) for the definition of the coefficient and the units in which it is stated. It would be a laborious matter to convert Huefner's coefficient to these units, and the magnitude of the experimental work was so much greater than his, and, in the writer's estimation, the method of experimenting was so much more reliable, that no attempt has been made to recompute the results in other terms. The form in which Col. Black and the writer have derived it is most favorable to practical application to the problem in hand.

As for the general accuracy of the analytical work, the results must speak for themselves. It would seem that Dr. Adeney's statement, "That the results obtained by these observers do not represent the true co-efficient of diffusion of oxygen in water becomes evident on carefully examining them" (page 83), and his further statement that these results have "no resemblance nor relationship to the true co-efficient," might have been accompanied with more explanatory matter for the benefit of those less familiar with the problem. Col. Black and the writer in their report give a plot, Fig. 1, showing the results of 114 tests made throughout a considerable range of temperature. Dr. Adeney quotes from page 94 of that report as follows:

"The values are somewhat scattering, and a closer analysis indicates that some unknown factor is involved. Exceedingly concordant results are readily obtained upon any one day, while upon the following day another group of concordant results will be obtained differing from the first. Barometric corrections were later applied without relieving the situation."

From this statement, Dr. Adeney concludes that our values have been arbitrarily selected, and will give misleading results. The plot, Fig. 1, shows the general character of the errors that have been referred to. There are admittedly imperfections in the process, and the

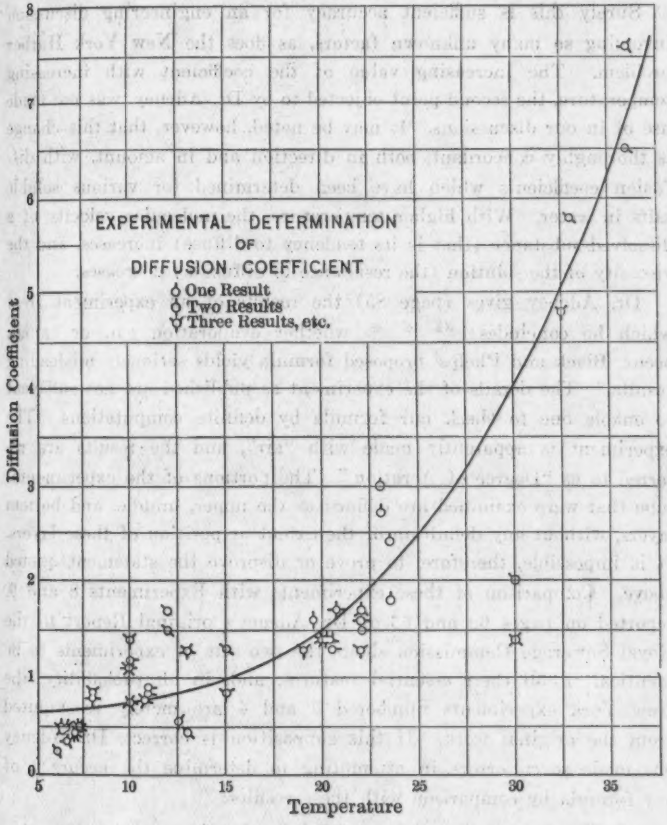

FIG. 1.

results are not of extreme scientific accuracy. For this reason, the work, which was originally carried out as a contribution to pure science, was not published as such. On the other hand, as stated on page 95:

"Within the range of values which have been employed in the computations in the text, errors resulting from the maximum divergence of individual tests from the average value of the curve are less than 5 per cent. at the five-foot depths and less than 2 per cent. at the twenty-foot depths."

Surely this is sufficient accuracy for an engineering discussion involving so many unknown factors, as does the New York Harbor problem. The increasing value of the coefficient with increasing temperature, the second point objected to by Dr. Adeney, was not made use of in our discussions. It may be noted, however, that this change is thoroughly concordant, both in direction and in amount, with diffusion coefficients which have been determined for various soluble salts in water. With higher temperature, the molecular velocity of a dissolved substance (that is its tendency to diffuse) increases, and the viscosity of the solution (the resistance to diffusion) decreases.

Dr. Adeney gives (page 85) the results of an experiment from which he concludes: "* * * whether evaporation can or cannot occur, Black and Phelps' proposed formula yields seriously misleading results." The details of the experiment as published are not sufficient to enable one to check our formula by definite computations. The experiment is apparently made with "air", and the results are referred to as "Degree of Aeration." The portions of the experimental tube that were examined are defined as the upper, middle, and bottom layers, without any definition of the extent or position of these layers. It is impossible, therefore, to prove or disprove the statement quoted above. Comparison of these experiments with Experiments 8 and 9, reported on pages 62 and 63 of Dr. Adeney's original Report to the Royal Sewerage Commission shows the two sets of experiments to be identical in all their essential features, and, in all probability, the New York experiments numbered 3 and 4 are merely recomputed from the original work. If this supposition is correct, Dr. Adeney has made seven errors in attempting to determine the accuracy of our formula by comparison with these results:

(1) The formula is misinterpreted in that it is assumed to give the increased oxygen content at any depth, whereas its derivation and our use of it show that it gives the total oxygen absorbed by a column of stated depth. This is plainly stated on page 91 of our report.

(2) Our 20° coefficient is used, although the temperature of the

experiments is about 8.5 degrees. Our coefficient for that temperature is just half the coefficient at 20 degrees.

(3) The "re-aeration" was measured by nitrogen, while our coefficient refers to oxygen. There is no evidence that the two gases behave similarly.

(4) The experiments are in sea water, whereas our coefficient refers to fresh water, and we state explicitly that the sea water coefficient is necessarily lower, owing to the increased viscosity of sea water. This effect would be exaggerated at low temperatures.

(5) The computed value was based upon the supposition that the water was free from oxygen at the start, whereas it contained more than 16% in each experiment. Proper use of our formula takes account of the original oxygen content, a self-evident matter which Dr. Adeney consistently overlooks.

(6) In recomputing his results to the basis of "per cent. saturation," the temperature of the room, 10° to 13.5°, is used, instead of the temperature of the water jacket, 8.5 degrees.

(7) In these recomputations, values of zero are arrived at in the middle and bottom layers, whereas in each case in the original experiments a definite amount of re-aeration was noted. The quantities are small, but too large to be ignored when the argument is based upon zero values.

If the writer is in error in assuming that these two sets of results refer to the same experiments, it is merely necessary to point out that they are obtained under identical conditions, so far as the conditions are stated, and, in any event, the writer will deal with the original work, which is fully described, rather than with the apparently recomputed values of the New York Report. The figures of the original report, of the New York Report, and of the former recomputed to the form of the latter, are given in Tables 1 and 2.

The columns referred to in Tables 1 and 2 are the long glass tubes. Air was bubbled through the top layers of three of these in series. The results of the first columns are not given, for the circulating currents established vitiated the diffusion effect.

The experiments are not capable of giving an accurate measure of the diffusion coefficient because of the large percentage errors that are possible and evident in the lower depths of all the columns. Neither are they planned to take advantage of our formula, which gives the

total oxygen absorbed in the entire column. In the course of establishing the formula, we derived an expression for the change in oxygen concentration at any depth. This is shown on page 92, just before the integration. While we have no determination of the coefficient for nitrogen in sea water, it may not be without interest to note that by this formula, under the stated conditions of depth, temperature, and initial content of the water, the increase in oxygen in a column of fresh water at the bottom layer, depth, 1 700 mm., would amount to but 0.1% of saturation, instead of 6%, which Dr. Adeney computes. In Experiment 9, in which the temperature was maintained constant

within 0.1°, the results were 0.16% and 0.08% in the two tables. In the other experiment the temperature varied 0.3°, and the results were 0.39% and 0.23%, respectively. Undoubtedly, all results are high, owing to changing temperature and circulation in the tubes. It is evident, however, that the diffusion coefficient of nitrogen in sea water is somewhat lower than that of oxygen in fresh water, and that the mathematical analysis of this problem by Col. Black and the writer, if not supported, is at least not invalidated, by Dr. Adeney's figures.

Discussions of theory and of laboratory investigations on such a complex problem as this are likely to be futile, unless the results can be controlled and checked against actual conditions. The problem of re-aeration is an enormously complicated one, but, fortunately, New York Harbor provides a full-scale experiment, and the various investigations which have been made on its waters have furnished a considerable mass of analytical and other data. It will be of interest, therefore, to inquire to what extent Dr. Adeney's values for re-aeration in a harbor water as a whole differ from those of Col. Black and the writer, and if there be serious difference, how the two sets of values compare with existing conditions. Dr. Adeney states* that any pollution which would not cause a greater rate of absorption than 0.055 c.c. of oxygen per liter per hour would exercise no apparent effect on the aeration of a tidal water. The context shows that he means the condition of aeration, not the rate of re-aeration. Col. Black and the writer have already discussed the errors of this point of view, which gives no consideration whatever to the initial conditions of aeration or of depth. It must be obvious that a saturated water will absorb no oxygen; that there must be a reduction from the normal condition of aeration before absorption begins; and that, furthermore, the greater this reduction the greater the absorption. The figure quoted refers to a mixture of salt and fresh waters in equal proportions, and the value for a mixture containing 75% of sea water is 25% greater. This is the statement taken literally and without question by Edlow W. Harrison, M. Am. Soc. C. E., upon which he based his computation cited by Col. Black and the writer (page 49) to show that the waters of New York Harbor could provide for the sewage of 60 000 000 people without reducing the normal oxygen. Dr. Adeney, in his New York report, makes no attempt to treat the question quantitatively, but points out the serious

* British Royal Commission on Sewage Disposal, Fifth Report, Appendix VI, p. 67.

variation in important factors, and believes that the rate of re-aeration may vary from zero to such a magnitude as to be of practical importance. His only approach to a quantitative statement is to the effect that rates of 0.067 to 0.077 c.c. of oxygen per liter per hour are probably maxima. The average of these two values is equivalent to 0.86 lb. per million gallons per hour, a figure which will be used later for comparison. This value refers to 6-ft. depths, and Dr. Adeney concludes that in greater depths the rate will vary inversely, so that in 12-ft. depths we may assign 0.43 lb. as Dr. Adeney's maximum. In Dr. Adeney's original report, 6-ft. columns were taken to represent actual conditions in practice. Recognition of the depth factor is apparently due to the Black and Phelps formula. Col. Black and the writer also realized the complex nature of the problem, but undertook a definite solution which would involve the most important variables. They estimated average rates of absorption, in 12-ft. depths, of about 0.045 lb. per million gallons per hour, although this figure varies considerably in the various portions of the bay.

Comparison of these figures with Dr. Adeney's maximum, after modification for depth, shows them to be about one-tenth as great. Dr. Adeney confesses his inability to determine an average rate, but claims that it is "of such magnitude as to be of great practical importance." Our figures are average rates, and represent an immaterial quantity in the treatment of the whole subject. While Mr. Harrison's estimate would probably be an unfair statement of Dr. Adeney's views, as now modified in his New York report, it should be noted that it is the only computation that has ever been made to show the value of the "streaming effect," and Dr. Adeney has made no attempt to correct it, or to replace it with a more conservative computation. The Black and Phelps formula has been applied to the conditions existing in New York Harbor, and, in conjunction with Col. Black's excellent mathematical analyses of the tidal conditions existing, has been used as a basis for a computation of the actual condition of the waters of various parts of the harbor. Instead of providing for 60 000 000 people without reduction of the normal oxygen of the waters, we find the effect of re-aeration to be practically negligible. If there be no reduction from the normal there will be no re-aeration. If 30% of the normal oxygen of the harbor waters be used up in sewage oxidation, so that the waters stand at 70% of saturation, the additional aeration

will amount to less than 1% of saturation in 12 hours. Under these conditions, oxygen obtained from the atmosphere by absorption would care for the sewage of about 250 000 people, out of a total of 7.4 millions which are provided for by the 30 per cent. The fact that, with less than this population contributing sewage to-day, the waters of the harbor do not stand at their normal oxygen content, but are on the average already reduced to approximately 70% of saturation, is of interest. The calculated condition, assuming practically no reaeration, agrees closely with the facts. A more severe test of our conclusions, however, is possible. The Metropolitan Sewerage Commission made 1 870 analyses for dissolved oxygen in and near New York Harbor during 1911. This work was confined mainly to typical cross-sections. Table 3 shows the original computations by Col. Black and the writer, in comparison with a summary of the Metropolitan Commission's results.

TABLE 3.—Dissolved Oxygen in New York Harbor Waters.

A. Calculated by Black and Phelps, February, 1911.

B. Analyses by Metropolitan Sewerage Commission for the Year 1911, Reported August 1st, 1912.

Location.	Percentage of saturation.	
	A	*B*
Lower Bay.		
End of flood	100	100
End of ebb	71	74
Upper Bay.		
End of flood	76	79
End of ebb	54	55-56
Hudson to 96th Street.		
End of flood	54	56
End of ebb	48	54
East River.		
Mouth to Hell Gate.		
End of flood	53	55
End of ebb	71	57
Hell Gate to Throgs Neck.		
End of flood	71	57
End of ebb	81	86

The computations refer to the areas indicated in Table 3, while the Commission's figures are necessarily for cross-sections. In each case the value for the area in question at the end of the flood is compared

with the average figures for flood and ebb at the cross-section down stream from the area in question; and at the end of the ebb with similar values for the cross-sections up stream from the area in question. In the single case of the Hudson River at 96th Street at the end of the ebb there are no up-stream data available. The figure given is the average value for the ebb flow at the mouth of the Hudson. Obviously, the character of the water remaining in this section at the end of the ebb is worse than the average ebb flow, a fact which is indicated in the discrepancy of these two figures. With a single exception, the remaining figures show a striking agreement. There is evidently something wrong with our value at the region of Hell Gate, which has influenced the computed value of the ebb-waters below Hell Gate and the flood-waters above. It might be suggested that there is an influence of the Harlem River shown here which was not properly taken into account in our computation.

The agreement between the computed and the actual conditions, although gratifying, is of itself of little practical moment. Its value lies in the fact that it demonstrates the substantial accuracy of the methods which have been used in the analysis of this problem, and makes it possible to use this same method in computing the probable effect of further increase in population, or of the discharge of additional quantities of sewage from regions not now tributary to New York Harbor. All the facts seem to support the view that aeration in New York Harbor is an immaterial factor in the whole problem of sewage disposal.

Upon the grounds of theory, experiment, and experience, therefore, the writer, much to his personal regret, finds himself obliged to differ from Dr. Adeney, whose personal acquaintance he has the honor to enjoy and for whose scientific work he has the most cordial regard.

DISCUSSION

Dr. Adeney.

W. E. Adeney, Esq. (by letter).—In this paper Professor Phelps does not offer any additional experimental evidence in support of the formula which Col. Black and he, in their Joint Report of 1911 to the Board of Estimate and Apportionment, have proposed for calculating the rate at which de-aerated waters become re-aerated, when exposed to natural conditions, in terms of time, depth, initial dissolved oxygen content, and the diffusion coefficient of dissolved oxygen in water.

The fundamental conception underlying this formula is that the re-aeration of de-aerated waters is effected by the absorption of oxygen by the layer of water exposed to the air; that the subsequent transmission of the dissolved oxygen throughout the underlying masses of water takes place strictly in accordance with Fick's law of diffusion; and that, as far as appreciable effects are concerned, no other natural agency or factor need be considered.

The only experimental evidence, which the authors have advanced in arriving at their proposed formula, are some figures, which they have put forward as indicating the diffusion coefficients of dissolved oxygen in distilled water at certain stated temperatures. These figures have been determined by a method which the authors of the formula designed especially for the purpose, but the working details of which have only been slightly indicated in the report referred to.

The experimental difficulties in the way of determining accurately the coefficients of dissolved gases in water are very great, and Hüfner, so far as the writer knows, is the only observer, among the few who have ventured into this field of investigation, who has endeavored successfully to overcome the most serious of these difficulties.

The writer has already pointed out, in Section II of the Report which he had the honor of presenting to the Metropolitan Sewerage Commission of New York in 1911, that the method in question does not determine the diffusion coefficient, but the rate of re-aeration of the water experimented with by quite a different factor, that is to say, by the downward "streaming" of dissolved oxygen from the exposed surface of the water; and, inasmuch as the water used by Col. Black and Professor Phelps in their experiments was not distilled, but contained decided quantities of mineral matters in solution, this "streaming" process must have been very rapid, with the result that the values which they obtained for the diffusion coefficients in distilled water were very much too high.

A rough estimate of the relative rates at which columns of de-aerated sea water may become re-aerated, by (*a*) downward "streaming" from the surface exposed to the air, and (*b*) by true diffusion

Dr. Adeney.

in accordance with Fick's law, may be obtained from the results of an experiment which the writer has described, as follows:*

"A U-shaped tube, each limb 1 600 mm. long and 50 mm. diameter, was filled with boiling sea water and immediately closed air-tight with indiarubber corks. When the water had cooled, the tube was further exhausted by means of a mercury pump. One limb was then uncorked, and the water in it saturated with atmospheric gases by a current of air drawn through the surface-layer to a depth of 50 mm. for 48 hours. After this, a sample was drawn from the bottom of the open limb, and one from the lower portion of the closed limb, about 200 mm. from the bottom. The gases were extracted from these and the nitrogen in each determined, with the following results [expressed in cc. at 0° C., and 760 mm. bar., per liter]:

Open Limb.	Closed Limb.
12.12	1.49

Six months later another sample was collected from the lower portion of the closed limb, as before, and the nitrogen in it determined; it was 1.73."

These results show clearly that, though the re-aeration of a column of de-aerated sea water, 1 600 mm. deep, and of uniform density, is relatively rapid, so that it may be completely saturated with air in 48 hours when evaporation freely occurs from the surface, it is so extremely slow when dependent on simple diffusion, that it may be altogether neglected in considering questions of the re-aeration of sewage-polluted tidal waters. It may be noted that the temperature of the laboratory during the first two days of the experiment described varied between 10° and 12° cent.

Professor Phelps himself has admitted that his method is faulty. On page 1629 he states in reply to the writer's criticisms:

"There are admittedly imperfections in the process, and the results are not of extreme scientific accuracy. For this reason, the work, which was originally carried out as a contribution to pure science, was not published as such."

By way of self-defense, he continues to remark that the accuracy of the method is sufficient "for an engineering discussion involving so many unknown factors, as does the New York Harbor problem."

Surely, the problem of determining accurately the diffusion coefficients of dissolved oxygen in water cannot be placed under the category of "involving so many unknown factors." The conditions necessary for the accurate determination of the diffusion coefficients in question are certainly quite well understood, although it may not be easy experimentally to ensure them; and, inasmuch as the whole superstructure of the formula depends on the accurate determination of these diffusion coefficients, the writer ventures to express the opinion that Professor Phelps would have been well advised had he submitted

* Section I in Appendix VI to the British Royal Commission's Fifth Report, p. 60.

a detailed description of his method to the consideration, in the ordinary way, of his brother chemists, before applying it to the solution of a problem of such wide and far-reaching importance as that of New York Harbor, affecting, as it does, the well-being of many millions of people, as well as the interests of a vast and rapidly growing commercial center. Had he done so, he no doubt would have had the benefit of the criticisms of other workers, and would not have been left long in doubt as to the nature of the "unknown factor" which has vitiated his coefficient determinations. The writer ventures to think that he has given the true explanation of this unknown factor, in his criticisms* of the method, in which he has shown that the experimental basis of that method is quite erroneous. Dr. Adeney.

Professor Phelps complains (page 1634) that the writer has not suggested a general expression applicable to the calculation of the average rate of re-aeration of tidal waters by "streaming." This was not done, because, to have attempted anything in the way of a working formula for the purpose, he would have had to follow the very undesirable course of making broad assumptions, for which there exists at present no scientific basis. In fact, he would have had to follow the course which he complains that Col. Black and Professor Phelps have adopted in arriving at their proposed formula. The writer is quite willing to admit that such a course would be warranted for the purpose of raising a discussion on the question, if restricted to purely scientific interest, but certainly not in connection with one of such vast practical importance as that of the powers possessed by the tidal waters of New York Harbor for the disposal of sewage matters, within limits of safety to public health, and to the amenities of their surroundings.

The writer has preferred to follow the usual custom by publishing a description of his experiments on "streaming," although they were simply pioneering experiments, and has to acknowledge that he has received the benefit of some helpful criticism from Professor Phelps. He gladly takes this opportunity of expressing his appreciation and thanks for that criticism. The writer has also to express his indebtedness to Professor Phelps for pointing out that the results of his experiments do not bear the precise and general value that has been placed on them by some writers in the United States, because, as already stated, they are only of a pioneering character, and are necessarily only true for the conditions of the particular experiments described.

The fact, however, that the proposed formula rests on an erroneous experimental basis, is not the only serious objection that may be urged against the position that has been taken by Col. Black and Professor Phelps on this question of re-aeration.

*Report to the Metropolitan Sewerage Commission of New York, 1911, p. 83.

Dr. Adeney

With reference to the particular question of the re-aeration of tidal waters, Professor Phelps assumes that the same factors obtain with sea water as with fresh water, and that it is effected solely by diffusion, according to Fick's law, from the exposed surface downward.

According to Professor Phelps' strongly expressed opinion, however, the surface layers of inshore tidal waters are fresher by reason of admixture with land waters, and, therefore, less dense than the heavier salt water below. In other words, the layers of water concerned in actually dissolving oxygen from the air, for subsequent diffusion below, are less dense than the lower layer of the water. Notwithstanding this, Professor Phelps assumes that diffusion will proceed according to Fick's law, just as it would were the water of uniform density throughout its depth. Again, he gives no experimental data in proof of this, and the writer knows of none himself. In the absence of direct evidence to prove it, Professor Phelps is not justified, in the writer's opinion, in stating that, because Fick's law holds good for the diffusion of dissolved oxygen in a liquid of uniform density, it must necessarily do so in one increasing in density in the direction of diffusion. Under these circumstances, the writer is entitled to hold the contrary view.

One further assumption, which Col. Black and Professor Phelps make, demands notice. It is stated on page 56 of their original report, and is as follows:

"Since the fundamental law of aeration is one of diffusion, and, furthermore, since the surface of any body of water is practically saturated at all times, it must be evident that no mere surface action can by itself affect the rate of diffusion."

No experimental evidence of any kind is given in support of this statement. The question is one on which the writer has made a considerable number of experimental observations since he published the description of his pioneering experiments on "streaming," all of which prove beyond doubt that the surface of a body of water, when exposed to atmospheric conditions, does not become saturated at any time as long as the layers immediately below it remain only partly aerated.

The writer has definitely found, by careful experimental observations, that, as oxygen is dissolved by the surface of any quiescent body of water, when de-aerated or only partly aerated, it passes practically as quickly downward through the lower layers, so that the surface does not become saturated until the dissolved oxygen content of the layers below it approach the condition of saturation.

He has found this to be true both of fresh water and of sea water. The only marked difference between the two is that in the sea water the transmission downward is quicker than in fresh water, when the surfaces of the two bodies of water are exposed to the air so that evapo-

ration can take place freely from them; and *vice versa* when the conditions are such as to prevent evaporation from the exposed surfaces. Dr. Adeney.

The writer has also found that when the surfaces of de-aerated columns of fresh water are exposed to the air, so that evaporation can take place freely from them, and when the columns themselves are maintained at a constant and uniform temperature, the downward distribution of the dissolved oxygen is so nearly uniform, for depths of about 1 000 mm., that the oxygen content of the water at that depth has been found to be nearly equal to that of the surface layer at various stages during the process of re-aeration.

Professor Phelps admits the correctness of the writer's observations on "streaming" in his experiments with columns of sea water, but assumes that "streaming" does not affect the practical question of the re-aeration of tidal waters, because it was caused, as he explains, in the case of the writer's experiments, by the formation of concentrated layers of water, the result of evaporation from the exposed surfaces of the experimental columns; and he assumes that the "streaming" would not occur in tidal waters, when the surface layers are fresher and, consequently, denser than the lower layers of sea water.

Again, Professor Phelps gives no experimental evidence in support of this assumption, and, in the absence of definite evidence, he is no more entitled to make it, than he is to assume that diffusion will occur according to Fick's law under the same conditions.

The writer has already pointed out that if a marked stratification obtains in a tidal water, and the land water lies on the surface of the sea water, the sewage matters, which are themselves carried by fresh water, will gather to the surface layer also and will there be re-aerated chiefly by "streaming."

The New York Harbor waters, however, are not thus stratified. The Metropolitan Commission states:*

"The general configuration of the bottom and of the main channels of the harbor is such as materially to aid in keeping the water well mixed. * * * The water is usually more saline at the bottom than at the top, but the difference is usually slight and there is apparently no sharp line of demarcation."

Professor Phelps would be justified, no doubt, in assuming that "streaming" would not extend to the lower layers of a tidal water, the surface layer of which consisted practically of wholly fresh water, and the lower layers of undiluted sea water, but he is certainly not justified in assuming, without experimental observation, that it would also not occur in tidal waters in which, as in New York Harbor, the water at a depth of 20 ft. contained, on an average, only 6% more sea water than at the surface. The experiments which the writer has made certainly do not justify such an assumption.

*1912 Report, pp. 26 and 27.

Dr. Adeney. The writer does not think that any useful object can be attained by following Professor Phelps in his detailed discussion as regards so-called calculated and observed results, because, until the scientific basis on which such a discussion can be usefully carried on has been definitely settled, it can only be juggling with figures to attempt to do so.

In his Report to the Commission (page 81), the writer has mentioned the chief factors, as far as they are known, which are concerned in the re-aeration of tidal waters exposed to natural conditions, and gives reasons for believing that:

"The rate of re-aeration must therefore be an extremely variable quantity from day to day, and even from hour to hour."

Again, on page 87, he states:

"It is quite evident that under their combined influence [*i. e.*, the factors concerned in re-aeration] the rate [of re-aeration] may vary practically from zero to a value of such magnitude as to be of great practical importance especially during summer season.

"It need scarcely be pointed out, however, that a good deal of work has yet to be carried out, both in the laboratory and on the open water, before a definite value can be put to the extreme rate at which re-aeration under the most favorable conditions would occur, or even to the average rate—both would certainly vary with different classes of inshore waters."

Mr. Phelps. EARLE B. PHELPS, ASSOC. AM. SOC. C. E. (by letter).—The writer wishes to thank Dr. Adeney for his frank criticism, which makes it possible to define clearly the points at issue. There is apparently complete agreement on the two propositions that diffusion alone is of no material advantage in the re-aeration of polluted tidal waters and that the phenomenon of "streaming," if it takes place, effects re-aeration to a material extent. This being the case, further discussion of the accuracy of the determination of the diffusion coefficient becomes irrelevant. The writer sees no reason to alter his opinion that figures of this degree of accuracy, although admittedly too imperfect for use in a journal of physical chemistry, still have a legitimate use, especially when the probable magnitude of the error is stated. A review of the original data, in the light of the criticism made, leaves the writer still of the opinion that Fick's law holds in this case, that the mathematical analysis of the problem is sound, and that the value of the coefficient as determined has a degree of accuracy better than that obtaining in other important engineering values that enter the problem, such as the measurement of stream flow and of sewage.

There remains, however, as relevant to this discussion, the single question: "Does streaming take place in New York Harbor?" Dr. Adeney apparently accepts the writer's explanation of the nature of the streaming phenomenon, so far as saline waters are concerned, in

that it is a gravitational movement of the more dense layers produced at the surface by evaporation. He objects, however, to the "assumption" that this process is not taking place in a body of water in which the density actually increases from the surface downward. Surely this is more than an assumption, and it calls for no experimental proof that lighter layers of water will not sink through heavier layers by the action of gravity. The quotation from the Metropolitan Sewerage Commission's report is not a sufficient basis for the statement that the waters are not stratified, if by stratified we understand an increase of density downward. The figures and diagrams of that report show such a condition almost universally, and the writer's experience, in the Charles River Basin at Boston, and elsewhere, indicates such a condition to be normal in estuary waters. Whether the density gradient be great or small, and whether or not there be a distinct line of demarcation (which is often found), the mere existence of a density gradient downward is obviously incompatible with a downward gravitational streaming of water. Mr. Phelps.

Dr. Adeney does an unintentional injustice to our formula when he states at the outset that it determines the rate of aeration in terms of time, depth, initial dissolved oxygen content, and diffusion coefficient; and (later) that "no other natural agency or factor need be considered." A study of the method of using the formula will show that the time factor is the mean time between uniform mixings, and that for its determination one must know all the physical conditions and natural agencies that assist in mixing the water, such as wind, tidal mixing, and the effect of passing boats. This work is now being extended by the determination of the time factor for streams of various types. Knowledge of this factor will make it possible to determine the rate of re-aeration of such streams. The formula has already been made use of in this way by the experts of the Royal Sewerage Commission of Great Britain, in its Eighth Report. The results show at once that the possibilities of re-aeration in such streams are far greater than in the case of deep estuaries.

The writer cannot agree that the correspondence between calculated and observed results in New York Harbor is only a "juggling with figures." The calculated results are based on the practical negligibility of re-aeration. The fact that they agree to a remarkable degree with the results of an extensive series of analyses made during the following year is certainly the most desirable kind of "additional experimental evidence," the absence of which Dr. Adeney regrets so keenly. If these calculations had been made by omitting all reference to re-aeration, the results would not have been altered materially. They do not involve any of the disputed points, and, without further reference to the other matters, they alone show the practical non-importance of re-aeration in New York Harbor.

Paper No. 1273

THE USE OF CEMENT FOR EXCLUDING WATER FROM OIL SANDS IN DRILLING WELLS.

By Paul M. Paine, Assoc. M. Am. Soc. C. E.

In connection with the drilling of oil wells, cement is being used in increasing quantities for excluding from the oil sand the water in strata nearer the surface. This water, if not prevented from going down into the oil sand, will displace the oil, because of its greater specific gravity, and eventually ruin the well. Unfortunately, the damage does not end here, for experiences in the older fields have shown that this flooding of the oil sand spreads gradually over wide areas, depending mainly on the porosity of the sand and the gravity of the oil, and, unless checked in some manner, will ruin neighboring wells. For this reason the encroachment of water into the oil-bearing strata is a serious problem in any oil-field, and is particularly difficult to overcome where the water strata are directly above or below the oil-bearing sand.

The mechanical difficulties and expense connected with this problem have led careless operators to take long chances at times, and, in many of these cases, where the work has not been successful, there has been serious injury, not only to such wells, but also to adjoining properties. A measure of State relief has been obtained in some States where laws have been passed requiring operators to remedy such defects, but it is generally agreed that the only permanently

satisfactory method is to shut off the water effectually at the time the well is being drilled and before the hole has been carried into the oil sand.

The development of deep drilling, which has come with the introduction of the use of casing, has seen marked advances in methods, and it is not unusual to finish wells with a 6-in. hole at a depth of 4 000 ft. or more. In such wells several "strings" of pipe may be used, the first and largest being carried down from the surface until it is "landed" at a suitable depth, or until it is "frozen" by caving material falling in against it from the walls of the hole and binding it so that it cannot be moved farther, either up or down. The next "string," the collars of which will run inside of the first one, is then put in, and drilling is continued until this second string is either landed or frozen, and so wells frequently contain strings of 15½-in., 70-lb., 12½-in., 40-lb., 10-in., 40-lb., 8-in., 28-lb., 6¼-in., 20 or 26-lb., and 4½-in., 12½-lb., lap-welded, screw casing. At the bottom of each of these strings there is a shoe with an outside diameter slightly greater than that of the pipe collars, so that, as the pipe is lowered, the collars will be sure to pass through any opening through which the shoe has passed.

Preventing the water from reaching the oil is effected by landing a tight string of pipe, called the "water string," at a level known to be below the lowest water stratum and above the oil sand. This is done before the hole is drilled into the latter, and, wherever possible, the water string is landed on a "shell," the general oil-field term for any hard compact rock. This is illustrated in Fig. 1. In some fields all that is necessary is to stop drilling and drive the pipe into this shell; the well is then baled dry, and, after standing a day or two, a baler is run in to ascertain whether or not the pipe is holding the water back. If water has come in, it means that the bond between the casing shoe and the shell is not tight, or that the casing leaks. The cause of the leakage may be determined by special devices, and then a suitable remedy may be applied. Often, however, a hard shell in which to land the casing cannot be found, and the pipe is stopped when the shoe is in some soft measure such as shale. In either case, it frequently happens that wells which have shown a satisfactory water test at the time of drilling, have developed water later, due to

gradual leaching through the interstices of surrounding porous measures. This uncertainty led to the search for a more thorough method of sealing off the water, and the use of cement has come to be recognized as the only positive remedy. The problem, then, is one of placing from 2 to 8 tons of cement between the casing and the wall, at the bottom of holes ranging in depth from 600 to 4 000 ft.

In all the methods described herein, when the hole has reached the desired depth at which to cement, it is reamed out wider for 60 or 70 ft. above the bottom with an under-reamer, a tool which widens the hole with cutting lugs that spring out when lowered below the casing shoe. This gives additional room for the cement and insures a better bond. The hole is also cleaned of mud and cuttings, and fresh water is run in. The simplest method of placing the cement is that known as "baling" it in. The hole is filled with water to the top of the casing, and the latter is raised until the shoe is 10 or 12 ft. from the bottom. The cement, mixed to a thick grout, is then run in in a specially devised baler which dumps when it reaches the bottom. When from 1 to 2 tons (dry weight) have been placed in this way, a plug is screwed into the casing collar at the top, and the casing is lowered. As the casing is full of water, the weight of the pipe forces a large portion of the cement out into the formation and up between the casing and the wall of the hole, as the casing shoe is lowered to the bottom. As a final precaution, the casing is driven, in order to force the shoe into the bottom as far as possible. Instead of using a baler, some operators prefer to run in the cement in a series of long narrow bags tied to the bottom of the drilling tools; when the bottom is reached, a few strokes of the tools loosen the bags and break them up so that the cement is freed. In connection with these methods the patented Baker "cement plug" is sometimes used instead of the one screwed into the top of the casing before it is lowered. This plug is of light cast iron, made so that it may be hung from the baler with soft rope and run down inside the casing. When lowered below the casing shoe and then raised with a slight tension, a set of clips catch on the shoe, and the bottom opening of the casing is effectually closed. The casing is then lowered, the cement is forced up on the outside, and the baler is loosened by a stronger pull which breaks the soft rope. The plug, being of cast iron, is easily drilled up.

A method of particular value in very deep wells, or in those in which the water string tends to "freeze" unless moved at frequent intervals, is that known as the disk method, in which patented packers are used. This requires that a "circulation" be obtained, that is, that there be a free passage for fluid pumped down inside the pipe to come to the surface on the outside. In order to obtain this, a 10 by 5 by 12-in. pump of the type used in the oil-fields for pumping mud in drilling wells with the rotary system, is set up and connected to the casing head with a section of 2½-in. pressure armored hose, as shown in Fig. 3. It is frequently necessary to work up to a pressure of several hundred

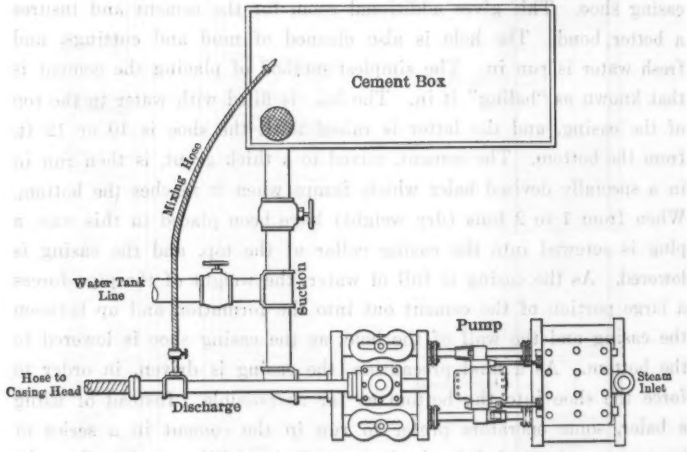

FIG. 3.

pounds before the fluid will create a passage on the outside of the pipe from the casing shoe to the surface. When this circulation has been obtained, the casing is suspended so that the shoe is 4 or 5 ft. from the bottom and enough fresh water is pumped in to insure a thorough cleaning of the bottom. The packers are of wood or of cast iron, and have heavy canvas or rubber washers which fill the space inside the casing, as shown in Fig. 2. The lower one is about 3 ft. long, and, after it has been placed in the casing, the pump suction is connected with the box in which the cement has been mixed just thin enough to pump readily. The cement is then pumped in against the lower packer, forcing it down until the cement box is drained; the top

packer follows, and water is then pumped in against the latter, pushing the combination of lower packer, cement, and top packer down the pipe. When the lower packer passes the casing shoe, it falls to the bottom of the hole and permits the cement to pass around the shoe and up on the outside of the casing. The top packer is of such length that when it has forced the cement out of the pipe and it strikes the lower packer, its top set of washers will not have passed out of the casing, and, as it cannot move farther, it will raise the pressure inside the casing and stop the pump. The casing is then landed on the bottom, the cement has been placed outside of the pipe at the bottom of the hole, and the packers, like the cement plug, are easily drilled up after the cement has set. The main objections to this method are the danger of the packers sticking while going down inside the casing and the fact that the lower packer may fall to the bottom in such way as to prevent the casing shoe from being landed squarely on the bottom, and thus get under it so that the bond is broken when the packer is drilled up.

The following method is in more general use, as it has seemed to secure better results and has no patented features: In this, as in the packer method, the principle of pumping in the cement under conditions that force it up on the outside of the casing is used, but this is done with an extra string of small pipe, usually 2½-in. tubing, which is lowered inside of the casing. After the hole has been drilled to the desired depth, reamed, and a circulation obtained, the casing is suspended with its shoe about 6 or 8 ft. from the bottom; the hole is filled with water to the top of the casing, and a string of tubing is run in until its bottom is slightly above the casing shoe. The packing head, shown in Fig. 4, is screwed into the casing collar at the top, and the gland in this head acts as a stuffing-box around the tubing. Then, with the casing full of water, when water is pumped in through the tubing, its only course is up on the outside of the casing. The surface arrangement for the pump is similar to that for the packer method (Fig. 3). On the bottom of the tubing has been placed either a bushing or a swedge nipple, reducing the opening from 2½ to 2 in. First, fresh water is pumped into the tubing, and this is followed with the cement grout; as soon as the cement is all in, the plug in the tubing tee above the packing head is unscrewed, and a wooden plug with a washer on it is dropped in on the cement. The tubing plug is then

replaced, and water is pumped in against the wooden plug, chasing the column of cement down the tubing. The water in the casing is incompressible, and the cement must travel around the shoe and up on the outside. The purpose of the swedge nipple at the bottom of the tubing is to show when the cement has passed out. The plug is stopped, and the pressure on the gauge at the pump goes up. The casing is then lowered to the bottom, and the tubing is pulled out as rapidly as possible so that whatever cement has remained inside the casing may be baled out before it has had time to set. The cement is then allowed from 10 to 20 days in which to set, after which the well is drilled a few feet ahead of the shoe and then baled dry. If no water has come in at the end of a 24-hour period, it shows that the work has been successful, and drilling operations are resumed.

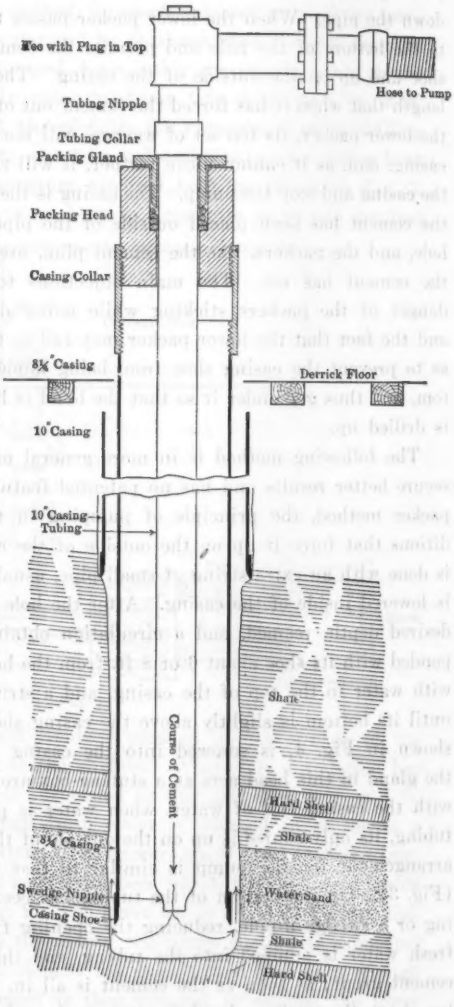

FIG. 4.

In one well cemented by the writer, a still lower water sand was encountered. Back of a string of 8-in., 28-lb. casing, 2½ tons of cement had been placed, and as it was desired to shut off all the water with the 8-in. string and use a 6-in. string to finish the well, the former was cut off about 200 ft. from the bottom and the hole was re-drilled off to the side of the 8-in. pipe left in the old hole. This is known as "side-tracking," and the new hole goes off to the side of the old pipe and down directly beside it. This gave an opportunity to learn how far up, on the outside of the casing, the cement had set, and it was found to be 65 ft.

In the preliminary operation of securing a circulation, the fluid may come to the surface on the outside of the pipe, even though it is not coming around the shoe, if a leak exists in the casing. This may be determined by continuing to pump and lowering the casing to the bottom of the hole; if there is a leak, the circulation will continue; if the circulation has been entirely around the shoe, then when the latter is placed on the bottom, the fluid will be held in and the pump pressure will be raised.

From 2 to 6 tons (dry weight) of cement are generally used, depending on conditions; and even larger quantities are inserted where an unusual cavity is to be filled. Before being mixed with water the cement should be screened, and particular care should be taken that no pieces of bags or strings get into the suction line. Preferences for different brands of cement are found in different localities, but there appears to be little advantage in any one kind of cement, if the time of initial set is long enough to cover the period of mixing and pumping it, and of lowering the casing. Sand should not be mixed with the cement, and the grout should be given every opportunity to set; for this reason the hole should be made as free from mud, oil, and gas as possible, the latter especially tending to prevent the set by keeping the cement in motion.

It sometimes happens, particularly in new territory, that after the oil sand has been penetrated and the well is being drilled still deeper, another water sand is encountered, known as "bottom" water. Under such conditions, in the presence of active quantities of oil and gas, the work becomes more difficult. The most effective method is to pull up the casing until the shoe is a short distance below the bottom of the oil sand, and then build a "bridge" in the hole below the shoe by

running in broken pieces of brick and common manila rope. This bridge closes the hole and forms a landing place for the casing shoe after the cement has been run in. More care in gauging the quantity of cement to be placed is necessary in this case, in order that none of it may reach the oil sand and clog it, thereby tending to interfere with the oil production.

ENGINEERING ACHIEVEMENTS AND ACTIVITIES OF NEW YORK CITY.*

By Alfred D. Flinn, M. Am. Soc. C. E.

Historical and General.

New York was founded as New Amsterdam, by the Dutch, in 1625, when two ships from Holland brought over settlers with their household and farming equipment and domestic animals. Under the direction of an engineer, Kryn Frederick, the town was begun by laying out a fort. There had been a trading post here, however, since 1613. In 1626, Peter Minuet bought the island from the Manhattan Indians for 60 guilders, equivalent to $24. By conquest, the settlement became an English colony in 1664.

Although an important port, it remained in a secondary place throughout the colonial period, and did not become the first city of the land, as to commerce and population, until 1770. The opening of the Erie Canal, in 1825, gave the City its first great impetus. Occupying originally only a small area at the southern extremity of Manhattan Island, the City, by growth and annexation, has greatly increased its territory and water-front. New York is now the greatest of all seaports, due to its geographical advantages, namely, its wonderful harbor and its easy lines for water and rail access to the interior of this great continent, to New England, and to the South Atlantic States. It is the terminus of the naturally cheapest route from the Mississippi Valley to the sea. It has a fine climate and a low death rate, 14 per 1 000 for 1912. It is one of the healthiest of the great cities of the world.

* An Illustrated Lecture, at the Reception given by the American Society of Civil Engineers, at the Society House, to the Foreign Delegates Attending the Sixth Congress of the International Association for Testing Materials, New York, September 5th, 1912. Enlarged for publication, and Revised, May, 1913.

Harbor and Traffic.

As shown by the map, Fig. 1, the harbor is naturally divided into several parts, well interconnected. At the entrance from the Atlantic is the Lower Bay, from which vessels pass through The Narrows into the Upper Bay, out of which branch the Hudson, or North, and the East Rivers, with the Harlem River linking them north of Manhattan Island. From the East River, through Hell Gate, commerce has access to Long Island Sound and New England waters, and the Hudson is navigable to Troy. On this map are indicated also the approximate locations of the principal artificially improved channels.

Into New York Harbor come the largest steamships afloat. In 1911 4 500 vessels, with a tonnage of 14 000 000, cleared for foreign ports. The total traffic of the harbor amounts to 100 000 000 tons annually. Vessels are sent to the port by many great oceanic, coastwise, and river lines. From 800 000 to 1 000 000 immigrants have passed through the Ellis Island station during each of the recent years. The imports of New York have amounted to $936 000 000, and the exports to $865-000 000, annually. Great numbers of tramp vessels come into the harbor from all over the world. Few more suitable anchorage grounds for naval vessels, where the public can see them conveniently, can be found than the Hudson River from 23d Street northward. Here the greatest fleet ever assembled has ridden safely at anchor. The river has a channel depth of 35 ft. or more as far as the City's northerly boundary. Harbor depths are indicated on Fig. 5.

Geology.

In The Bronx and on Manhattan Island above 14th Street, in general, mica schist, gneiss, or limestone, outcrops or is not far below the surface; but south of 14th Street the bed-rock descends steadily, and is everywhere covered heavily with glacial drift. Long Island and Staten Island are morainal, with rock usually at considerable depths, except for a ridge of poor serpentine outcropping on Staten Island, and one outcrop in the northerly part of western Long Island. Railroad, subway, and water tunnels, bridge and building foundations, and other engineering constructions are profoundly affected by this geological formation. Most picturesque of all the local geological formations is the great trap rock sill, known as The Palisades, extending from the harbor northward for 20 miles along

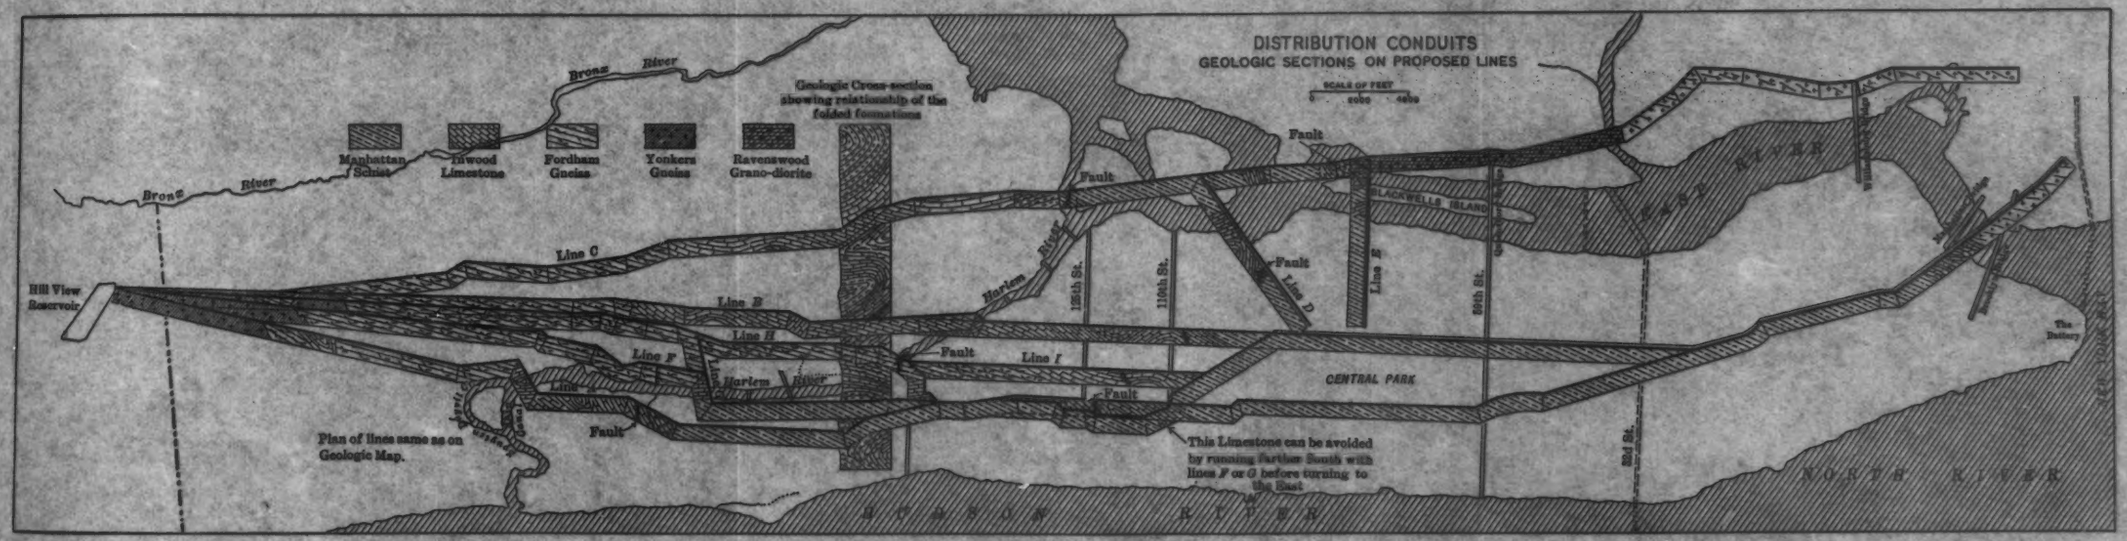
the west bank of the Hudson. Attaining a height of some 400 ft, this sill forms a barrier which has had to be pierced by many a tunnel for the railroads approaching from the West.

Within the past 20 years, explorations with wash, diamond, and shot drills, and subsequent excavations for large engineering works have greatly enriched our knowledge of the details of the geological structure. Tunnels and pipe lines for the Catskill Aqueduct and the rapid transit subways have developed north and south lines from Yonkers to Staten Island, and the great railway and gas tunnels, together with water and subway tunnels, have supplied data for east and west sections of the formations from the Hudson to the Suffolk County line. The rock contours for Manhattan Island have been well established and are shown on a few maps. As in most of these explorations the engineers have been assisted by expert geologists, the results have been intelligently interpreted and permanently recorded. Plate LVIII reproduces some of these geological sections.

During recent years extended observations for sewage disposal purposes have greatly enlarged the knowledge of tidal currents and kindred phenomena in the harbor, bays, and rivers. Figs. 1 and 5 give some of the most recent information concerning these currents, and the depths of water.



Resources, Industries, Geography, and Population.

To-day, the metropolis of the western hemisphere ranks first in population among the cities of the world, and is second only to London as a financial center. In February, 1912, the capital and undivided profits of its banks and trust companies totaled $581 000 000; at the same date, the deposits aggregated $3 226 000 000. In addition, the deposits in savings banks in the greater city exceeded $1 000 000 000. Summing these, it appears that the grand total of deposits approximates $4 500 000 000.

The estimated total value of real and personal property is $10 000 000 000; total bonded debt, $800 000 000; gross public indebtedness, more than $1 000 000 000. Against this indebtedness can be offset the 5 500 parcels of real estate owned by the City, with an estimated valuation of $1 300 000 000, and the equipment of the City departments on which a value of $40 000 000 has been set. Central Park is valued at $380 000 000, and Bowling Green, for which the annual rental was

INDIA PIPER

long ago, two pepper-corns a year, is now worth $1 735 000. Within a few years, it is believed, the valuation of the park lands alone would be equivalent to the total funded debt.

By an interesting compilation of figures, someone has shown that, from 1900 to 1910, the net increase of land values in New York City was more than the combined gross output of all the gold and silver mines of the United States by $170 000 000, and greater by $278 000 000 than the aggregate dividends paid during the same 10 years by all the railroads of the United States. Even at such prices, New York real estate, in the main, is considered a profitable investment.

The port of New York is the greatest railroad terminus. New York City is also one of the greatest manufacturing communities; it has 26 000 factories, and the products of its broadly diversified industries have now a value of $2 000 000 000 per year.

Greater New York, created in 1898 by consolidating a number of related cities and towns, comprises five boroughs: Manhattan, occupying the island of that name—"Little Old New York"; The Bronx, on the main land to the north and east; Queens and Brooklyn, on the western extremity of Long Island; and Richmond, which is Staten Island, to the south, at the entrance to the harbor. Numerous small islands are distributed among the boroughs. The total land area is 327 sq. miles, of which 85 000 acres, or 133 sq. miles, are vacant. The water-front extends for 577 miles, including islands and navigable inlets, but none of the New Jersey shore, and the area of the water surface of the harbor is 210 sq. miles.

The City's inhabitants number 5 373 000, as estimated for July 1st, 1913, by the Department of Health; but the whole community directly dependent for existence on the wonderful harbor is far greater, and aggregates approximately 7 000 000 persons. The population is increasing at the rate of 35% each decade. On the average, a baby is born every 6 min. Curves plotted on Fig. 6 indicate the rates of increase of population for the several boroughs and the greater city. Of Greater New York's inhabitants, 12% live in areas having a population density of 400 or more per acre, and 11% in areas having 10 or less per acre. The total of foreign-born is about 2 000 000; of these, 485 000 are from Russia, 340 000 from Italy, 253 000 from Ireland, 280 000 from Germany, 193 000 from Austria, 73 000 from Hungary, 78 000 from England. and 57 000 from Sweden and Norway. In the Boroughs of

FIG. 5.

Manhattan and The Bronx 45.4% of the white population are foreign born, and only 15.8% are of native parentage.

Greater New York's increment of population each 2 years is equivalent to a Jersey City or a Kansas City, a Bucharest or a Nottingham, and the annual gain would make an Albany, a Bridgeport, a New Haven, or a Grand Rapids, a Havre or a Geneva. New York's 5-year growth would people a Boston, a Cleveland, a Baltimore, or a Liverpool, and the increase between the last Federal census and the one a decade earlier would have supplied enough inhabitants for a Philadelphia, a Moscow, or a Peking.

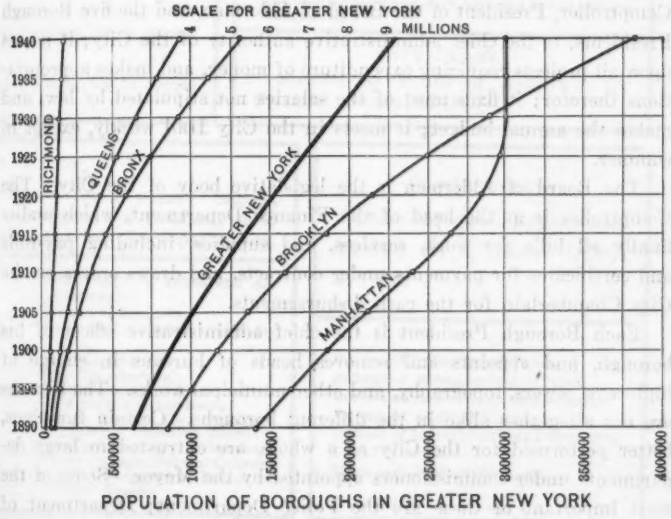

FIG. 6.

In New York there are more than 1 000 000 Jews. The negroes number 121 000, and have increased 10% in a decade. Residents of New York who were born in the Kaiser's empire would populate a Hanover; those from the Czar's domain, an Odessa. The Scandinavians are equivalent to one-sixth of the population of Stockholm. There are enough Italians to fill Turin. Those who once dwelt under the Turkish crescent and in the shadow of the Balkans would fill ten or twelve cities as large as Cettinje. Public utilities administration

and civic government are not a little complicated by these large and diverse foreign elements in the population.

City Government.

New York City is governed under a charter from the State of New York. A Mayor, five Borough Presidents, a Comptroller, the President of the Board of Aldermen, and a few minor city officials are elected once in 4 years, and a board of 73 Aldermen, every 2 years. Plate LIX indicates diagrammatically the general scheme of organization of the City government.

The Board of Estimate and Apportionment, made up of the Mayor, Comptroller, President of the Board of Aldermen, and the five Borough Presidents, is the chief administrative authority of the City; it passes upon all projects requiring expenditure of money, and makes appropriations therefor; it fixes most of the salaries not stipulated by law, and makes the annual budget; it meets in the City Hall weekly, except in summer.

The Board of Aldermen is the legislative body of the City. The Comptroller is at the head of the Finance Department, which audits finally all bills for work, services, and supplies, including pay-rolls and certificates for payments under contracts, and draws orders on the City Chamberlain for the cash disbursements.

Each Borough President is the chief administrative officer of his borough, and appoints and removes heads of bureaus in charge of highways, sewers, topography, and other municipal works. The bureaus are not altogether alike in the different boroughs. Certain functions, better performed for the City as a whole, are entrusted to large departments under commissioners appointed by the Mayor. Some of the most important of these are the Police Department; Department of Water Supply, Gas, and Electricity; Department of Bridges; Department of Docks and Ferries; Department of Public Charities; Law Department; Health Department; Department of Taxes and Assessments; Street Cleaning Department; Bureau of Weights and Measures; Tenement House Department; Fire Department; Park Department; Board of Education, of 46 members, from as many districts; Civil Service Commission; and Department of Correction.

From time to time, for the performance of unusual duties, special commissions have been created by statute. Among these may be men-

OF NEW YORK CITY.

ORGANIZATION OF NEW YORK CITY GOVERNMENT.

BOROUGHS OF GREATER NEW YORK:
Manhattan, Brooklyn, The Bronx, Queens, Richmond.

BOARD OF ESTIMATE AND APPORTIONMENT.

FINANCES, FRANCHISES, PUBLIC IMPROVEMENTS.

Consists of the Mayor, as Chairman, the Comptroller, the President of the Board of Aldermen, and the five Borough Presidents.

Mayor, Comptroller and President of Board of Aldermen, each has three votes; Presidents of Manhattan and Brooklyn, each has two votes; Presidents of Bronx, Queens and Richmond, each has one vote.

CONTROL OF CITY'S EXPENDITURES.

Annual budget is approved by Board of Estimate and Apportionment and then submitted to Aldermen; if latter take no final action in 20 days, budget is deemed adopted as submitted.

Certain special expenditures need previous authorization of Board of Estimate only:

Board of Water Supply, for additional sources, no limit;
Commissioner of Water Supply, Gas, and Electricity, for water supply purposes, not to exceed $2 000 000, in one year;
Rapid transit facilities, no limit;
Docks and ferries (on recommendation of Commissioners of the Sinking Fund), not to exceed $5 000 000, in one year.

BOARD OF ALDERMEN.

(Legislative).

Consists of 73 members elected for 2 years. President of Board is elected as such by the people. Salaries: President, $5 000; members, $2 000.

(The abolition of this board has been recommended frequently.)

CITY CLERK.

Elected by Board of Aldermen for 6 years. Salary, $7 000.

BOROUGH PRESIDENTS:

Elected for 4 years; salaries as below:
have charge of following bureaus:

MANHATTAN.	BROOKLYN.	BRONX.	QUEENS.	RICHMOND.
$7 500.	$7 500.	$7 500.	$5 000.	$5 000.
Highways, Sewers, Buildings, Hall of Records, Public Baths and Public Comfort Stations, Public Bldgs. and Offices, Public Works.	Highways, Sewers, Buildings, Topographical, Encumbrances and Permits, Public Bldgs. and Offices.	Design, Topographical, Highways, Sewers, Buildings, Public Bldgs. and Offices.	Highways, Sewers, Buildings, Topographical, Street Cleaning.	Highways, Sewers, Buildings, Public Works, Engineering Construction, Topographical, Street Cleaning, Public Bldgs. and Offices.

THE MAYOR.

Chief Executive. Elected for 4 years. Salary, $15 000. Is Chairman of Board of Estimate and Apportionment. Appoints heads of city departments.

Police Department.
Department of Health.
Fire Department.
Department of Street Cleaning.
Department of Water Supply, Gas, and Electricity.
Law Department.
Department of Parks.
Department of Docks and Ferries.
Department of Charities.
Department of Correction.
Bellevue and Allied Hospitals.
Department of Buildings.
Department of Bridges.
Tenement House Department.
Department of Taxes and Assessments.
Bureau of Licenses.
Bureau of Weights and Measures.
City Magistrates.
City Chamberlain.
Commissioners of Accounts.
Civil Service Commission.

The Mayor also appoints members of following Boards: Assessors, Armory, Education, City College, Normal College, Art Commission, Board of Water Supply.

COMPTROLLER.

Chief of Finance Department. Elected for 4 years. Salary, $15 000.

Bureau of Collection of Taxes.
Bureau of Miscellaneous Revenue.
Bureau of Assessments and Arrears.
Bureau of Audit of Claims.
Bureau of Investigation and Statistics.
City Payments.
Stock and Bond Division, etc.

COMMISSIONERS OF THE SINKING FUND:

The Mayor, Comptroller, City Chamberlain, President of Board of Aldermen, Chairman of Finance Committee of Aldermen.

Has charge of sale and leasing of all public property, including real and personal estate, and of the investment of moneys which constitute the sinking fund for the redemption of the City's debt.

PUBLIC SERVICE COMMISSION OF THE FIRST DISTRICT.

(A State Board appointed by the Governor)
Five Commissioners, at Salary of $15 000.

Has supervision in Greater New York of matters relating to public utilities, such as railroads, street railways, gas and electricity; and is charged with construction and operation of rapid transit facilities. All expenses are paid by the City.

tioned The Aqueduct Commission (1883 to 1910), which constructed the New Croton Aqueduct and most of its appurtenant reservoirs; The Rapid Transit Railroad Commission (1894 to 1907), which built the first subway and was superseded a few years ago by the State organization known as the Public Service Commission of the First District, in charge of the very extensive system of subway and elevated railways now in course of construction, as well as many other important matters; and The Board of Water Supply (created in 1905), which is building the Catskill Aqueduct and reservoirs for obtaining an additional public water supply.

Engineer corps, with chief and consulting engineers at their heads, are maintained by the several boroughs and such departments and commissions as have charge of the construction and maintenance of public works. The Chief Engineer of the Board of Estimate and Apportionment reports on all public works projects brought before that board, and hence occupies the position corresponding most closely to that of city engineer in many cities, although he has no construction in charge. In the office of this Board there is a Franchise Bureau, the engineers of which examine proposed franchises for public utilities, and devote some attention to existing franchises to see that the terms are complied with.

In the Comptroller's office there is a small corps of engineers whose duty it is to examine periodically during progress of construction all work of an engineering character being done for the City, in order to determine, before partial and final payments are approved, whether the contract requirements have been satisfied. These examinations are made rapidly, and are in addition to the detailed supervision and inspection by the engineers of the department conducting the work.

Altogether, New York employs 2 000 engineers and engineering assistants of various ranks and kinds; the total number of regular city employees is 85 000, and in addition, 22 000 are temporarily engaged, principally in connection with elections and other occasional work. The annual pay-roll amounts to $89 000 000. The City's annual budget is approximately $200 000 000, in addition to which $80 000 000 are spent otherwise for public purposes each year, such as additional water supply works, rapid transit railroad subways, street improvements, and docks. Practically all employees are under a civil service

system, controlled by entrance and promotion examinations, and directed by a Municipal Civil Service Commission.

The receipts of the City Treasury in 1912 were $524 000 000—$154 000 000 from taxes, water rents, and similar items; $334 000 000 from the sale of securities; $10 000 000 from assessments; $5 700 000 from the liquor tax; and $1 800 000 from the rapid transit contracts. The City will pay in 1913 for interest and sinking fund charges on its debt $55 000 000. The Department of Education, in 1912, spent $39 000 000. The City spent $24 000 000 that year for the new Catskill Water Supply System, and invested $14 000 000 in subway construction. It cost New York $9 000 000, in 1912, to clean its streets, $10 000 000 to put out fires, and for police protection $17 000 000.

For governmental purposes, Greater New York's territory is also divided into four counties: New York, Kings, Queens, and Richmond, and the creation of a fifth, Bronx County, was referred last fall to the voters of that portion of the City. Bronx County will elect officers some time in the year 1913, and these officers will assume their duties on January 1st, 1914. The counties have to do principally with certain courts, records of real estate transfers, and kindred matters.

The National Government maintains within the city limits a custom house, an immigration station, federal courts, several post offices and numerous branches, a navy yard, an army departmental headquarters, and a number of fortifications. The New York post office does an annual business of nearly $600 000 000. The world-famous West Point Military Academy, founded in 1794, is 55 miles up the Hudson River, and is reached by a delightful sail; here the Government is spending millions of dollars on beautiful new buildings.

City Map.

Probably the earliest demand for an official map of the City or its parts arose in connection with assessing real estate for purposes of taxation. Ward maps are mentioned in records of the city government nearly a century ago. A law passed in 1857 established the methods of taxing real estate which are still in use, and directed that the tax commissioners should appoint a surveyor from among the City Surveyors to make surveys, correct the ward maps, and prepare new maps. One of the oldest official maps is the Randall map, giving a street plan south of 155th Street; it was authorized by the Legislature

in 1807, and filed in 1811. There are, however, older private maps extant.

A law enacted in 1892 required the Commissioners of Taxes and Assessments to prepare a "block map of taxes and assessments," with triplicate copies, the original to be filed in the office of the Commissioners, one copy to be for the Deputy Tax Commissioners, one for the Bureau of Arrears of the Finance Department, and the third for the Bureau of the Water Register. These block maps, styled the permanent tax map, have been completed for all portions of the greater city having established street systems; they comprehend all Manhattan and Brooklyn, and that portion of the Bronx Borough west of the Bronx River. For the remainder of the City, the map is known as the tentative tax map. The permanent tax maps are drawn to a scale of 50 ft. to 1 in., the tentative tax maps to a scale of 80 ft. to 1 in., and smaller scales, on 14 by 22-in. sheets, and bound in volumes containing 35 sheets, together with an index and title sheet.

Land value maps, 142 in number, are published annually by the Department of Taxes and Assessments. These maps cover the whole City, and are for the following purposes: (1) to aid in assessment by giving each assessor a comprehensive view of his territory, with comparable figures on every street; (2) to assist the Commissioners in passing upon petitions for reductions of assessed valuations; (3) to enable the public to judge of the fairness of the assessor's work, and to aid the department by suggestions.

From 1652 to 1874 New York City had an area of 22 sq. miles. In 1874, 20 sq. miles were added; in 1895, 20 sq. miles more; in 1898, 260 sq. miles. The present area is sixteen times the original. In 1912, 523 330 parcels of real estate were assessed.

Topographical maps, based on careful surveys, have also been prepared for Manhattan, Brooklyn, and The Bronx; those for the Boroughs of Queens and Richmond are in progress, the surveys having been very nearly completed, the maps for Queens about half drawn, and those for Richmond well started. There are few good maps of the numerous pipes, ducts, and other structures buried beneath the streets. Recently, however, the Borough of Brooklyn established a Bureau of Sub-surface Structures, the engineers of which have made a creditable beginning in compiling maps showing all structures under the streets of that borough. Other boroughs also are directing attention to this

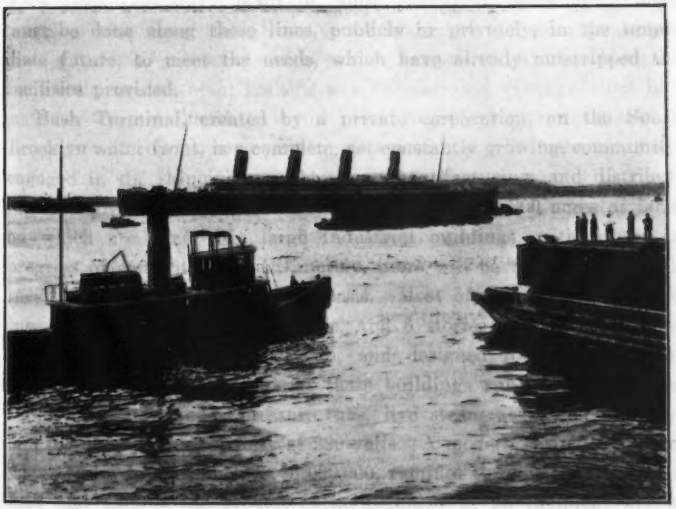
sorely needed set of records. Unfortunately, much of the necessary information is lacking, and can be obtained only from excavations for new work or repairs made from time to time or from test trenches dug across the streets.

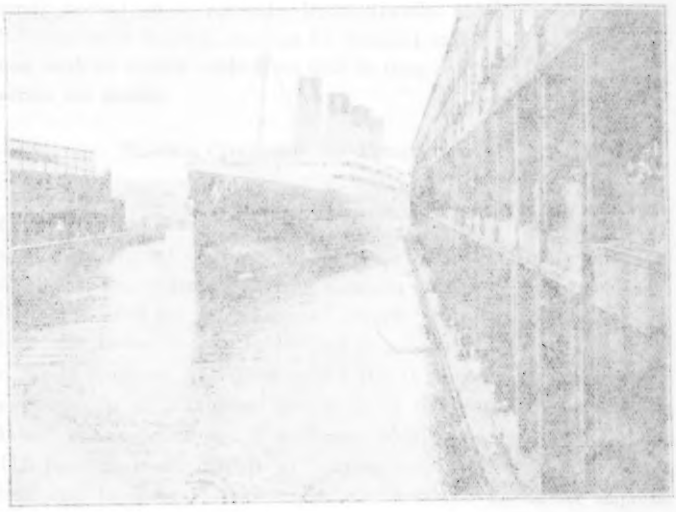
Harbor Channels and Freight Terminals.

The Lower Bay is comparatively shallow, so that, for modern commerce, artificial channels are necessary. From time to time, for many years, the Federal Government has improved New York's harbor by deepening and widening existing channels and dredging new ones. It is now possible for vessels of the deepest draft (40 ft.) to enter or leave the harbor and to be berthed at all stages of tide. The tidal range is moderate, averaging only 5 ft. It ranges from 4.4 ft. at the southern tip of Manhattan to 7.2 ft. in the East River near Long Island Sound. Compare these figures with 9.6 ft. in Boston Harbor, 11.5 ft. at Antwerp, 17.6 ft. at London, and 21.3 ft. at Liverpool. In total, the Government has expended $18 500 000 on harbor improvements at the Port of New York.

From 25 to 35 years ago, few American harbor engineering enterprises attracted more popular attention than did the Hell Gate improvement in New York Harbor. Rock reefs, which were very dangerous to vessels, obstructed the East River near its connection with Long Island Sound. Through these narrow, tortuous passages the tidal flow rushed with high velocities and very troublesome cross-currents and eddies, which gave the place its original name, "Whorl Gate." On September 24th, 1876, in 7 426 lin. ft. of tunnels in one of these rocks, Hallets Point, was fired the largest single charge of high explosives, 48 000 lb., which had been attempted to that date. Work was continued intermittently by various methods. On October 10th, 1885, Flood Rock, of 9 acres area, was partly demolished by the explosion of nearly 300 000 lb. of dynamite and rackarock in 21 670 lin. ft. of tunnels, from which 80 000 cu. yd. of rock had been excavated. Subsequent to the blast, the shattered rock was removed by dredging, continued for 20 years, and completed by recent drilling and blasting from scows and the removal of the loosened rock by a powerful dipper-dredge. By these operations the channel has been rendered safe and given a depth of 26 ft. for a width of 1 200 ft.

FIG. 7.—CHELSEA STEAMSHIP TERMINAL. THE "OLYMPIC" WEARING AND WARPING INTO SLIP, USING NORTHWEST CORNER OF PIER AS A FULCRUM IN THE MANEUVER. OBSERVE FLOATING FENDERS WHICH ASSIST IN BREASTING THE VESSEL OFF THE PIER. STEAMSHIPS ALWAYS DOCK WITH BOW INSHORE.





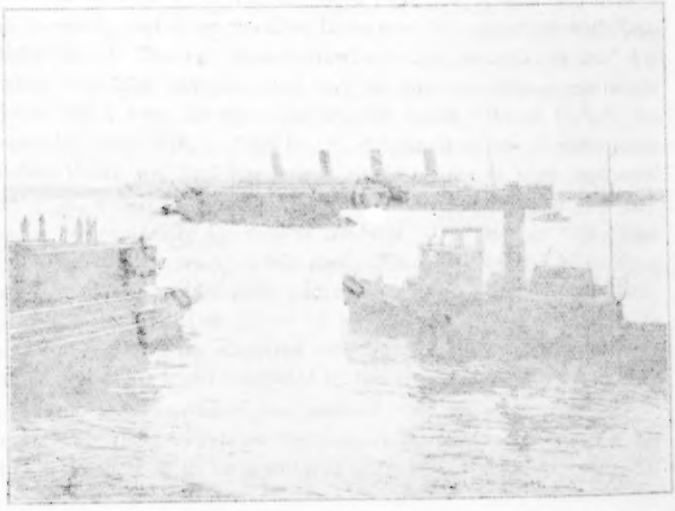


FIG. 8.—THE "OLYMPIC" IN MID-STREAM, NORTH RIVER; ALSO FERRYBOATS, FREIGHT-CAR FLOATS, AND STEAM TUGS.

Of wholly different character has been the Ambrose Channel improvement, at the southerly entrance to the harbor, begun in 1899 and carried on partly by contract and partly by Government plant. By suction-dredging 50 000 000 cu. yd. of sand, gravel, and mud, a channel, with 40 ft. depth at low water, 2 000 ft. wide and 7 miles long, has been created. The sea-going dredges, used exclusively, deposited the excavated material in deep water several miles out in the ocean. On this work the Government has used four specially built dredging steamers, each equipped with two 20-in. centrifugal pumps and each capable of discharging into the steamer's bins, an average of 6½ cu. yd. of hard-packed fine sand or 10 cu. yd. of loose sand and fine gravel per minute. The average liquid capacity of each pump is 86 cu. yd. per min. An average total cost as low as about 6 cents per cu. yd. of solid material, has been attained by the U. S. Engineers in charge. The contract price was 9 cents, and the contractor finally abandoned the work. In round figures, the total cost of improving this entrance to the harbor, formerly known as the East Channel, has been $5 000 000.

Private corporations have constructed large plants for warehousing merchandise and effecting transhipment economically from vessel to railroad. Attention is directed to the Bush Terminal and the New York Dock Company's plant in South Brooklyn. Very much more must be done along these lines, publicly or privately, in the immediate future, to meet the needs, which have already outstripped the facilities provided.

Bush Terminal, created by a private corporation, on the South Brooklyn water-front, is a complete, yet constantly growing, community, engaged in the shipping, warehousing, manufacturing, and distributing of a great variety of merchandise. It occupies 200 acres of land, on which are nine very large industrial buildings, with others in progress of construction. Ultimately, there will be thirty such buildings. There are also 130 warehouses. Most of the industrial buildings are 700 ft. long, 75 ft. wide, and 6 stories high, of reinforced concrete, unburnable construction, and designed for floor loads of 200 lb. per sq. ft. Throughout these buildings run pipes and wires supplying water under pressure, gas, live steam at 100-lb. pressure, and direct-current electricity at 220 volts. A modern sprinkler system, which alone has cost nearly $1 000 000, ramifies through all the buildings and assures the prompt extinguishment of an incipient fire in

the contents of any portion of the premises. One of the industrial tenants is a large paper manufactory, said to be the only one at tidewater. This paper plant has a capacity of 100 tons per day. Seven modern piers, each about 1 300 ft. long, accommodate steamship lines which send vessels to all parts of the world. The railroad yard can store 2 000 cars. The terminal has its own locomotives, tugs, lighters, and motor trucks; its post office, telegraph office, and express station. The economy and other advantages of such adjustment of commercial functions and the means for performing them are self-evident.

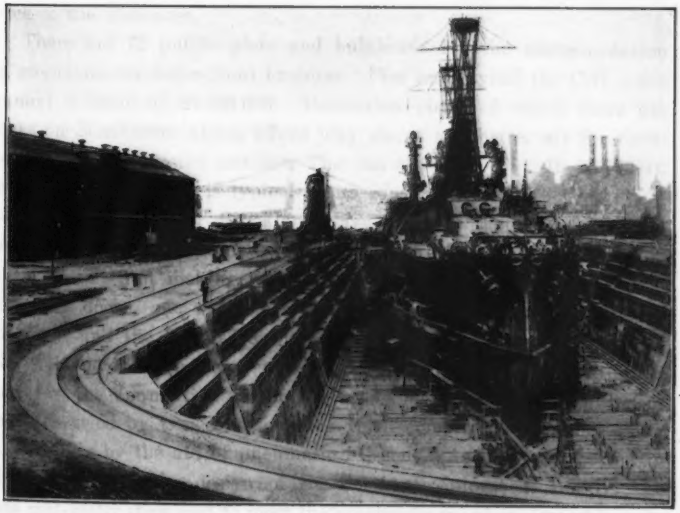
Docks and Ferries.

To accommodate the vast commerce which seeks the port, there are about 150 large privately-owned piers on Manhattan Island alone, and 850 piers in all, of which the City owns 230; there are many more on the New Jersey shore, where several great European steamship lines have their termini. The City has recently constructed nine 800-ft. piers immediately below 23d Street, on the Hudson shore of Manhattan, most of which are 125 ft. wide, with double-decked steel pier and bulkhead sheds. The piers are of wooden piles, with creosoted plank decks having concrete covering. The street façades of the pier sheds are of reinforced concrete, and the steel columns in them have jacking girders at their bottoms so that settlement may be compensated by using jacks and placing shims between the column bases and their masonry pedestals. These Chelsea piers accommodate some of the greatest transatlantic liners, but were hardly completed before the building of 900-ft. steamers showed them to be inadequate; consequently, two have been extended temporarily to 925 ft. Eight new piers are nearing completion in South Brooklyn.

For the development of a steamship and railroad terminal and an extensive system of docks at Jamaica Bay, on the Long Island shore, the City has appropriated $1 000 000 to begin the dredging of the bay, and the Federal Government has started the deepening of the entrance. The dredged materials are to be deposited back of the bulkhead lines.

Great projects are being studied for other improvements on the Long Island shore; for larger piers on the middle western shore of Manhattan, and for the better organization of the port as a whole, so as to facilitate the transfer of merchandise between ships and rail-

FIG. 9.—BUSH TERMINAL: VIEW FROM BALLOON AT AN ELEVATION OF 1 500 FEET.



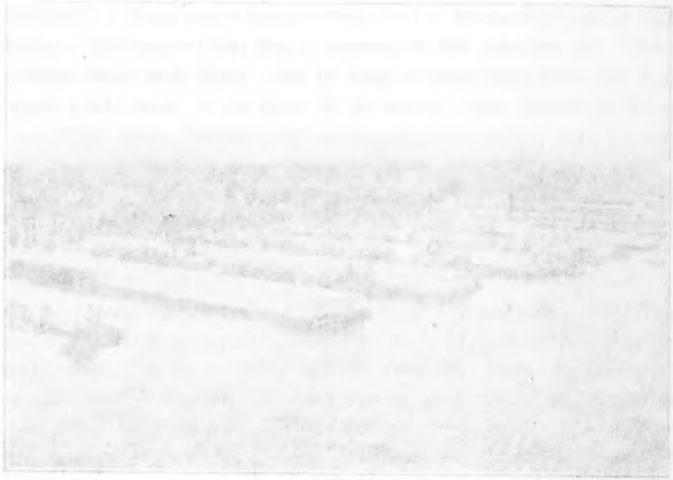


FIG. 10.—BROOKLYN NAVY YARD: DRY DOCK NO. 4, WITH BATTLESHIP "UTAH". FORTY-TON LOCOMOTIVE CRANE AT LEFT. WILLIAMSBURGH BRIDGE IN BACKGROUND.

roads and warehouses. For the new Manhattan piers, lengths up to 1 200 or even 1 500 ft. are being discussed, and the estimates of cost range from $15 000 000 to $25 000 000. Owing to the opposition of the Army Engineers to the moving of the pier-head line farther from the shore, a portion of the length of the proposed piers may have to be obtained by excavating the slips into the land. If the scheme is carried out on these lines, this will involve great expense for the acquisition of property, and much of the excavation will be in rock, if some of the locations suggested are adopted. Quays and diagonal piers have been suggested, in lieu of piers extending perpendicularly from the shore line. Several schemes for an elevated, surface, or underground marginal railroad along the western water-front of Manhattan are receiving serious consideration. Such a system of tracks is intended to inter-connect all the railroad and steamship lines entering this part of the City, and to serve the warehouses and other commercial establishments in the vicinity so as to curtail cartage and other handling charges and reduce the time required for freight movements. Connection has been proposed, by means of under-river tunnels exclusively for freight, to great railroad car classification yards on the New Jersey shore and the meadows back of the Palisades.

There are 72 public piers and bulkheads for the accommodation of miscellaneous water-front business. Pier leases yield the City a net annual revenue of $3 000 000. Recreation piers, of which there are eight on Manhattan alone, afford play places and better air for thousands in the congested sections. The one shown in Fig. 12 is 722 ft. long, 50 ft. wide, and is typical in its construction.

The New York, or Brooklyn, Navy Yard is the most important in the country. It contains extensive plants for building and equipping naval vessels and making naval repairs of all sorts. This yard has four dry docks, one of timber, one of timber and concrete, one of masonry, and the fourth, recently completed, of concrete. Dry Dock No. 4 is notable for being the largest on this side of the Atlantic, and for the foundation difficulties overcome. After the failure of methods tried by two contractors, a third completed the undertaking successfully by the aid of pneumatic caissons. As the years passed in these endeavors, the design of the dock was improved, and its size was materially increased to meet the constantly growing sizes of vessels.

As now completed, the dock is 700 ft. long, 110 ft. wide at the entrance, and has 35 ft. of water over the sill. It is wide enough to accommodate any vessel which can pass the Panama Canal locks, and any not exceeding 685 ft. in length. It cannot now receive the greatest modern commercial steamships, but if the building containing the central power plant of the navy yard should be moved, the dock can readily be lengthened.

Erie Basin, on the South Brooklyn water-front, is widely known to ship owners. Around this body of water are collected many establishments engaged in ship building, repairing, and outfitting, and here are several noteworthy floating dry docks. One recently completed has a length of 425 ft. and a lifting capacity of 7 000 tons; it is 100 ft. wide over all, and can receive vessels of 21 ft. draft. Its bottom platform and pontoons are of timber, and it has hollow side-walls of steel. Having an ample pumping equipment, it has raised vessels of its full capacity in 35 min., and smaller ones in from 15 to 20 min.

For protecting the shores and reclaiming lands partly under water, many miles of bulkhead or sea wall have been built, and this work is constantly being extended. Two principal types are used: one where there is rock foundation at reasonable depth, the other where the bottom is soft. The latter is known as the mud-flotation type. This wall is of comparatively light section, and supported on vertical piles. Other vertical piles are driven back of the wall to support a platform just above mean low water, on which is carried the few feet of filling. Heavy rip-rap is deposited among the piles, to a considerable depth below the bottom of the wall, and spreads to a wide base beyond the toe of the wall and back of the platform piles. Inclined piles are driven from the top of the rear platform piles to the bottom of the wall piles. By this construction, the wall is materially relieved from lateral thrust. For founding the rock type of wall, concrete in bags is first deposited under water to level up the inequalities of the rock before placing the lowest course of concrete blocks. For the construction of both types of walls concrete blocks, weighing from 30 to 90 tons, fabricated in yards on the water-front, are transported and set with the aid of a 100-ton floating derrick. Thousands of acres of land have been reclaimed and protected by these walls.

Scores of ferry-boats are run by the railroads and other corporations, principally between Manhattan and the other shores of the

ENGINEERING ACTIVITIES
OF NEW YORK CITY.

port, and the City operates ten boats from the south extremity of Manhattan to Staten Island and Brooklyn. Some of these are among the largest and swiftest ferry-boats afloat, and all the modern ones have screw propellers. Ferry rides from Cortlandt Street to Weehawken (West Shore Railroad), from South Ferry to Staten Island, from 42d Street, Manhattan, to Broadway, Brooklyn, and from 99th Street, Manhattan, to College Point, in Queens Borough, afford good views of the water-fronts and harbor. One of the common sights is a pair of huge car floats, each containing 23 freight cars, with a steam tugboat between, propelling them from one steamship or railroad terminus to another.

Barge Canal.

To provide water transportation across New York State, for bulk freight principally, a system of canals is being constructed to replace and extend the Erie Canal, dug during the period from 1817 to 1825, and the Oswego and Champlain Canals. It is known as the Barge Canal, and will cost $110 000 000. Fourteen terminals, for the accommodation of the canal-boats which will come down the Hudson, are to be built in the various boroughs of New York City where they will be convenient for the local distribution of goods or for transhipment. There are to be thirteen canal ports besides New York City, and the total cost of terminals is put at $20 000 000. Lack of such terminals was a principal cause of the commercial failure of the canals in recent years. Aggregating 445 miles in length, these canals will have a usual depth of 12 ft.; width at bottom, 75 to 94 ft.; and 57 locks large enough to pass 3 000-ton barges. It is anticipated, however, that barges having a capacity of 800 to 1 500 tons will be more commonly used. The completion of these canals is expected in 1915.

The Barge Canal has been located so as to follow the natural waterways much more closely than the old canals, and therefore, in large measure, it is a river canalization. Besides the constructed canals, the system embraces 350 miles of river and lake navigation. When this project is completed, there will be within the State 1 050 miles of such waterways, and along them will be dwelling 90% of the State's population. In addition, the Canadian and Vermont frontiers of the State have 500 miles of lake and river navigation, and the Hudson River affords 150 miles more, making a grand total of 1 700 miles.

Railroads.

Ten great railroad systems, each combining a number of important railroads, terminate at New York Harbor. Until recently, most of them have been able to deliver passengers and merchandise on Manhattan Island only by ferry. For a long time the New York Central and the New York, New Haven and Hartford Railroads have approached from the north and northeast by bridges. To accommodate the greatly increased traffic of these two systems, the Grand Central Station, on 42d Street, is being rebuilt of much greater size, with extensive changes in tracks and streets, involving a total expenditure of $140 000 000, in round numbers, exclusive of buildings not used directly for railroad purposes.

Grand Central Terminal.

To devise a terminal where space is practically unlimited, is a simple proposition; but to accommodate in a congested metropolitan center 5 000 000 residents and several more millions of commuters and miscellaneous travelers, is not simple. The four tracks of the New Haven Railroad, the two tracks of the Harlem Railroad, and the four tracks of the Hudson River branches of the New York Central Railroad converge into Park Avenue, and their traffic must be absorbed at or near 42d Street. The results of the efforts to solve this problem in the most congested district of the country, where property values approach the fabulous, are shown in Figs. 16 to 21.

The main track level occupies nearly the entire area between 42d and 50th Streets and Madison and Lexington Avenues, with a loop at the south end, around which equipment may move. This level has 19 miles of track, with 29 tracks adjacent to platforms. In-bound trains in Park Avenue are diverted at either 57th or 52d Streets to the five westerly tracks connected with the loop. Passengers are unloaded on these platforms, and the train then passes around the loop to the storage tracks on the east side of the yard. Out-bound trains leave from the stub tracks in the center of the yard.

The suburban level extends from 42d to 52d Street, with a maximum width of 707 ft. It also has a loop for turning, and the method of operation is similar to that for the main-track level. The suburban level has about 15 miles of track and 17 platforms. The total area of the two levels is 79 acres.

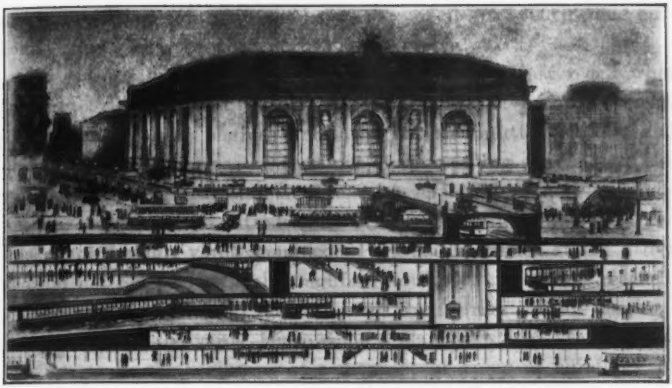

FIG. 20.—GRAND CENTRAL TERMINAL: SEVEN LEVELS OF ELEVATED, SURFACE, AND SUB-SURFACE TRAVEL. THE BRIDGE CARRIES PARK AVENUE OVER 42D STREET.

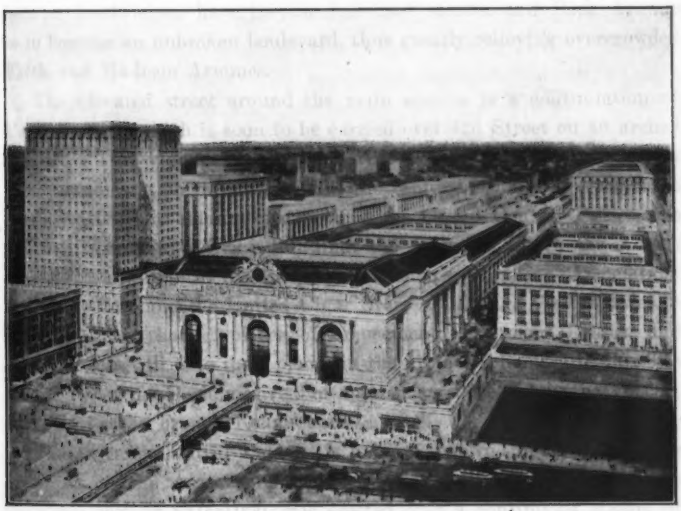

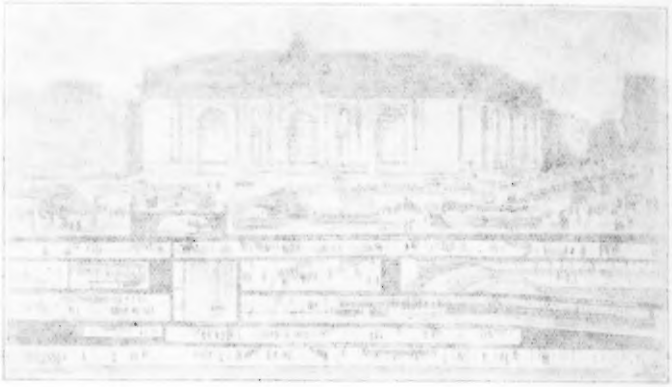

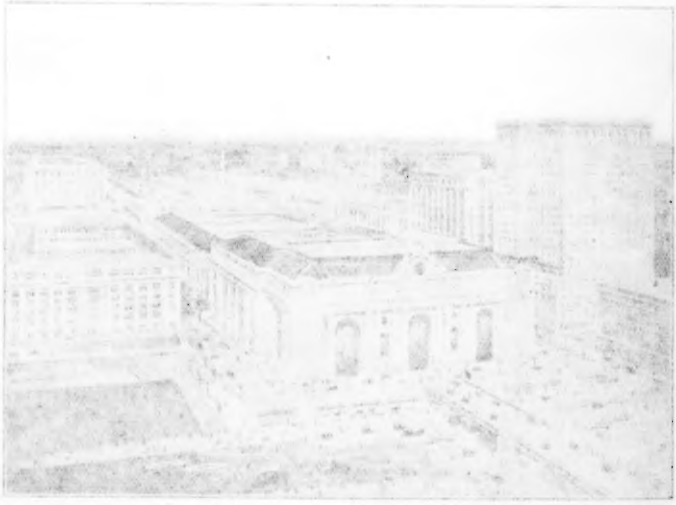

FIG. 21.—GRAND CENTRAL TERMINAL: THE NEW STATION AND THE BRIDGE CARRYING FOURTH AVENUE OVER 42D STREET. BILTMORE HOTEL (AT THE LEFT), AND OTHER BUILDINGS (LEFT AND RIGHT) ERECTED BY THE RAILROAD COMPANY OVER THE TRACKS.

If this terminal were worked to its maximum capacity for 24 hours, using it purely as a station, and providing holding capacity for equipment at outlying points, it could take care of about 3 300 in- and outbound trains, or approximately 2 300 000 people.

To grasp fully what is being accomplished one must recall what formerly existed. Here, on the street level, was a maze of tracks, over which smoking engines and noisy trains shuttled by day and night. Crossing this area on the lines of intersecting streets were elevated footbridges with stairways at each end. The whole spectacle was an eye-sore. The introduction of electricity did away with the smoke, but the ugly yards remained. Park Avenue ended at 42d Street and did not reappear as a thoroughfare until 50th Street was reached.

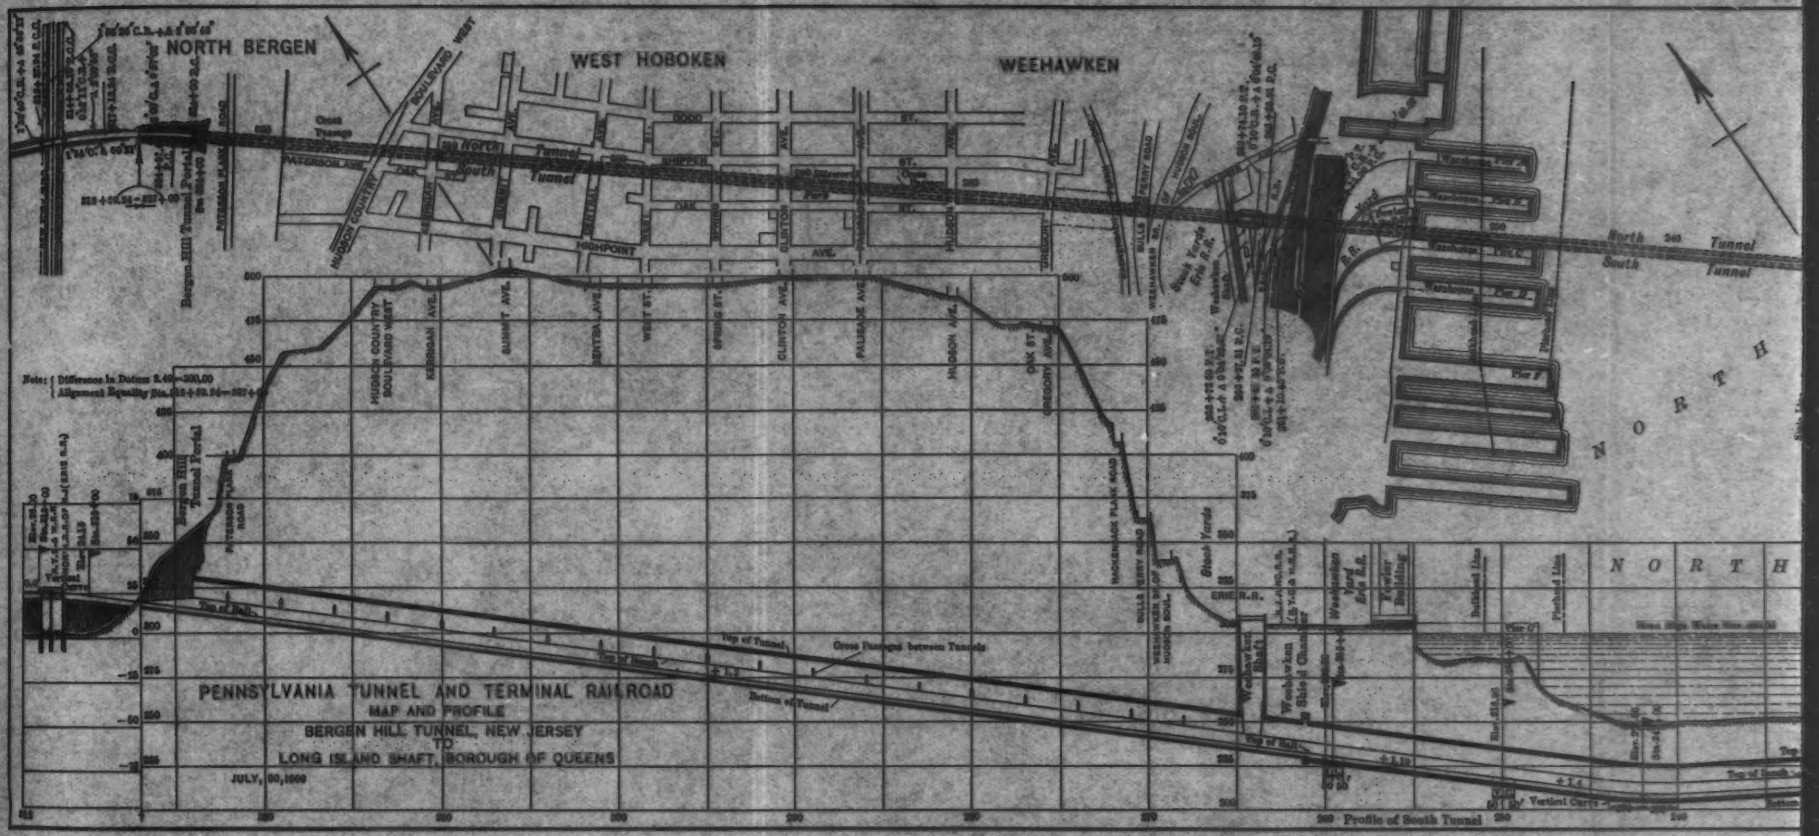
The New York Central Railroad owns the air rights of all the property comprising the yards, hence came a plan by which the main station was to be the beginning of a magnificent group of buildings, of uniform architecture, which would extend over all the tracks, not only hiding them, but adding to the attractiveness and usefulness of the whole section. In addition, all the cross-streets from 45th to 50th Streets, some of which had been carried over the old yard with only narrow footbridges, have become full-sized streets, and Park Avenue is to become an unbroken boulevard, thus greatly relieving overcrowded Fifth and Madison Avenues.

The elevated street around the main station is a continuation of Park Avenue, which is soon to be carried over 42d Street on an arched viaduct. This viaduct will be constructed by the City. In addition to the main station, which occupies the center of the group, there are now completed or under construction: the Grand Central Palace, the Railroad Company's Office Building, the Biltmore Hotel, the Adams Express Building, the Railroad Young Men's Christian Association, the Yale Club, and the United Cigar Stores Building. As the development proceeds, hotels, places of amusement, apartment houses, and other edifices will take their places in the group. The architecture has something of the Doric motive, but approaches more closely the Tuscan, modified by the French Renaissance.

The "Grand Central Palace" is a large, twelve-story loft building occupied by the Association of Wholesale Furniture Dealers. This building, costing $2 000 000, was erected over a continuous stream of in- and out-bound trains, without disturbance of the schedule, in 8

months and 18 days; the steel frame was erected at night (between 11 P. M. and 7 A. M.) and riveted during the day.

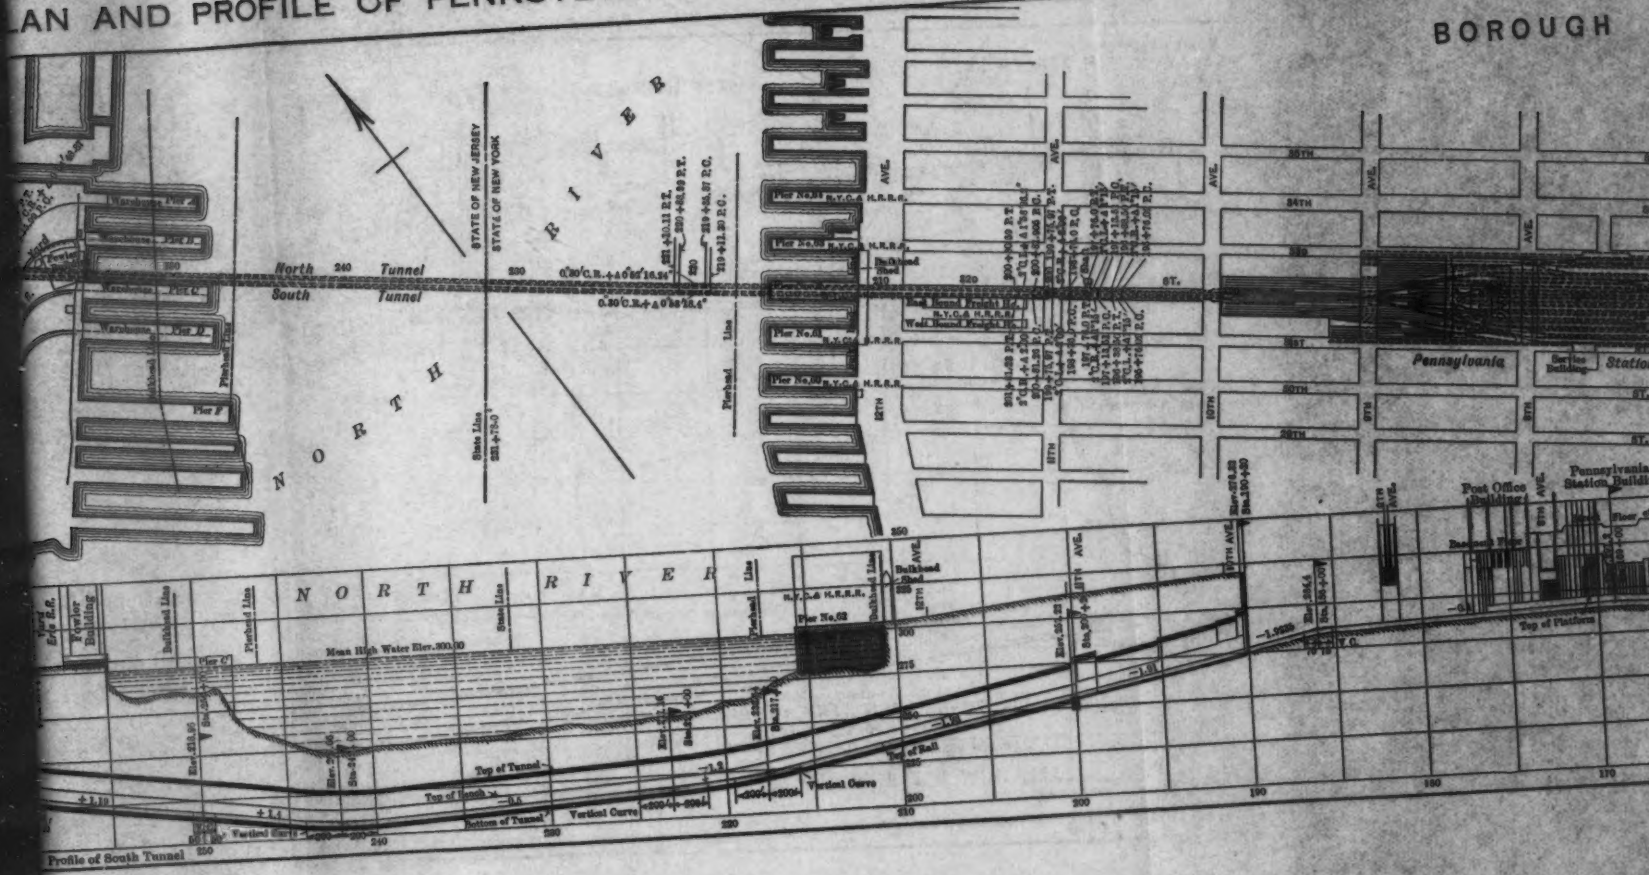
In Fig. 17 are shown the excavating operations in the rock on the site of the station building. There have already been used nearly 800 000 lb. of dynamite. The largest single item of work is the excavation, requiring the removal of approximately 3 100 000 cu. yd. of material, of which about two-thirds are rock. Earth and rock from the excavations are utilized for widening the roadbed for additional tracks along the Hudson River and on the Harlem Division. Much of the excavating has to be done near buildings owned by other parties. The general character of this work is indicated in one of the illustrations. In this particular case the building was underpinned for a depth of 30 ft., the excavation in front of it being 45 ft. deep.



A steel deck, over the suburban level station, supports the express level tracks, which cover an area of about 38 acres, with provision for building columns to be inserted later. Above the express level there are about 1¾ miles of viaducts. The main station building contains approximately 29 000 tons of steel. Provision is made in this structure for carrying the central portion up to a height of 20 stories. In the entire terminal, including tracks, viaducts, and buildings now definitely determined upon, there are approximately 150 000 tons of steel. Portions of the new terminal have been in use for some time. It is expected that within a year most of the work will be completed.

Pennsylvania Terminal.

A great system of tunnels, aggregating 13.7 miles in length, with a magnificent passenger station between Seventh and Ninth Avenues, 31st and 33d Streets, was completed in 1910 by the Pennsylvania and Long Island Railroad systems. These tunnels start far back from the New Jersey shore. Two single-track tubes pass beneath the Hudson River and as far as the station yard; two double-track tunnels cross Manhattan Island, and four single-track tubes pass beneath the East River and to terminals well inland on Long Island. When this great project is completed, it will have cost, for real estate, structures, and equipment, $160 000 000.



Besides the tunnels and station, the project comprises numerous large freight yards in New Jersey and on Long Island, with car-float terminals at Greenville, on the New Jersey shore, and at Bay Ridge,

AND CITY.

in Brooklyn; extensive revision of the railroads, both in New Jersey and Long Island, involving the elimination of scores of street grade crossings; and the New York Connecting Railroad, 12 miles long. This latter road, now under construction, makes physical connection between the Pennsylvania and Long Island Railroads and the New York, New Haven and Hartford Railroad, thus completing an all-rail route for passengers and merchandise from New England and Eastern Canada to the West, South, and Southwest. To carry the Con-

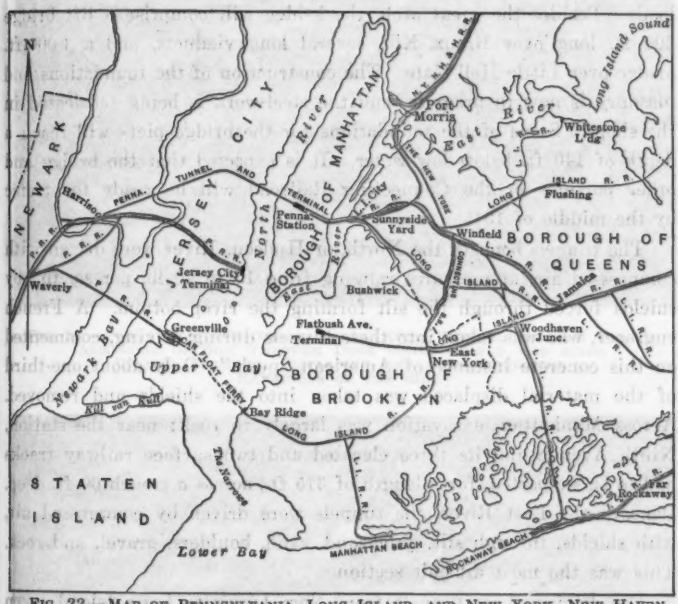

FIG. 22.—MAP OF PENNSYLVANIA, LONG ISLAND, AND NEW YORK, NEW HAVEN AND HARTFORD RAILROADS WITHIN METROPOLITAN DISTRICT.

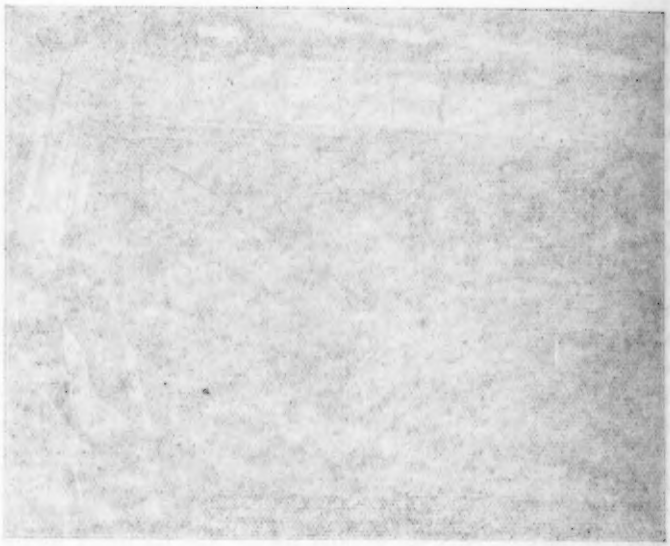
necting Railroad from Long Island to the main land, a succession of high viaducts and bridges over three estuaries, together 3 miles long, and for four tracks, is being built, crossing the East River at Hell Gate with an arch of 1 000 ft. span and 300 ft. rise, towers 250 ft. high, and a clearance of 140 ft. for vessels. This will be the longest arch span in the world.

It is claimed that Hell Gate Bridge, 15 840 ft. long, will be the longest and largest steel viaduct in the world. Tay Bridge in Scot-

land is 10 780 ft., and the Ohio River Bridge, at Cairo, Ill., 10 560 ft. The Hell Gate arch alone is estimated to cost $6 000 000 of the $30 000 000 total for the Connecting Railroad. Into the bridge structures will be erected 80 000 tons of structural steel, 400 000 cu. yd. of Portland cement concrete reinforced with 4 000 tons of steel, besides large quantities of granite. Some of the steel members will be 10 ft. in diameter and weigh 180 tons each, requiring special heavy cars for their transportation. It has been proportioned for very heavy live loads. Besides the great arch, the bridge will comprise a lift bridge 300 ft. long over Bronx Kill, several long viaducts, and a 1 000-ft. bridge over Little Hell Gate. The construction of the foundations and masonry is now in progress, and the steel-work is being fabricated in the shops. Some of the foundations for the bridge piers will reach a depth of 140 ft. below low water. It is expected that the bridge and other portions of the Connecting Railroad will be ready for traffic by the middle of 1915.

The tunnels beneath the North, or Hudson, River were driven with compressed air, at pressures ranging from 15 to 40 lb. per sq. in., by shields forced through the silt forming the river bottom. A French engineer, who was taken into these tunnels during driving, commented on this concrete instance of American "push." Only about one-third of the material displaced was taken into the shields and removed. Across Manhattan, excavation was largely in rock; near the station, Ninth Avenue and its three elevated and two surface railway tracks had to be supported, for a length of 375 ft., across a trench 60 ft. deep. Beneath the East River, the tunnels were driven by compressed air, with shields, through silt, quicksand, sand, boulders, gravel, and rock. This was the most difficult section.



For driving these tunnels from New Jersey to Long Island seven shafts were sunk, six of which required caissons. Operations were also carried on from portals in New Jersey and on Long Island, and from the great open excavation for the station building and its yard. One shaft was located at each North River margin, one near the middle of Manhattan Island, and two at each shore of the East River. They were large enough to permit the introduction of the tunneling shields. One shaft on the Manhattan shore of the East River was constructed so as to give permanent access to the tunnels. The depth of the deepest shaft was 125 ft., and the greatest horizontal dimensions were 100 by

154 ft. (Weehawken shaft at its top, New Jersey); the smallest shaft was on Manhattan, 22 by 32 ft. and 65 ft. deep. The East River shore shafts are circular, 18 ft. in diameter.

Over the North River tunnels the maximum depth of water is 53 ft., and the tunnel invert, or bottom, is 97 ft. below mean high water. The steepest track grade is 1.93%, and this grade is 1 780 ft. long. These tunnels are 37 ft. apart, center to center. Beneath the East River there are two 1.5% grades, the longer being 4 050 ft. Ventilating fans are installed at the bottoms of the North River shafts, in the building at the Hackensack portal, and in the buildings above the East River shafts. There are also drainage pumps in these shafts. Ventilation, however, is effected largely by the piston action of the moving trains, causing frequent displacements of the air in the tunnels.

Throughout these tunnels, the signaling is three-position upper-quadrant, and, as a whole, represents one of the largest single installations of the kind yet undertaken. The electro-pneumatic system, with interlocking machines and other equipment, and controlling apparatus of the latest and most improved design, is used throughout.

Light signals are used under the Pennsylvania Station and Post Office Building, throughout the Pennsylvania Station Yard, in the North and East River Tunnels, and under the platform shelters at Manhattan Transfer. The use of such a signal in the open—exposed to daylight—is particularly novel, but, as conditions made it imperative, an arrangement of lights and lenses was developed, after a considerable number of experiments, that gives satisfactory color indications under the worst conditions, namely, sunlight directly over the lenses. The change in color, or the giving of the different indications, is effected by the opening and closing of relays, the lenses being colored and placed so as to give the night aspects of the semaphore signals.

Alarm boxes are located in all tunnels at intervals of about 800 ft. These boxes are equipped with two levers; one painted blue and marked "Power", and the other painted red and marked "Fire." If it is desired to cut off the power from the third-rail, the blue lever is pulled, which sends in two rounds of the box number to the sub-station feeding the third-rail, and trips the circuit breakers in the sub-station and switching station. The alarm is also given in the offices of the train director, train and locomotive despatcher, power director, and the

interlocking station controlling the movement of trains in the section in which the trouble occurs. If the red lever is pulled, the power is cut off the third-rail, and four rounds of the alarm are sent in, as above.

The Pennsylvania Station Yard is 3 500 ft. long, from Tenth to Sixth Avenue, and 510 ft. wide, from 31st to 33d Street. Its area is 28 acres, and, to make way for it, 500 buildings were removed, and 3 000 000 cu. yd. of rock were excavated. Concrete retaining walls, aggregating 7 800 lin. ft., were required. The storage capacity of this yard is 222 cars. Beneath the yard and station, 65 ft. below street level, there are 5 200 lin. ft. of trucking subways and pipe galleries.

One of the principal features of the station is the separation of incoming and outgoing passengers. Incoming passengers pass from the train platforms by way of short stairways or elevators to the exit concourse, and thence to the street exits. Outgoing passengers enter the main concourse, and pass to platforms by way of train gates and stairways. The following are some of the principal dimensions and data of this station:

Area of building, 7.74 acres;
Length, 784 ft.; width, 430 ft.;
Building supported on 650 steel columns;
Greatest weight on one column, 1 658 tons;
Weight of building steel, 27 000 tons;
Average height above street, 70 ft.;
Maximum height above street, 154 ft.;
Wire glass used in roof construction, $\frac{3}{8}$ in. thick, 220 tons;
Gross aggregate of concrete used in station, 962 833 cu. ft.;
Water-proofing used, 1 797 964 sq. ft.;
Exterior of building, Milford pink granite, 500 000 cu. ft.;
Brick, 15 000 000;
Number of electric lights in station, in terms of 16-c.p. lamps, 30 000;
Arcade, 46 ft. wide, length, 216 ft.;
Dining-room, 56 ft. wide, length, 112 ft.;
Lunch-room, 56 ft. wide, length 112 ft.;
Main waiting-room, length, 277 ft.; width, 108 ft.; height 150 ft.;
Two sub-waiting rooms, 56 by 100 ft.;
Engagement room, 18 by 28 ft.;
Hospital, 21 ft. 8 in. by 16 ft. 6 in.;
Nursery, 27 ft. by 46 ft. 3 in.;
Two private waiting-rooms for funeral parties, one 16 by 18 ft. 6 in., one 16 ft. 8 in. by 21 ft. 8 in., one equipped with elevator to train platform;

Exits, 34th Street, stairway and escalator, capacity 12 000 people per hour.

The sub-river tunnels have shells 23 ft. in diameter, made up of flanged cast-iron and cast-steel segments, bolted together, weighing 6 tons per lin. ft. All tunnels are lined with concrete and shaped so as to provide foot-paths at the level of the sills of the car windows. Beneath these foot-paths, ducts for wires are embedded in the concrete. The weight of the empty completed tube is 16 tons per lin. ft.; with the maximum train load, it is 23 tons; the weight of silt displaced was 21 tons. The ratio of weight of completed tunnel to displaced silt is 0.74.

Hudson and Manhattan Tunnels.

The Hudson and Manhattan Tunnels now afford to several railroads terminating on the New Jersey shore means for delivering passengers at many points on Manhattan Island, besides serving as a part of New York's street and interurban transportation system and extending out to Newark. The original Hudson River Tunnel, begun about 1874, was long notorious on both sides of the Atlantic because of its physical and financial disasters. The Hudson and Manhattan Railroad Company now has four tubes under the river, a total of 18 miles of tunnel, and a commodious underground terminal containing many spaces for concessionaires, and surmounted by two twenty-two-story office buildings on Church Street, between Cortlandt and Dey Streets, Manhattan, besides numerous subterranean stations. This project, not yet finished, is involving an expenditure of $39 000 000, exclusive of power-house and equipment, and a total expenditure estimated at about $70 000 000.

Beginning in 1902, the final project has progressed steadily. The northerly tunnel of the old pair, from 15th Street, Jersey City, to Morton Street, Manhattan, was holed through on March 11th, 1904, by shield excavation, with compressed air. In the southerly tunnel of this pair a novel modification of shield tunneling methods in soft ground was very successfully tried. The doors in the front of the shield were kept closed at times while the shield was being driven ahead through silt, the soft material thus being forced aside and not taken

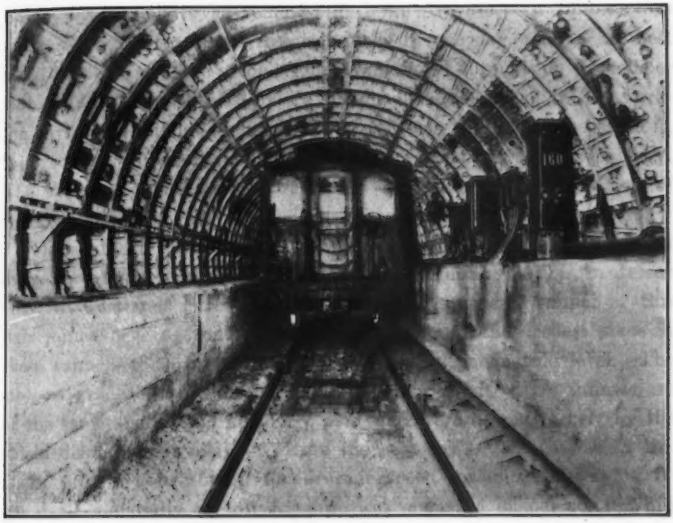

FIG. 31.—"HUDSON TUBES": INTERIOR VIEW, SHOWING CONCRETE SIDE-WALLS AND SIGNAL APPARATUS.

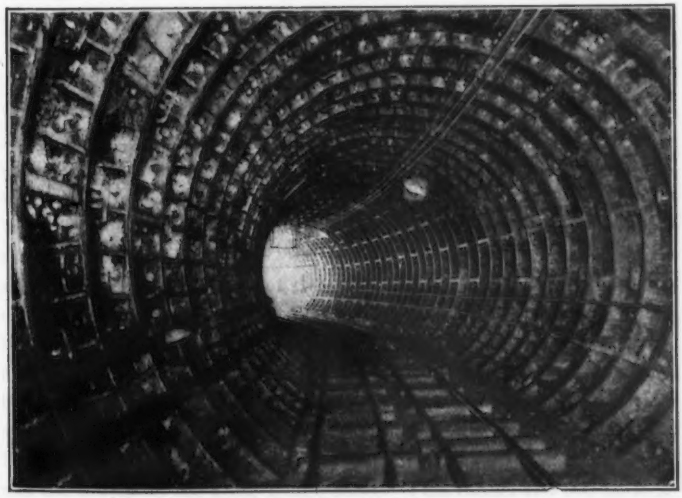

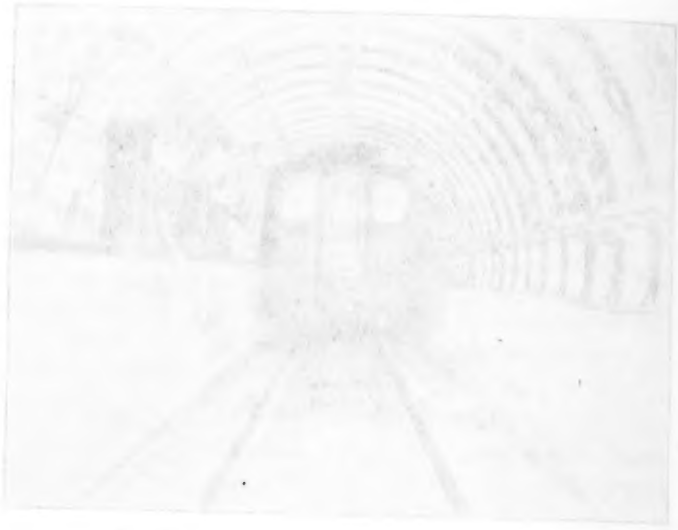

FIG. 32.—"HUDSON TUBES": CURVE IN THE EAST-BOUND TUNNEL AT MORTON AND GREENWICH STREETS, SHOWING CAST-IRON LINING.

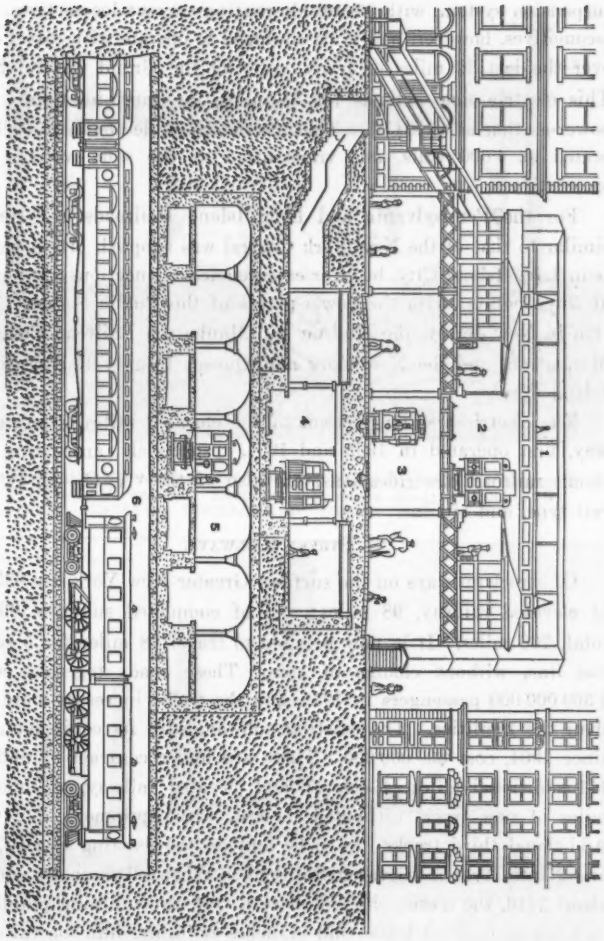
inside the tunnel, to be removed at large expense. In this way as much as 62 lin. ft. of progress was made in one day, and in the best week 348 lin. ft. This second tunnel was holed through on September 30th, 1905, its length of 5 100 ft. having been excavated in 334 working days. The outside diameter of the cast-iron lining, or tube, is 16 ft. 7 in., and the inside diameter, 15 ft. 3 in., the flanges being 8 in. deep. The sharpest curves have a radius of 150 ft. This first portion of the system was officially opened on February 25th, 1908.

The southerly pair of tunnels was not in the original project; they extend from the old Pennsylvania Railroad terminal station, in Jersey City, to Cortlandt Street, Manhattan. The southerly tunnel of this pair joined headings on January 27th, 1909. At the deepest place in these tunnels the base of rail is 91.5 ft. below mean tide level. The steepest grade is about 4.5 per cent. The Cortlandt Street tunnels are of the same size as the northerly pair, and were driven largely by the shield displacement method. Here the best day's advance was 72 lin. ft. in three 8-hour shifts; the average speed through silt was 19 ft. per day. Generally the air pressure was about 25 lb. per sq. in., but occasionally a pressure as high as 38 lb. was necessary. All the tunnels passed through some rock near the New York shore. The subway connecting these tunnels in Manhattan is being extended to the Grand Central Station.

Belmont Tunnel.

The Belmont, or Steinway, Tunnel, extending from the Grand Central Station, Manhattan, under the East River to Queens Borough, is a part of the Dual Rapid Transit System, although constructed as a private enterprise and never used. It consists of two 15.5-ft., parallel, single-track, shield-driven, cast-iron-shell, concrete-lined tubes, except where in rock, on shore. The tubes are 28 ft. apart on centers. Under the river, only a portion of the material was admitted through the shields and removed. Most of the excavated earth and large quantities of clay were deposited in deep water over the tunnel to increase the thickness of the roof. At times, the top of a shield was washed bare, and, at other times, boulders were encountered which had to be blasted before the shield could be advanced. The maximum depth of water above the tunnel location was 60 ft. Four shafts were sunk from which to drive the tunnel, two on Manhattan, one on a reef in mid-stream, and the fourth on the Long Island shore. This tunnel is 9 000 ft. long,



from the Grand Central Station to the Queens terminus, and cost $8 500 000.

Electric Propulsion.

All these great railroad projects, and several others which seem small only by such comparison, have involved the adoption of electricity as the motive power. Indeed, without recent electrical achievements, some of these projects would not have been feasible. Earlier attempts to solve some of these same problems by other means led only to failures.

Following a serious railroad accident in the Park Avenue Tunnel approach to the Grand Central Station, attributed to obscuration of signals by smoke and fog, the State of New York, in 1903, enacted legislation requiring, with other improvements, the substitution of electricity as the tractive power before July 1st, 1908. The "A. C.—D. C." third-rail system was adopted by the New York Central Railroad, with multiple-unit motor cars for suburban service, and 95-ton, 2 200-h.p. electric locomotives for long-haul trains. Cross-connected, duplicate power-houses were built at Port Morris and Yonkers, to generate 3-phase, 25-cycle, alternating current, at 11 000 volts, for transmission by cables, of which a great length is in ducts. Rotary converters, in numerous, conveniently-located sub-stations, change this current to 660-volt direct. Both power-houses are equipped with 625-h.p. water-tube boilers, and 5 000-kw. Curtis turbo-generators. The electric zone extends for 35 miles on the Hudson main line, to Croton Station, and for 25 miles on the Harlem Division, to North White Plains. In July, 1907, the first scheduled trains were run by electric power.

The New York Central Railroad is now having built ten 100-ton electric locomotives of an improved type, bringing its total up to fifty-seven. Although of 15 tons less weight, the new locomotives will be 50% more powerful than the old ones, and have 25% greater speed capacity. Each is rated at 1 400 h.p. continuously, and 5 000 h.p. for short-time maximum. Capable of exerting a pull of 13 500 lb. for one hour at 54 miles per hour, each one of these locomotives is expected to be able to haul a train weighing 1 000 tons, at a speed of 60 miles an hour continuously. There are four trucks of four wheels each under each locomotive, hence they are known as 4-4-4-4 type. A good idea of the appearance of such a tractor may be obtained from Fig. 40.

FIG. 33.

On the other hand, the New York, New Haven and Hartford Railroad adopted an alternating-current, overhead-trolley, cradled-catenary suspension system, with 93-ton alternating-current locomotives. These locomotives, however, had to be equipped to operate with direct current over the last 12 miles of track, entering the Grand Central Station. This electric zone extends for 34 miles, to Stamford, Conn., with a power-station at Cos Cob. The current is single-phase, 25-cycle, generated at 4 000 volts, and transmitted at the same voltage to the locomotives.

For the Pennsylvania and Long Island Railroads, a system very similar to that of the New York Central was adopted. Its power-house is in Long Island City, but, for emergencies, connections were arranged at three points: with the power-plants of the Public Service Corporation in New Jersey, the Hudson and Manhattan Railroad Company in Manhattan, and the New York and Queens County Railway in Long Island City.

The electric traction systems of the elevated railways and the subway, first operated in 1902 and 1904, respectively, antedating all the steam railroad electrifications, are also of the "A. C.—D. C." third-rail type, and similar.

Street Railways.

Of street railways on the surface, Greater New York has 635 miles; of elevated railway, 98 miles; and of completed subways, 33 miles; total, 766 miles. It is now possible to travel 18 miles for 5 cents, on one line, without change of cars. These roads together conveyed 1 560 000 000 passengers in 1911, and the traffic increases more rapidly than the facilities. The existing subway, with its equipment, in use since 1904, cost $90 000 000. There are under contract or authorized, 111 additional miles of subway and elevated railway, to contain 312 miles of new track, estimated to cost, with equipment, $325 000 000. Additional third tracks are to be laid on the existing Second, Third, and Ninth Avenue Elevated Railroads. When all these are completed, about 1916, the metropolis will have a system containing parallel lines in zones of heaviest traffic and branches radiating into the various outlying sections affording rapid transportation at low cost. As thus enlarged, the system is known as the Dual System of Rapid Transit, and is expected to have an annual capacity of 3 000 000 000 passengers, exclusive of the surface street railways.

FIG. 40.—NEW 100-TON ELECTRIC LOCOMOTIVE OF THE NEW YORK CENTRAL RAILROAD.

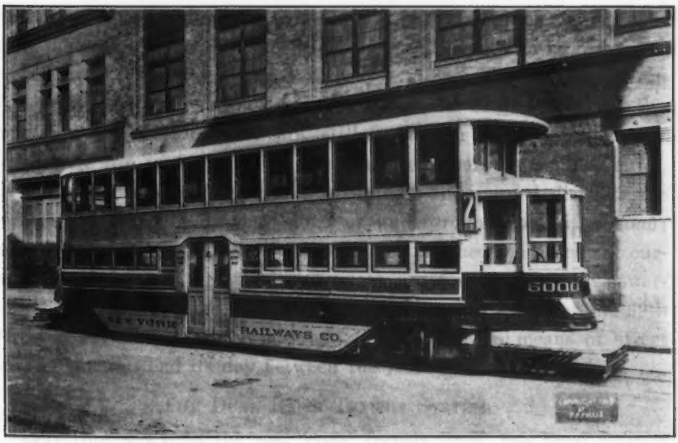

FIG. 41.—STREET RAILWAY CAR OF LATEST TYPE. DOUBLE DECK, WITH STEPLESS SIDE ENTRANCE.

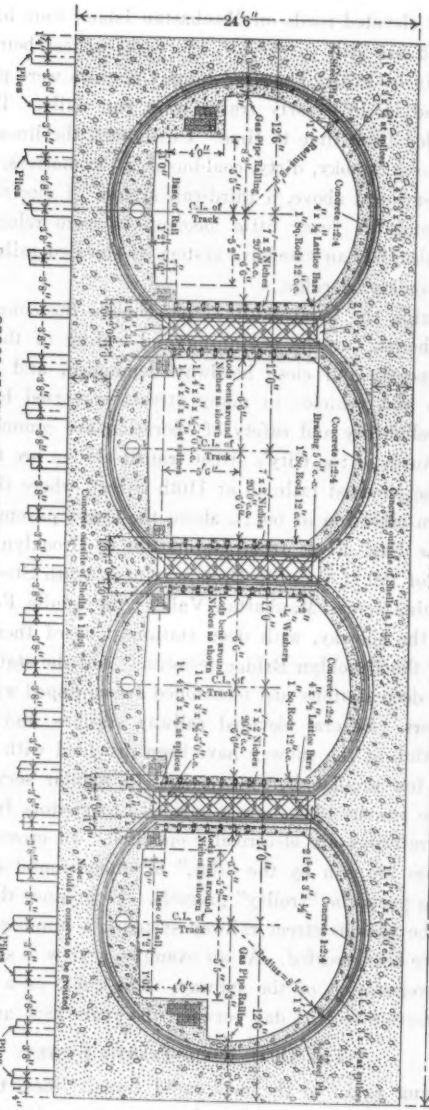

The first elevated roads on Manhattan Island were built about 1870 to 1878, and are still in service, the very earliest being operated by endless chain in 1870. The first dummy engines were put on the road in 1871, and in 1876 forty trains were run daily. The system has been extended from time to time. Until 1902, the lines were all operated with noisy, smoky, dirty, coal-burning locomotives, but about that year, as mentioned above, a third-rail system of electric traction was completed and the fussy little locomotives were relegated to limbo. Brooklyn, also, has an extensive system of elevated railroads, radiating from the Brooklyn Bridge.

Considering the great hosts of passengers, the congested travel in the "rush hours," at the beginning and ending of the business day, the high speeds, and close headway demanded, and the throngs of pedestrians and vehicles in many streets traversed by surface cars, truly the reliability and safety of operation are commendable. Noteworthy features of the City's street transit system are the high reverse curve in the elevated railroad at 110th Street, where the tracks attain a maximum elevation of 60 ft. above the street pavement; the tunnel beneath the East River from Manhattan to Brooklyn; the parabolic steel arch, of 180 ft. span, in Broadway near 129th Street, carrying the subway trains across Manhattan Valley; the 4-mile Fort George rock tunnel of the subway, with deep stations, one of them 180 ft. below the street; the Brooklyn Bridge terminals, and the stations of the subway. The deep stations just mentioned are equipped with large passenger elevators. Several elevated railway stations and the Manhattan Valley station of the subway have been provided with escalators. Excepting a few archaic horse-cars, still in regular service, the first of which were run in 1832, now a curiosity to visitors from other cities, all street railways are electrically operated. In crowded districts the surface cars are run by the "slot," or underground conduit, system; in outlying parts the "trolley" prevails. To produce the necessary current for the various street railway systems, a number of large power-houses have been erected. As an example, a view is shown of the 59th Street power-station of the subway. The cable as a means of street railway traction had its day between the years 1885 and 1900.

The Dual Rapid Transit System.

Referring again to the new rapid transit lines, the Dual System derives its name from the fact that two companies, the Interborough

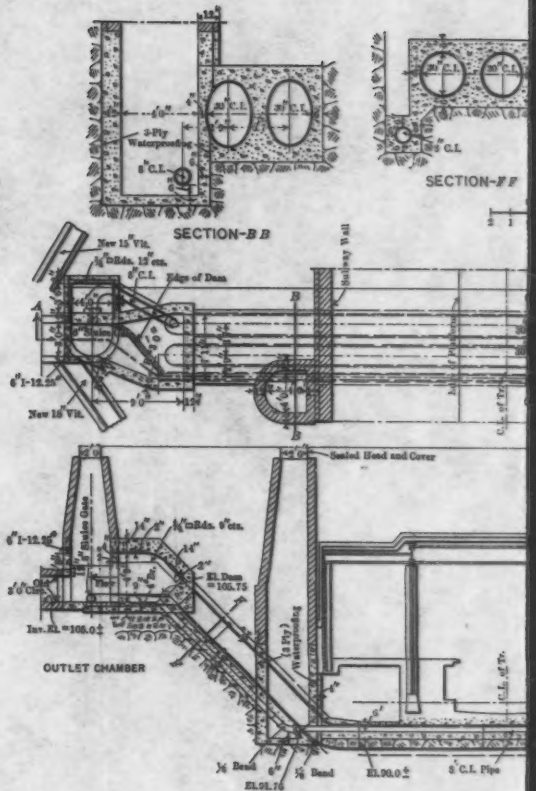
Rapid Transit Company and the Brooklyn Rapid Transit Company, combine with the City in constructing, equipping, and operating the roads. The former company retains the existing lines in Manhattan and The Bronx, and will obtain most of the extensions in these two boroughs, together with the subway into Brooklyn which it now has, certain new connections in that borough, the Steinway Tunnel, extended, and connections over the Queensboro Bridge to Queens. The latter company continues to hold all its elevated lines in Brooklyn, and will get most of the new subway and elevated lines in that borough, and, in addition, most of the lines across the East River Bridges, with important new subway connections on Manhattan Island, south of 59th Street. The Brooklyn Rapid Transit Company is equally interested with the Interborough Company in a number of lines extending into Long Island City, in the Borough of Queens, and will acquire rights to extend the Brooklyn lines through to Jamaica, in the southeasterly part of Queens. Some portions of the lines are to be used by the two companies jointly. The fare is to be 5 cents on each system.

The City is to design, construct, and own the new subways, but agrees to lease them to the companies for 49 years, with definite provisions for recapture in whole or in part, at stipulated times. The companies are to equip and operate the subways. Extensions and improvements of the elevated lines are to be constructed and equipped by the companies. The leases for the elevated road extensions will run for 85 years from completion, but the old franchises are in perpetuity. The City is to share in the profits of operation. The Interborough Rapid Transit Company agrees to expend $56 000 000 for the construction and $21 000 000 for the equipment of new lines, in addition to its total investment of $48 000 000 in the first subway. Thus the Interborough will have an aggregate investment of $125 000 000 in subways, extensions, and equipment. The Brooklyn Rapid Transit Company is to spend $13 000 000 for the construction of new lines to be included in its system, and $21 000 000 for the extensions and improvements of its present lines. In addition, the Brooklyn Company is to devote $26 000 000 to the equipment of the lines which it is to operate. An aggregate new investment of $60 000 000 is thus required of this company.



In the new subways, the station platforms will be long enough for ten-car express trains and six-car local trains, and no station plat-

forms will be located on curves; this latter feature in the first subway has been found disadvantageous, and even dangerous. Nor will four tracks be placed in one tunnel; experience has indicated that such construction is not conducive to satisfactory ventilation. Partitions will separate the spaces for the pairs of tracks. An endeavor is to be made to lessen the heat in the new subways; in the old subways this becomes oppressive in warm weather. This heat has been attributed to the operation of the great numbers of electric motors and of the brake shoes; the resulting discomfort has been enhanced by the constant and excessive overcrowding of the cars. The new subways are to be larger than the old one. The latter has a height of 12 ft. 10 in. above base of rail and a width of 12 ft. 6 in. for each track. In the new Brooklyn subways, the corresponding dimensions will have a maximum value of 15 ft. and 14 ft., and minimum values of 13 ft. 2 in. and 13 ft. 6 in., respectively. Double-decked subways will be used in narrow avenues and streets.

For the subway structure built in trench, the framework will be of structural steel, and the walls, roof, and partitions of reinforced concrete, the types being similar, in the main, to those of the first subway. Under the Harlem River, the special four-track tube construction shown in Fig. 42 is to be used. In building new subways of the cut-and-cover type, no open trenches are permitted, as was done in the earlier work, where they would interfere with street traffic. Instead, temporary planking, strongly supported, is substituted for the street pavement, and the contractor's operations are carried on beneath. Many difficult problems of detail in the support of elevated and surface railways, and of buildings, and in the relocation of sewers, water and gas pipes, and electric conduits have to be solved. As can be readily appreciated by engineers familiar with operations of this character, the readjustments in the sewerage systems have been particularly troublesome. Solutions of two or three of these problems are given by way of examples and for their inherent interest. The illustrations on Plate LXIII will assist in making the description easier of comprehension. For crossing the Lexington Avenue subway at 106th and 110th Streets, two inverted siphons have been constructed during 1912. By the introduction of these two siphons, it has been possible to keep the subway as near the street surface as ordinary sub-surface pipes permit, saving 10 ft. in depth of excavation through wet material, and about $800 000

in the cost of construction. Incidentally, considerable reduction in the height of stairways is secured to the 110th Street subway station, which is an important consideration, as it affects beneficially the traveling public for all time.

These siphons take the flow from two trunk sewers in their respective locations. The 106th Street sewer has a section 5 ft. 7½ in. high and 5 ft. 0 in. wide, and serves an area of 109 acres, having a run-off of 240 cu. ft. per sec. at times of excessive storms, and a maximum dry-weather, or sanitary, discharge of 9.8 cu. ft. per sec. The 110th Street sewer has a section 8 ft. high and 12 ft. wide, and drains an area of 327 acres, having a storm-water run-off of 356 cu. ft. per sec., and a dry-weather discharge of 29.4 cu. ft. per sec. The following tabulation gives in detail the sizes and lengths of these siphons:

Location. (Manhattan.)	Storm-water pipe.	Dry-weather pipe.	Horizontal length, in feet.	Depression of pressure pipes from grade line, in feet.	Difference of invert elevation at chambers, in feet.
Lexington Ave. and 106th St....	Two 48-in.	One 24-in.	159	13.8	0.15 ±
Lexington Ave. and 110th St....	Two 78-in.	One 42-in.	256	15.5	0.26 ±

These inverted siphons have been provided with the most improved permanent features which have been developed, as follows: The sanitary flow is confined to the small pipe during dry weather, at all stages of tide. The changes of section at the chambers, and all bends, are easy and gradual. The clean-out manholes are located at the cast-iron bends of the dry-weather pipe. Removable split pipes are bolted at the bottom of the clean-out manholes. These provisions make it possible, if necessary, to rod the small pipe between the clean-out manholes and oblique legs between the chambers and the clean-out manholes. By-pass pipes, with sluice-gates, have been added at each chamber, to be used at times when it is necessary to clean the small pipe. With temporary dams erected just outside of the inlet and outlet openings of the small pipe, and the sluice-gate opened, the dry-weather flow will be diverted into one of the storm pipes, and it will then be possible to pump out the water from the small pipe, in order to conduct cleaning operations without interference by the flow.

It is thus seen that the arrangement is such as to render obstructions to the flow unlikely; but, should any occur, ample provisions have

been made to remove them. This has been secured satisfactorily without the installation of any motors and pumps, or any movable parts, which would require constant attention and are likely to get out of order.

An inverted siphon designed for Southern Boulevard and 144th Street, The Bronx, in connection with subway construction, is also shown among the illustrations on Plate LXIII.

While this treatment of the sewer problem in connection with subway construction is one which is resorted to in extreme cases only, these siphons are found to work well. They follow substantially the plan and principles of the siphon constructed by the Rapid Transit Commission in 1902 at 149th Street and Railroad Avenue, which works satisfactorily and has never required cleaning. Five inverted siphons have already been built in Brooklyn, in connection with the Fourth Avenue subway work, and the sixth (at Hudson Avenue and Fulton Street) is now under construction. The plans shown on Plate LXIII, which are more or less typical for many cases, are supposed to be the "last word" in sewer siphon design, provision being made for any conditions likely to arise.

For the new elevated railways, the designs adopted are much more pleasing in appearance than the old structure, as indicated by Fig. 39. When all improvements are completed, most of the elevated lines, old and new, will have three tracks, the middle one being for express service "down town" in the morning and "up town" in the late afternoon.

Bridges.

Spanning the East River from Manhattan to Long Island, there are four steel bridges which rank among the greatest in the world. Three are cable suspension bridges, and the most northerly is a cantilever. Brooklyn Bridge, constructed from 1870 to 1883, the oldest and still the most important of them all, has a river span of 1 596 ft., a width of 86 ft., a total length of 6 016 ft., and cost $16 000 000. Nearly 400 000 persons cross it daily. Manhattan Bridge has a river span of 1 470 ft., a total length of 6 855 ft., a width of 123 ft., and cost $14 000 000. Williamsburgh Bridge has the longest span, 1 600 ft., and next to the greatest length, 7 308 ft.; its width is 90 ft., and its cost $14 000 000. Over it pass 250 000 people each day. Queensboro, or Blackwells Island Bridge, the cantilever, has two river spans, of

1 182 and 984 ft., with piers on Blackwells Island. It has the greatest length, 7 449 ft.; it is 90 ft. wide, and cost $13 500 000. Williamsburgh Bridge was opened to traffic in 1903; the other two in 1909. The Brooklyn Bridge towers are about 275 ft. high and the others 325 ft.; the clear height above high tide is 135 ft., for all.

Washington Memorial Bridge spans the Harlem River from the heights of Upper Manhattan to The Bronx, with two 508-ft. steel arches. It is 2 377 ft. long, and was built in 2½ years, at a cost slightly less than $3 000 000.

Pelham Bridge, in The Bronx, is an example of reinforced concrete, with 105-ft. arches. It is 2 000 ft. long, and cost $500 000. Across the narrows in Kensico Reservoir, the Board of Water Supply has built a reinforced concrete bridge 925 ft. long, with five 127-ft. arches having piers of a maximum height of 100 ft.; and at the Ashokan Reservoir a three-hinged reinforced concrete arch of 200 ft. span and 50 ft. rise, with two ribs of I cross-section.

Besides the conspicuous bridges described, several other notable ones have been projected, and there are hundreds, of many types, in existence in New York City, ranging from small wooden highway structures to massive railroad draw-bridges. Most beautiful of all, and possibly the oldest, is High Bridge, 1 450 ft. long, of fifteen semicircular, cut-stone arches, eight 80-ft. and seven 50-ft. spans, on tall masonry piers, supporting the Old Croton Aqueduct over Harlem River, not far from the Washington Bridge. It was built about 1848, at a cost of $1 000 000. Its top is 120 ft. above the river surface. Ten of its piers are on pile foundations.

Bridge projects around New York City cannot be dismissed without at least brief mention of proposed structures across the North River. Up to date, the Hudson has not been bridged south of Poughkeepsie (70 miles north of New York City Hall), where a notable railroad cantilever spans the stream. For years, with intermittent insistence, a bridge of mammoth proportions has been exploited to accommodate railroad and street traffic between lower Manhattan and New Jersey. A clear span of approximately 3 000 ft. being an unalterable condition, the engineering uncertainties and enormous cost have prevented its construction. Successful tunneling beneath the river has rendered it less necessary. However, there is still in contemplation an interstate bridge to afford easier access from upper Manhattan to the high land immediately opposite.

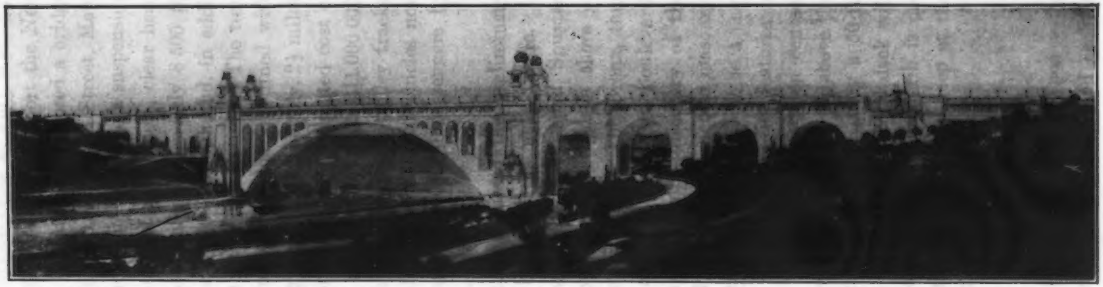

FIG. 56.—HENRY HUDSON MEMORIAL BRIDGE (PROPOSED), OF REINFORCED CONCRETE.

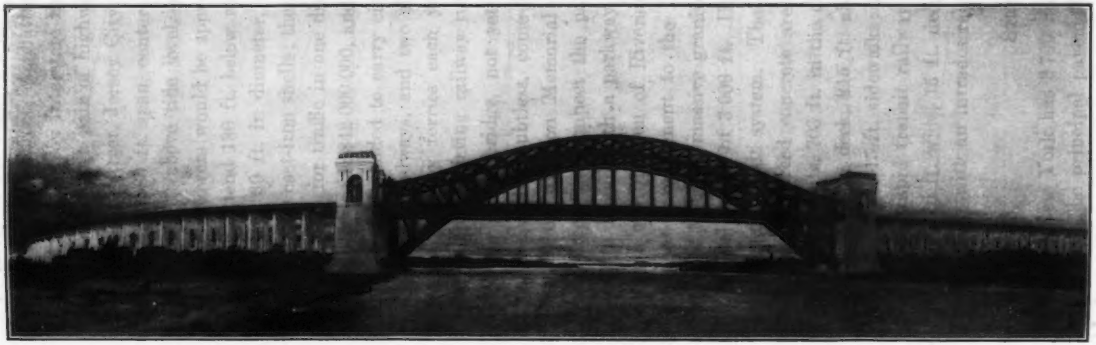

FIG. 57.—HELL GATE BRIDGE OF NEW YORK CONNECTING RAILROAD. 1 000-FOOT STEEL ARCH.

Formerly it was suggested that this bridge cross at Fort Washington Point (179th Street, Manhattan), but in a recent report the New York and New Jersey Interstate Bridge Commission proposed a bridge at 57th Street and a pair of highway tunnels from Canal Street, Manhattan, to 12th Street, Jersey City. The bridge would be a suspension structure of 2 880 ft. span, center to center of main piers, clear head room of 170 ft. above tide level, and total length of nearly 8 500 ft. Its two main towers would be approximately 600 ft. high and, in addition, would extend 180 ft. below water to rock foundations. The tunnels would be 30 ft. in diameter, driven with shields and lined with concrete inside cast-iron shells; their length would be, roughly, 2½ miles. Each would be for traffic in one direction only. The estimated cost of this great bridge is $42 000 000, and that of the two tunnels $11 000 000. The bridge is intended to carry eight rapid transit and trolley tracks, two four-line roadways, and two sidewalks. Six million vehicles now cross the river by ferries each year, and 158 000 000 passengers by ferries and the existing railway tunnels.

Another great bridge, not yet built, has passed the preliminary stages, and will, doubtless, come into being in the near future. It is the Henry Hudson Memorial Bridge, which will span Spuyten Duyvil Creek and connect the parkway along the Hudson shore of Manhattan Island with a parkway to be laid out in The Bronx, thus forming a continuation of Riverside Drive and Lafayette Boulevard. Planned as a monument to the Dutch navigator's discovery of the river, it is to be of massive granite and reinforced concrete masonry, with a total length of 3 000 ft. Ultimately, this bridge will be a part of the rapid transit system. The most noteworthy of its features is the main, reinforced concrete arch, of 725 ft. span between centers of springing joints, 703 ft. in the clear, with its soffit 180 ft. above the water. The main deck, 215 ft. above the stream, will carry a 50-ft. roadway and two 15-ft. sidewalks; 25 ft. beneath it a second deck will support four rapid transit railway tracks. The main arch rib is designed to be 70 ft. wide, 15 ft. deep at the key and 28 ft. deep at the springing line, with an intrados radius of 485 ft.

Streets.

Greater New York has 3 700 miles of streets, of which 2 000 miles are paved. The principal pavements are of stone, wood, and asphalt blocks, and sheet-asphalt, with much macadam in outlying sections.

STANDARD CROWNS OF PAVEMENTS BOROUGH OF MANHATTAN.

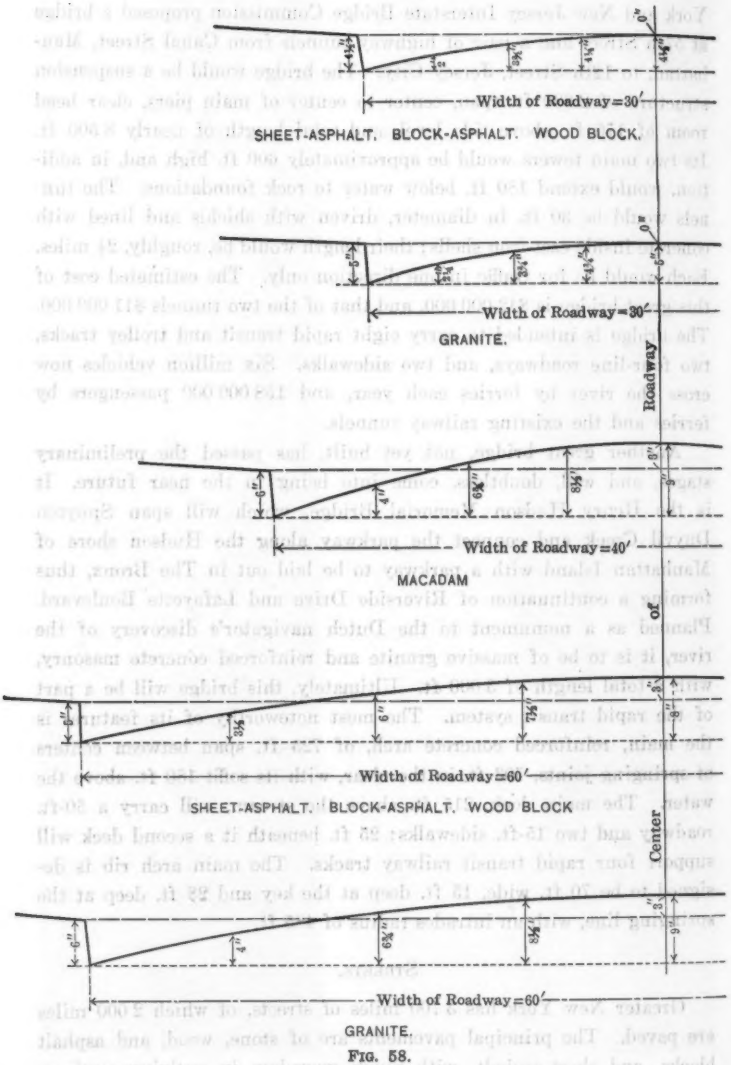

FIG. 58.

As being more or less typical of the street practice of the city, there are shown in Fig. 58 diagrams of the standard cross-sections of several kinds of pavements as constructed in Manhattan Borough. Fig. 59 shows the details where the roadway and sidewalk meet in the gutter and curb, or edgestone. Although this cross-section is drawn for sheet-asphalt pavement, the curb sections for other kinds of pavement are almost identical. The values of the letter dimensions of Fig. 59 are as follows:

STANDARD STREET CURB SECTIONS.

Depth of curb, in inches.	DIMENSIONS, IN INCHES.		
	A	B	C
5	16	18	17
6	16	18	18
7	14	16	19
8	14	16	20

On many streets traffic is so heavy that the pavements are worn rapidly. The destruction or injury of street surfaces is greatly increased by frequent openings for pipes and other sub-surface structures, which are but indifferently restored.

In all boroughs of Greater New York the streets in the older sections were more or less accidental in arrangement, and but little has been possible in the way of improvement other than an occasional widening or modification of grade; but, generally, the streets of the city are laid out in rectangular systems. In some newer sections street systems planned by real estate companies, with little attention to surrounding neighborhoods, have been perpetuated. Generally, the rectangular systems have uniform spacings between streets in any given section; but in the oldest districts, and in some others where topography has been permitted to control, crooked streets of irregular width and spacing are found, with grades also less skilfully regulated.

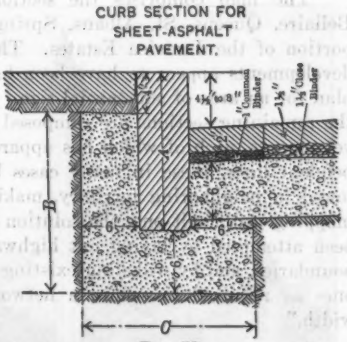

FIG. 59.

Under a rule of the Board of Estimate and Apportionment, no street with a width of less than 60 ft. will be placed upon the City map unless it is less than 1 500 ft. in length, or unless the damage which would result to buildings is greater than the probable benefit resulting from widening. The street widths, therefore, may be said to range from 60 to 100 ft., the former being that usually fixed for the minor streets, while that for the more important arteries ranges from 70 to 100 ft., with an approximate average of 80 ft. An effort has been made to absorb all private developments within the City plan, this course being essential for the reason that the City is without power to assist property owners in closing streets which have been dedicated unless the title can be recaptured by the abutting owners or unless the City is in possession of the fee. In most of the old private streets the fee has been lost, and in all such cases the Board attempts to adjust the old lines by straightening them as necessary and by providing an adequate width. An excellent illustration of this treatment is afforded in a recent map of a large area in the Borough of Queens, concerning which the engineers of the Board recently made a report, from which the following is quoted:

"The map comprises the sections known as Hollis, Holliswood, Bellaire, Queens, St. Albans, Springfield, Laurelton, Rosedale, and a portion of the Jamaica Estates. The Jamaica Estates and Laurelton developments appear to have been based on a systematic and suitable plan for an area of substantial size. With the exception of Holliswood, the remaining sections are composed of a large number of separate developments, each of which has apparently been carried out along independent lines, these in many cases being inconsistent with those followed in neighboring territory, making the problem of comprehensive mapping a difficult one, the solution of which, however, has in general been attempted by laying out highways to follow the former sectional boundaries, and by widening existing thoroughfares and laying out new ones as required to secure a network of traffic arteries of adequate width."

This may be taken as typical of the solution usually attempted, although in many instances the result has not been as satisfactory as in this case.

Manhattan has a comprehensive street scheme which has been followed consistently and rigorously for many years. In accordance therewith, the island has been developed north of the old city, the boundary of which may be drawn at 14th Street, or approximately

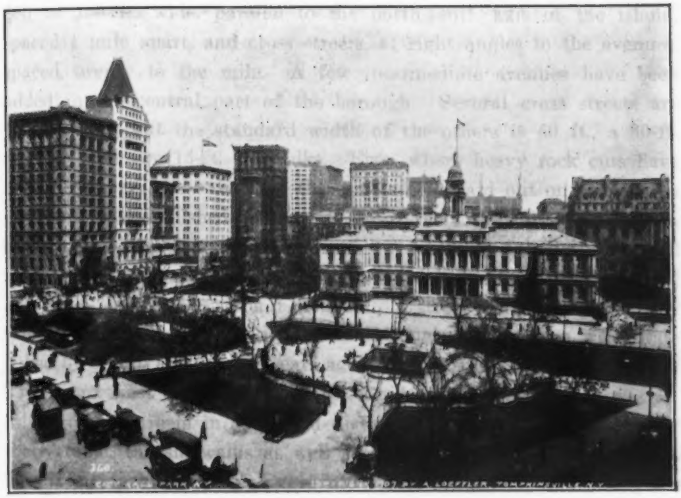

FIG. 60.—CITY HALL AND PARK, LOOKING NORTH, BROADWAY AT LEFT.

FIG. 61.—WOOLWORTH BUILDING, POST OFFICE, AND CITY HALL, WITH SURROUNDING "SKY-SCRAPERS," FROM THE MUNICIPAL BUILDING.

2¾ miles from the Battery. The plan is a gridiron, with avenues, from 100 to 150 ft. wide, parallel to the north-south axis of the island, spaced ½ mile apart, and cross streets, at right angles to the avenues, spaced twenty to the mile. A few intermediate avenues have been added in the central part of the borough. Several cross streets are 100 ft. wide, but the standard width of the others is 60 ft., a 30-ft. roadway and two 15-ft. sidewalks. Even where heavy rock cuts have been necessary, not only have the streets been laid out on these lines and built to established, easy grades, but the lots between have been excavated to conform thereto. Broadway, the old colonial post road to Albany, is the only important diagonal street in this gridiron, and only for a part of the way is it diagonal. A street system for practically the whole area now constituting the Borough of Brooklyn was established by a map about forty years ago. That portion of the Borough of The Bronx west of the Bronx River was mapped in 1895.

Many old streets in congested districts are proving inadequate for their traffic, the sidewalks as well as the roadways being too narrow. Illegal encroachments have aggravated these conditions, and finally the City has resorted to drastic remedies. In lower Broadway and adjacent streets, for example, buildings are being shorn of architectural adornments and other parts which project beyond the legal building line, at a cost of hundreds of thousands of dollars. Instead of disfiguring the buildings, as might have been supposed, the work has been done so skilfully in many cases that appearances have been improved. Rarely have the changes been objectionable.

As is evident along many of New York's streets, in some places painfully, little or no control is exercised over the relationship of buildings to their surroundings as to height, architectural style, or color. Such inexcusable and deliberate inharmonies as the City Investing Building, beside the Singer Building, should not again be perpetrated. However, unnecessary ugliness has finally attracted intelligent attention, and definite efforts are being directed toward the creation of more beautiful structures and groups. Several civic centers are definitely being planned. Architecturally, New York has made notable improvement during recent years.

Street Cleaning.

In Queens and Richmond the borough president has charge of the street cleaning, but in the remaining boroughs the Department

of Street Cleaning is charged with this function. Its duties are: (1) Sweeping and cleaning, sprinkling, flushing or washing, and sanding of the streets; (2) Removal of ashes, street sweepings, garbage, light refuse, and rubbish; (3) Removal of snow and ice from leading thoroughfares and from other streets to the extent practicable. In the 124 sq. miles served by the department are 1 900 miles of streets, of which 1 300 are paved. From the 24 000 000 sq. yd. of pavement cleaned, 546 000 tons of sweepings are gathered yearly, by about 3 000 men. Of ashes, more than 2 000 000 tons, of garbage 315 000 tons, and of light refuse and rubbish nearly 190 000 tons were carried off in 1911 by 1 425 collectors; and 904 000 cu. yd. of snow were removed from falls aggregating 18.7 in. Ashes, street sweepings, and similar refuse are used for filling low-lying lands, about 35% going to Riker's Island, where 63 acres have been reclaimed from the tide and 173 additional acres are being filled. Salable wastes, such as paper, tin cans, rags, bottles, rubber, and leather, are picked out during the handling of the rubbish. Offal and garbage, including dead animals, are treated by a digesting process, recovering fats, hides, hair, glue, and fertilizer.

Public Buildings.

Of public and semi-public edifices worthy of remark, New York, considering its youth, has a creditable number. Besides those mentioned in other connections, the City Hall, the Stock Exchange, the Custom House, the Public Library, the Metropolitan Museum of Art, the American Museum of Natural History, Columbia University, New York University, with its Hall of Fame, the College of the City of New York, St. Patrick's Cathedral, Cathedral of St. John the Divine (still in course of construction), St. Luke's Hospital, General Grant's Tomb, and the Brooklyn Institute of Arts and Sciences, are conspicuous in their several localities.

Many of the public school buildings catch the eye of the passer-by. Morris High School, in The Bronx, erected in 1900, is English Gothic in style, and cost $648 000. It accommodates 2 531 boys and girls, and contains two good gymnasiums, physical and chemical laboratories, and one of the best auditoriums in the city schools, capable of seating 1 200 persons. Erasmus Hall, Brooklyn, a group of buildings arranged about a quadrangle, after the English college style, is not yet completed; the buildings in place were erected between 1904 and 1910

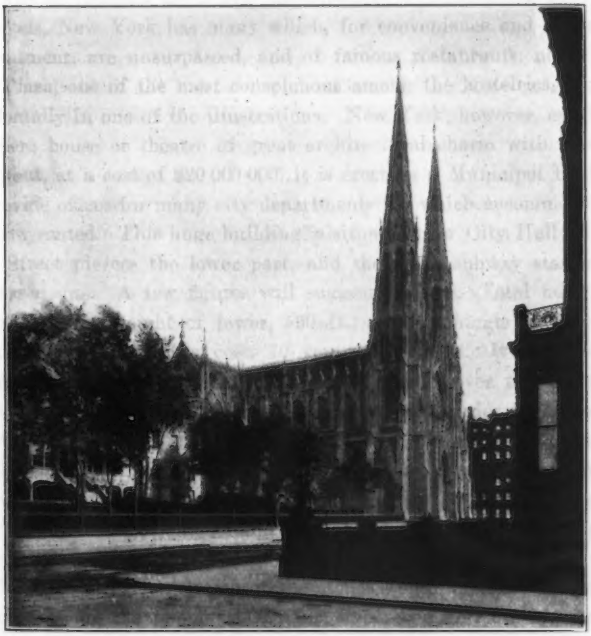

FIG. 67.—ST. PATRICK'S CATHEDRAL, FIFTH AVENUE.

at a cost of $770 000. It has detached buildings for different phases of work, such as physical and chemical laboratories and gymnasiums, and accommodates 2 500 boys and girls. Manual Training High School, Brooklyn, erected 1901-02, cost, including its equipment, $770 000, and accommodates 2 500 boys and girls. It contains machine, wood-working, foundry, and tin shops, with complete equipment, for boys; dressmaking, millinery, cooking, and housekeeping departments, for girls. DeWitt Clinton High School, Manhattan, erected 1903-04, at a cost of $892 000, accommodates 3 500 boys. It contains a gymnasium and full laboratory equipment, also a lunchroom in the top story. Public School No. 62, Manhattan, facing Seward Park, erected 1903-04, cost $660 000; it has a large auditorium, a gymnasium, and a domestic science department, and accommodates 4 250 boys and girls.

Famous all over the country, New York's shops, especially the prominent department stores, deserve passing mention, for their buildings and equipments are largely the products of engineering activities. Of hotels, New York has many which, for convenience and luxury of appointment, are unsurpassed, and of famous restaurants, not a few. The Plaza, one of the most conspicuous among the hostelries, appears incidentally in one of the illustrations. New York, however, can boast no opera house or theatre of great architectural charm with fine setting; but, at a cost of $20 000 000, it is erecting a Municipal Building to provide offices for many city departments for which accommodations are now rented. This huge building is situated near City Hall; Chambers Street pierces the lower part, and there are subway stations in the basements. A few figures will suggest its size: Total floor area, 850 000 sq. ft.; height of tower, 590 ft.; cubic contents of building, about 15 000 000 cu. ft.; cost, 70 cents per cu. ft. It required 37 horses to haul each of the twelve 50-ton girders, over the Chambers Street arch; two 30-ton derricks transferred each girder in mid-air to two other 30-ton derricks to set it in place. There are 40-ton stones on the concourse floor; 30-ton stones in the architrave course on the fourth floor; the column sections, from the first to the fourth story, weigh about 18 tons; the column caps at the fourth story weigh about 16 tons; on the twenty-first story the column sections weigh 10 tons; on the thirty-fifth story some of the stones weigh 10 tons. The foundations are of the pneumatic caisson type, common among the tall

buildings south of 14th Street. Some of the caissons are the deepest ever sunk for a building, being 147 ft. The basements are below tide. Like other modern New York office buildings, the Municipal Building is of "steel-cage" construction, and is faced with granite. It will have thirty-two passenger elevators traveling from the street level to the twenty-fifth story, and special elevators in the tower above. It will have a very complete mechanical and electrical equipment. Every effort is being exerted to render the structure and most of its furnishings unburnable.

"SKY-SCRAPERS."

Approaching the City from any direction, by day or night, its excessively tall buildings fascinate the beholder, and continued observation only increases the wonderment, as their number, the enormous value, and the great multitudes of persons housed, penetrates one's comprehension. The "sky-scrapers" constitute the most characteristic physical aspect of the City on lower Manhattan Island. Tallest of all is the Woolworth Building (750 ft.), which has recently been completed. Quite as wonderful as this structure are the rapidity and precision with which it has been created and the organization which has done it. Within 18 months from the day the foundations were started, many offices, already rented, were ready for occupancy. Following in height and interest are the Metropolitan Tower, in Madison Square, 700 ft.; the Singer Tower, 612 ft.; City Investing Building, 500 ft.; Park Row Building, 382 ft.; "World," "Tribune," "Times," Bankers Trust, Whitehall, and Hudson Terminal Buildings, with scores more almost equally deserving of mention.

On Manhattan Island there are 1 200 buildings having 10 stories or more; of these, 120 have more than 16 stories, and 15 have more than 25 stories. Of the following numbers of stories there is one building each: 31, 32, 38, 41, 45, and 55; and three buildings have 33 stories. The total number of buildings on the island is estimated at 120 000. For "sky-scrapers" the average height is 13 stories.

Nearly or quite all the great public and business buildings of the City have been created by the collaboration of engineers and architects. By the Civil Engineer many interesting foundation and structural problems have been solved. The hauling of steel members weighing as much as 60 tons apiece has severely tested street pavements and sub-surface structures, and the transportation and erection of such

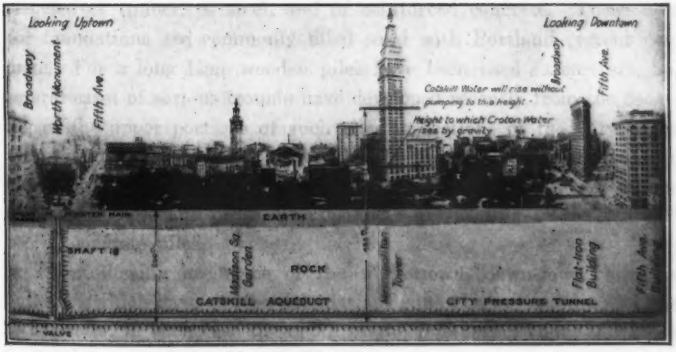

FIG. 73.—TALL BUILDINGS AT MADISON SQUARE; PANORAMA SHOWING CITY PRESSURE TUNNEL.

heavy pieces have given railroad and other engineers hard nuts to crack. Heating, ventilating, pumping, lighting, elevator and other mechanical equipment in these great buildings frequently mount in cost high in the hundreds of thousands of dollars, and exceed in capacity and power the public service plants of small towns. About fifty years ago the first I-beams rolled commercially were used in the Cooper Union and a few other New York buildings. They were of iron, and these buildings were the first in the world to have rolled iron structural members in their frames. Now thousands of tons of structural steel are used in the City's new buildings every year.

With the development of "steel-cage" and fire-proof construction the height and weight of buildings have increased rapidly. To support such buildings satisfactorily on Manhattan Island, new types of foundation became necessary, especially south of 14th Street, where the rock is at considerable depth below tide level and is overlaid with sand and gravel which admit water freely. Pneumatic caissons were developed to meet this need. Both cylindrical and rectangular shapes have been used. By this means exterior walls and columns and interior columns are supported on the bed-rock. At least one building, the Stock Exchange, has its subterranean stories enclosed and made possible by a coffer-dam of connected rectangular caissons. Large pneumatic caissons have been used also in sinking to rock some of the shafts for railroad and water-supply tunnels. Caissons are variously constructed of timber, of steel, and of reinforced concrete. Those used for foundations are commonly filled solid with Portland cement concrete. For a long time wooden piles have been used extensively, but several cases of serious trouble have developed recently from the decaying of the upper portions of such piles in sections of the City where the ground-water has been lowered by the more thorough drainage incident to extensive underground construction, especially sewers and subways. These and other circumstances are leading to the frequent use of concrete piles.

The following are some of the well-known, down-town, business buildings which have caisson foundations sunk through sand and water to bed-rock; in each case the depth of the foundation below the street level is given in feet: No. 42 Broadway, 53; Whitehall Building, 55; Bankers' Trust Building, 69; Trinity Building, 82; Fidelity Building, 83; United States Realty Building, 85; Singer Tower, 92; Liberty

Tower, 94; Western Union Building, 101; Woolworth Building, 125; Municipal Building, 150, this last being the deepest in New York City.

Telephone and Telegraph Systems.

But for its engineering activities, modern New York could not have come into being, and could not be nourished and maintained. Without telephones, engineering, business, and social activities alike, would be impracticable on the present scale. Sixty-two exchanges, 500 000 telephones, 6 000 men, and 7 500 girls, making 2 000 000 connections daily, 1 200 000 miles of underground wire, and countless intricate appurtenances, make up New York's distance-speaking system. It has been developed in 35 years, is growing at the rate of 100 telephones a day, and is constantly being improved. The New York company alone is connecting as many instruments as there are in all Great Britain and Germany combined. New York's long-distance telephone, telegraph, cable, and wireless systems give immediate communication with all points on the globe having electrical means for transmitting information.

Telephone, telegraph, and practically all other, wires are placed in ducts under the street pavement, except in some outlying districts where this improvement has not yet been effected and the ugly poles still disfigure the streets.

Electric Light and Power.

In ever-increasing measure, electricity is illuminating the streets, houses, shops, and factories of the City, and supplying the power for its industry. To meet this demand some notable power-generating stations have been built by the Edison companies, from which radiate miles of conduits through all the boroughs. Another station, which when completed will be among the largest in the world, is in course of construction. Fully inter-connected, no accident in any one station can interfere with the current supplied to any part of the district. The perfecting of the steam turbine has wrought startling changes in some big power-stations, and will force similar changes in others. Waterside Station, having a capacity of 500 000 h.p., burning 2 000 tons of coal daily, and supplying 5 000 000 lamps, is the largest of its kind in the world. The Edison system, covering 21 sq. miles, embraces 33 sub-stations and has 5 000 employees, who make more than 5 000 000 telephone calls a year in conducting their work. It

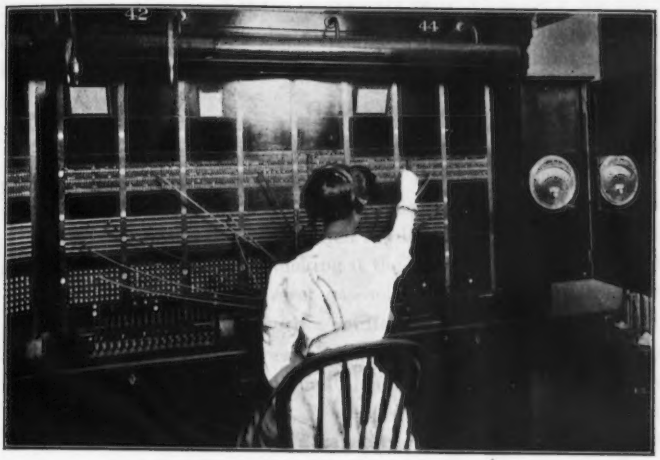

FIG. 76.—NEW YORK TELEPHONE SYSTEM: A RECEIVING SWITCH-BOARD IN A MODERN EXCHANGE. AT THIS BOARD TRUNK-LINE CONNECTIONS ARE MADE. ONLY ONE OF TWENTY-ONE SECTIONS OR MULTIPLES IS SHOWN. OPERATORS AT THESE BOARDS DO NOT TALK WITH SUBSCRIBERS, BUT ONLY WITH OTHER EXCHANGES.

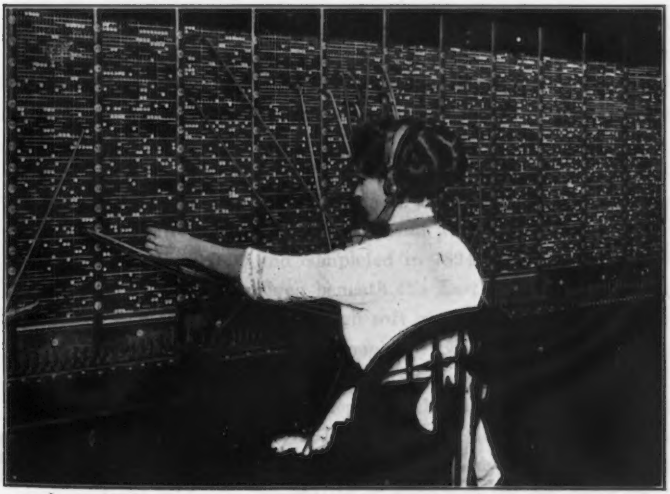

FIG. 77.—NEW YORK TELEPHONE SYSTEM: AN OUTGOING SWITCH-BOARD IN A LARGE EXCHANGE. AT THIS BOARD CONNECTIONS BETWEEN TRUNK LINES AND SUBSCRIBERS' WIRES ARE MADE. OPERATORS AT THESE BOARDS TALK WITH THE PERSON ANSWERING THE 'PHONE.

supplies 92 000 customers. So reliable has been the service that in 30 years the current has left the mains only twice, once for a few hours because a great fire nearly destroyed the original station, and again for a few moments when changing to the first modern station.

Gas.

Gas is used extensively for lighting, cooking, and industrial purposes. Many plants, large and small, for its manufacture, are scattered about, but most interesting is the one in course of development at Astoria, in Queens Borough, which is ultimately to have a capacity of 500 000 000 cu. ft. per day, making it the largest in the world. These works already include the largest gas-holder in the world, with a capacity of 15 000 000 cu. ft., with a reinforced concrete tank 300 ft. in diameter, 57 ft. deep; and rapid coal unloading towers and bridge having a capacity of 2 000 tons in 10 hours; the capacity of the bucket is 7 tons, and, with its trolley, it weighs 20 tons; also in the group are brick coke pockets having a capacity of 33 000 cu. ft., to which coke is delivered directly from the retorts, and thence into railroad cars. The largest gas mains beneath the streets are 60 in. in diameter. An innovation is the making of the cast-iron pipe joints with lead wool, or shredded lead, caulked with pneumatic hammers. Many streets and parks are illuminated by gas, Welsbach or similar mantles being used extensively. All told, there are 3 640 miles of gas mains. There are five gas companies supplying New York City; the largest of these, the Consolidated Gas Company, was formed in 1884 by combining six companies.

For conveying illuminating gas from the works at Ravenswood, on the western extremity of Long Island, to Manhattan, a tunnel beneath the East River and Blackwells Island was projected in the early Nineties. Begun in 1892 and completed in 1894, this tunnel, 2 106 ft. long, was the first to be driven beneath the East River. It is a little more than 10 ft. in diameter through soft ground, and 8½ ft. high and 10½ ft. wide in sound rock, large enough for two 3-ft. and one 4-ft. gas mains. It was driven from a shaft 139 ft. deep at 71st Street, Manhattan, and another of the same depth on the Ravenswood shore. The minimum thickness of roof is 40 ft. beneath the west channel and 100 ft. beneath the east channel. Superficial examinations and some pipe soundings led to the expectation of solid rock for the whole length,

but several wide zones of soft, decomposed, and water-bearing rock were encountered under the channels, requiring compressed air up to 48 lb. per sq. in. and tunneling shields, with segmental cast-iron lining. Gas was first delivered through the tunnel on October 15th, 1894. A second tunnel is now in progress, in the same vicinity, for additional gas mains, connecting Astoria, on the Long Island shore, with East 111th Street, Manhattan.

Parks.

Father Knickerbocker's children delight to play as well as to work. New York has many public parks, large and small, aggregating 7 580 acres; many public playgrounds, and innumerable private amusement resorts. Most notable among the parks are Central and Riverside Parks, Manhattan; Prospect Park, Brooklyn; Van Cortlandt, Pelham Bay, and Bronx Parks, in The Bronx; and Forest Park, in the Borough of Queens.

Central Park is, beyond question, more widely known than any other park in America. Its site, when purchased in 1856, was waste land occupied by "squatters' shanties," slaughter houses, bone-boiling works, and similar ugly and unsavory buildings. Its present valuation is more than sufficient to offset one-quarter of the City's total public indebtedness.

Bronx Park contains famous zoological and botanical gardens, with many collections of rare specimens. Although possessing some natural interest, all these parks owe their present attractiveness largely to skillful landscape engineering. In Battery Park, at the south tip of Manhattan, there is an unusually instructive and well-arranged aquarium.

An extensive system of boulevards leads through panoramas of park and city, mountain and marsh, river and ocean. Begun many years ago, it is still in course of development, and, owing to the automobile, is being projected even beyond the City's confines. In connection with its water supplies, the City owns many thousands of acres of land, which can ultimately be made enjoyable as an outer park system. The Bronx Parkway Commission, organized in 1907, has taken the initial steps toward rescuing the Bronx River and its banks, from Bronx Park to the Kensico Dam. Along this stream a scenic drive and continuous park are gradually to be developed to connect the parks and boulevards within the City with the outlying reservoir

lands and the beautiful residential districts of Westchester County and the regions beyond. Ultimately, this system will be linked with the State boulevards and park reservations leading to the Catskill Mountain water-sheds. Realization of these schemes, now well in hand, will perfect for the New York metropolitan district and all the lower Hudson Valley towns a park system of such beauty, extensiveness, and accessibility as but few great communities can possess.

Sewerage and Sewage Disposal.

In the important field of sanitary engineering, New York must confess to being laggard, at least in so far as the disposal of its sewage is concerned. With so extended a water-front, bordering such vast bodies of water, it has been easy to prolong the sewers to the shores and let the crude sewage flow at innumerable points into the rivers and harbor. Even communities situated miles inland, either by trunk sewers directly, or indirectly through the rivers, have used this same simple method of getting rid of their water-borne filth. With increase of population this practice has caused nuisances and menaced health, especially through the oyster and other shell-fish beds in the outlying bays, and the public bathing establishments along the water-front, where 2 000 000 baths are taken annually. There are 3 000 miles of sewers in the forty cities of the metropolitan district, 1 700 miles being in New York City. A few small sewage treatment plants have been indifferently operated for a number of years. Others are being constructed and better methods adopted.

The subject is now receiving, from the Metropolitan Sewerage Commission of New York City, that broad study which is needed; this study by experts will aid materially in planning an adequate and comprehensive system for the whole basin draining into New York Bay. Five years have already been spent in extensive investigations of the condition of the harbor, of tidal movements, of currents, of population, topography, existing sewer systems, and of many other phases of the problem of collecting sewage and storm-water and properly disposing thereof, for the whole interstate metropolitan drainage basin. In these studies the Commission has from time to time had the assistance of distinguished English and American sanitarians. Tentative plans for definite engineering works have been drawn and approximate estimates of cost made. The Commission has found that the methods by which sewage is disposed of demand immediate and far-reaching

improvement. It is impracticable to construct a system or systems of conduits to collect the sewage from the whole district and convey it to one place for disposal. The district must be subdivided, and various methods of treatment and discharge, suitable to local requirements, must be adopted.

Revision of existing local systems and the construction of large trunk sewers and treatment works will probably be undertaken in a future not many years remote.

Some of the administrative and physical obstacles in the path of improved sewerage are suggested by the following facts: There are eighty communities concerned, and they are situated in two independent, sovereign States. A suitable metropolitan sewerage district would comprise an area of about 700 sq. miles, practically all within 20 miles of New York's City Hall, of which about one-half is in each of the States of New York and New Jersey. The Federal Government also would be a party to any comprehensive scheme. There are many diverse and conflicting, commercial, manufacturing, political, and recreative interests involved. Of the proposed district, 180 sq. miles are bodies of water ranging in depth from about 5 to 150 ft., with maximum velocities of flow ranging from 2 to 10 ft. per sec., the latter occurring in parts of the East River.

The densities of population per square mile were, in 1910: In New Jersey, on the Rahway River water-shed, 253; in the Joint Outlet Sewer district, 1 700; in the Passaic Valley, 5 800; in the New York Boroughs, Queens, 2 900; Richmond, 1 700; The Bronx, 13 400; Brooklyn, 25 500; and Manhattan, 112 300. Some of the most congested areas border on parts of the harbor naturally least able to purge themselves of the inflowing sewage. In 1910, the total sewage was about 635 000 000 gal. daily, and the Metropolitan Sewerage Commission has estimated that by 1940 the volume will be doubled. Through The Narrows there flow at each tide approximately 12 000 000 000 cu. ft., the excess of water moving seaward over that returning being roughly 1 300 000 000 cu. ft.

Although backward in the treatment of its sewage, Greater New York has built some remarkable sewers, having many miles 10 ft. or greater in diameter, in Brooklyn and The Bronx principally. Some of the largest sewers are 15 ft. in diameter. The "combined" system of sewerage is almost universal.

Brooklyn has more than 925 miles of sewers, ranging in diameter from 6 to 187 in., many miles being of very large sizes. The flat topography has been one important reason for the large sewers. In the course of its development southward and eastward the borough's closely built section spread over the ridge of high land which divides its area, instead of growing inland from the shores in the outlying portions. This circumstance injected unusual conditions into the sewerage problems. In these new sections house-building has gone on rapidly. These districts could not be drained into the sewers of the older city. Sewers constructed along natural drainage lines to the southerly shores would have been long and excessively costly, traversing wide areas not requiring sewers for many years; would have needed a long time for construction, delaying relief to developed sections; and would have discharged the sewage toward Coney Island, Gravesend Bay, and other large seaside resorts. Consequently, the region was divided into nine districts, within each of which natural drainage lines were followed as closely as feasible. From some of these districts the combined sewage, and from others the house sewage only, was diverted westward into The Narrows, by two large trunk sewers which pierced the ridge with tunnels. From still other districts the collected sewage was conducted to purification works. This system includes nearly 100 miles of brick sewers from 30 to 180 in. in diameter, and 600 miles of 12 to 24-in. pipe sewers, besides four pumping stations and modifications of existing purification works. It cost nearly $15 000 000.

In The Bronx, many recently constructed principal outfall sewers have been built of reinforced concrete. An approximately rectangular cross-section, with invert of large radius, has been used extensively. In many places foundations of timber piles and platforms have been necessary. Across flat, low lands adjoining the shores, these large sewers have to be built projecting above the natural surface of the ground in order to secure proper hydraulic conditions for the discharge, and avoid having tidal water form a comparatively still basin, reaching far back into the sewer, in which deposition of solids would take place. This latter fault is common in the older sewers of more than one borough. One very large storm-water relief sewer in the western part of the borough (Webster Avenue) was driven for a considerable portion of its length as a tunnel through the rock ridge sepa-

rating the drainage area from the Harlem River, into which it was desired to discharge the water.

In the Borough of Queens, where there are still thousands of acres of market gardens outside the several closely-built community centers, large districts are still without sewers, and in others existing sewerage is distressingly inadequate. For this borough, the problems of sewerage and sewage disposal are of unusual complexity. Many large trunk

sewers have been built, up to such sizes as 7 by 16 ft., 8 by 12 ft., and 15 ft. in diameter. Some of these connect with large sewers in Brooklyn, emptying into the East River. A number of pumping stations and treatment plants are in operation. With 40% of the area of the greater city, a present average population density of only 4.6 persons per acre in comparison with 39.9 in the neighboring borough of Brooklyn, and greatly improved rapid transit facilities in immediate prospect, it is evident that wisely considered sanitary engineering activities must have a large place in the programme of this borough for several years to come, and that the present 230 miles of sewers must be largely increased.

In Richmond, the sewerage problem, thus far, has been of relatively simple solution, the topography and the location of the borough being favorable.

Water Supply.

Although situated on the shore of a great river, New York is obliged to go many miles for a sufficient supply of potable water. The Hudson is a tidal estuary for 150 miles, and, under usual conditions, its waters are brackish for 70 miles above the City, and, under some conditions, for 85 miles. The Boroughs of Manhattan and The Bronx are supplied from the Croton water-shed, of 360 sq. miles area, and from the upper Bronx River and the Byram River water-sheds, of 22 sq. miles combined area. All these sources have been developed since 1840 by improving seven natural ponds and constructing twelve impounding reservoirs, with an aggregate capacity of 105 000 000 000 gal. For these reservoirs, fifteen large masonry and earth dams have been required. Most famous among them is the New Croton Dam, 2 168 ft. long, with a maximum height of 300 ft. above its lowest foundations. Its waste-weir is 1 000 ft. long, and the whole structure contains 850 000 cu. yd. of rubble, cyclopean, and cut-stone masonry.

Brooklyn gets most of its water from the Ridgewood system of reservoirs, wells, and infiltration galleries, lying east of the City, on Long Island. Queens and Richmond Boroughs get water principally from wells and other small sources, developed for the most part by private companies, some of which have been purchased by the City. All the Brooklyn water is pumped by municipal pumping stations, much of it more than once in order to deliver it at the required eleva-

tions. A large part of the water for the other boroughs also is pumped, and much of it is pumped again at private expense to reach the upper stories of tall buildings, by pumping equipments located in the buildings. The total daily consumption of the greater city is about 500 000 000 gal., equivalent to nearly 100 gal. for each person of the census population, for public, private, and industrial purposes.

Having outgrown these supplies, the City in 1906 began the construction of a great system of new works to obtain a large additional supply from the Catskill Mountains, about 100 miles north of the City on the west bank of the Hudson. Here four contiguous water-sheds, aggregating nearly 1 000 sq. miles, are to be developed successively as needed, during the next 25 to 50 years, at a total cost estimated at $200 000 000. In Esopus water-shed, Ashokan Reservoir, of 130 000 000 000 gal. capacity, is now approaching completion; it is 12 miles long, 1 mile wide, with high-water level 590 ft. above tide, maximum water depth 190 ft., and 13 sq. miles of water surface. To impound water in this reservoir, 6 miles of dams and dikes are being built; the largest is Olive Bridge Dam, 4 650 ft. long on top, with a masonry portion 1 000 ft. long and 240 ft. high, the remainder being earth dike with concrete core-wall. The reservoir has a waste-weir of concrete 1 000 ft. long, and a dividing weir and dike 2 000 ft. long severing the reservoir into two basins.

From this reservoir Catskill Aqueduct extends 127 miles to Silver Lake Terminal Reservoir, on Staten Island, having a capacity of 400 000 000 gal., with a branch into Queensboro. Seven standard types of conduit are used in various parts of the aqueduct, depending on topographical and geological conditions, namely, cut-and-cover, built of concrete in a trench and covered with embankment; grade tunnel, through hills and mountains, at hydraulic gradient; pressure tunnel, beneath wide deep valleys, Bronx and Manhattan Boroughs and part of Brooklyn; 9½- and 11-ft. riveted steel pipes, jacketed with concrete and lined with mortar, for crossing narrow deep valleys; reinforced concrete pipes, 9½ and 17 ft. in diameter, for crossing shallow depressions and for a by-pass around Kensico Reservoir; lock-bar and riveted steel and cast-iron pipes, for delivery mains to the street distribution pipes, and flexible-jointed cast-iron pipes for crossing under The Narrows to Staten Island. The aqueduct will have a sure daily capacity of 500 000 000 gal.

About 25 miles north of the City, Kensico Distribution and Storage Reservoir, having a capacity of 40 000 000 000 gal., will contain sufficient water to supply the City for a number of weeks should the flow in the aqueduct north of it be interrupted. Kensico Dam, requiring 1 000 000 cu. yd. of masonry, will be 1 843 ft. long, and 300 ft. high. Its foundations are now being excavated to a maximum depth of 130 ft. Near both Olive Bridge and Kensico Dams, fountains, containing about 1 500 water jets each, with concrete basins 450 ft. long and 250 ft. wide, will aerate the water through 2-in. nozzles as it is drawn into the aqueduct. At several places large Venturi meters, built into the aqueduct with bronze throats, 90 in. in diameter, will measure the water. Provision has been made for a filter plant of 600 000 000 gal. maximum daily capacity when needed, by securing a site contiguous to the aqueduct 2¼ miles down stream from Kensico Reservoir.

A feature of the aqueduct which has attracted popular interest is the crossing of the Hudson, about 60 miles north of the City, 4 miles above West Point. This is accomplished by a pressure tunnel in the granite, 1 100 ft. below the river surface and 3 000 ft. long between shafts. Some of the preliminary explorations were made by pairs of inclined diamond-drill borings in the rock from 1 500 to 2 000 ft. long, driven from chambers in the shafts 250 ft. underground. The shaft at the easterly margin of the river is to serve not only as a waterway but also as an access and drainage shaft. Like the tunnel, it is 14 ft. in diameter. Its top is about 400 ft. below hydraulic gradient; nevertheless, it must be closed in such a way that it can be readily opened whenever necessary. For this cover a dome-shaped steel casting, weighing about 45 tons, was adopted, and is now being made. It is to be 17 ft. in diameter and 6 ft. 4 in. high. To hold it securely in place against the 5 000 000 lb. total upward pressure of the water, it will be anchored to the concrete shaft lining and the surrounding granite by 36 bolts, 4½ in. in diameter and 50 ft. long. Each bolt will be forged in one piece, of nickel-chrome steel, heat treated. The pull on each bolt caused by the water pressure alone will be 75 tons, to which an allowance for temperature stresses has been added.

A few incidentals of the Catskill system indicate the magnitude of the project. To replace roads to be submerged, 40 miles of new highways are being built around Ashokan Reservoir alone. As the cost of these roads, like that of other parts of the work, is defrayed

by the proceeds of 50-year bonds, an investigation was made to determine the most permanent type of pavement. Vitrified brick paving blocks with Portland cement grout joints, on a concrete base, with concrete edgings, was chosen. Nevertheless, because of the high first cost of brick roads in this locality, and because the question as to who should

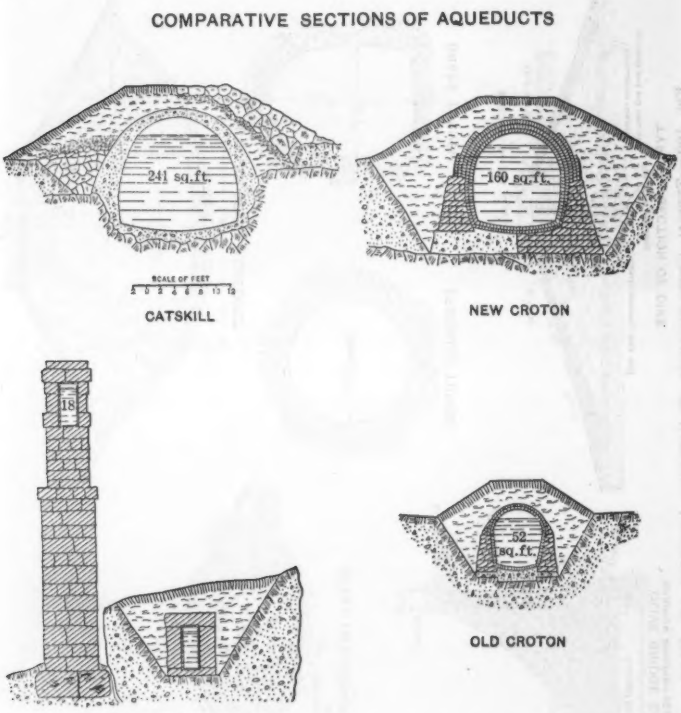

FIG. 101.—COMPARATIVE CROSS-SECTIONS OF NEW YORK AND ROMAN AQUEDUCTS.

maintain these roads had not been settled, the City authorities have decided to pave a large portion of the roads with macadam of a bituminous nature. All bridges are reinforced concrete. The City's lands along the aqueduct and around the reservoir are bounded by 100 miles of stone walls and 165 miles of heavy galvanized wire fence with reinforced concrete posts.

Two aqueducts bring water from the New Croton Reservoir: One is 34 miles long, and has a daily capacity of 80 000 000 gal. It is mostly cut-and-cover work, and was built in 1842. The other, completed in 1891, is 31 miles long, is practically all in tunnel, and has a daily capacity of 300 000 000 gal. Plans for filtering the Croton water have been perfected, a plant having a maximum daily capacity of 400 000 000 gal. is to be built soon at Jerome Park Reservoir, in The Bronx. This rapid sand filtration plant will be the largest of the type in the world. Since the removal of color and odor is an important function in treating Croton water, coagulant is to be used. In the plant there will be a house for preparing the chemicals, a mixing chamber, six covered settling basins, of a combined capacity of 88 000 000 gal., extending over 12 acres, five gate-chambers, 80 covered mechanical filters having together a net filtering surface of 2.7 acres, and a 350 000 000-gal. filtered-water reservoir, with groined arch roof, occupying 55 acres. The filtering medium is specified to comprise not less than 8 in. of gravel in four layers, and 2½ ft. of sand having an effective size between 0.60 and 0.70 mm., with a uniformity coefficient not greater than 1.65. The rate of filtration is to be 125 000 000 gal. per acre daily. About 800 000 cu. yd. of excavation are required, and 350 000 cu. yd. of concrete masonry.

City Water Tunnel.

To deliver the great quantity of water obtained from the Catskill Mountain water-sheds into the distribution pipe systems of the City, advantage has been taken of the favorable geological conditions. From Hill View Equalizing Reservoir, at the northerly city boundary, a pressure tunnel 18 miles long is being driven in a generally southerly direction through The Bronx and Manhattan into the heart of Brooklyn. By successive steps, the diameter of the tunnel is reduced from 15 ft. for the first 40 760 ft. to 14 ft. for the next 26 190 ft., to 13 ft. for 4 540 ft., to 12 ft. for 9 050 ft., and finally to 11 ft. for the remaining 15 090 ft. It is being driven in solid ledge rock, at depths below the earth's surface ranging from 200 to 750 ft., with a rock roof nowhere less than 150 ft. thick.

For constructing the tunnel twenty-four shafts have been sunk, the most southerly seven requiring pneumatic caissons of heavily reinforced concrete to reach the bed-rock, which is overlaid by porous, water-

bearing material. Beneath the Harlem River the tunnel is 15 ft. in diameter and 330 ft. below the water surface. It crosses the East River, near the Manhattan Bridge, at a depth of 700 ft., with a diameter of 11 ft. All but three of the shafts are located in public parks or other public property, and substantially all the tunnel's length is beneath streets and parks, thus avoiding the expensive acquisition of real estate. To have delivered the Catskill water through pipes would have required thirty-two 48-in. cast-iron pipes or sixteen 66-in. steel pipes. With most of the north-south avenues already overcrowded with subsurface structures or needed for rapid transit subways, it would not have been feasible to find suitable locations for so many large water pipes; but even if room for them could have been found, their cost would have been nearly twice as great; they could not have been permanent, and the annoyances caused by laying them in the busy streets would have been unbearable.

With two exceptions, the shafts, besides their use for construction, will be the connections between the tunnel and the street mains. In each connection shaft, from the chamber at its top to a point at least 95 ft. below the top of sound rock, one or two steel pipes, some 57 and others 81 in. in diameter, are to be embedded in, and lined with, concrete; their finished waterway diameters will be 48 and 72 in. At the top of each of these riser pipes there will be a bronze pipe cross, or shaft cap, with two horizontal, flanged openings, 30, 36, or 48 in. in diameter, for the pipe connections. To each of these will be bolted an all-bronze gate-valve, ordinarily to be kept open, but closed in case of injury or repairs to the valves beyond. For routine control operations, a heavy, cast-iron, bronze-mounted gate-valve will be attached close to the bronze valve. In the top of each shaft cap an opening of the same diameter as the riser is to be made to give access to the tunnel, whenever unwatered, for inspection or repairs. A Venturi water meter in each pipe connection, outside of the chamber but near it, will measure the water delivered at that point. Automatic pressure regulating valves are provided for many of the connections, where the gravity pressure of the Catskill supply will be greater than the pressure desired in the street pipes.

As an ultimate means for closing any riser so that the bronze valves or shaft cap could be removed without putting the tunnel out of service, an all-bronze valve of special design is to be placed at the lower end

FIG. 110.—REINFORCED CONCRETE CAISSON OF ONE OF THE SHAFTS OF THE CITY WATER TUNNEL OF THE CATSKILL AQUEDUCT, IN BROOKLYN. VIEW DURING CONSTRUCTION, BEFORE SINKING WITH AID OF COMPRESSED AIR.

FIG. 111.—AIR LOCK ON TOP OF CONCRETE CAISSON OF ONE OF THE SHAFTS OF THE CITY WATER TUNNEL OF THE CATSKILL AQUEDUCT, IN BROOKLYN.

of the riser. As a safeguard against great loss in the event of an accident, such as a serious break in one of the large water mains, or an explosion, which might injure the top of a shaft so as to permit a great rush of water, these riser valves are to be constructed so as to close automatically whenever the velocity of water flowing through them exceeds materially a certain predetermined value. Their design provides for ready removal from the shaft, and they will be shaped so as to cause minimum hydraulic losses when wide open, which will be their ordinary position. To prevent water ram so violent as to be dangerous to the street pipes and the shaft tops, the automatic closing of the valve will be controlled by an internal dash-pot, so that no riser valve can close in less than about 10 min.

Rapid progress is being made in excavating this City water tunnel. In two years about 3 000 000 lb. of dynamite have been used in blasting out the solid rock. It is to be lined throughout with concrete. The distances between shafts range from 2 500 to 5 000 ft. Two shafts will be suitably constructed for pumping out or unwatering the tunnel. At two places great bronze valves (66 in. in diameter) will be placed across the tunnel, so that a portion of it, instead of the whole, can be put out of service for cleaning or repair. This tunnel is so unusual a feature of a water-works system that it has been described at some length. Besides the advantages already mentioned or suggested, this tunnel with its pipe line extensions will interconnect all the boroughs. The existing systems are for the most part independent of one another.

Records show that periods of greatest excess or deficiency of available quantity of water do not occur coincidentally on the three principal groups of water-sheds (Long Island, Croton, and Catskill) from which the City obtains its water supply. Consequently, another advantage arises from interconnecting these systems by the City water tunnel, which may prove of great value in the future, namely, that each system can be depended on for a somewhat greater supply than would be permissible if each were limited to its absolutely safe capacity standing alone. In other words, in the event of an extreme drought on any one water-shed, the others will be able to make up, at least in part, for the deficiency.

High-Pressure Fire System.

For better protection against fire in the most valuable business portions of Manhattan and Brooklyn, high-pressure fire-service systems

of water mains and pumping stations have been constructed and are being extended. These mains are from 6 to 24 in. in diameter, of cast iron, extra heavy, and strong enough for service pressures up to 300 lb. per sq. in. All the hydrants are of special design, and the branch pipes connecting them with the main pipes are 8 in. in diameter. In Manhattan there are now 106 miles of pipes and 18 miles are under construction; in Brooklyn there are 40 miles. Both suction and delivery piping are arranged in loop systems, thus avoiding dead ends, and interconnecting the pumping stations so that each station in a system can supply all hydrants and draw from all sources of supply.

Five pumping stations, constantly manned, are ready on a moment's notice to force water into the pipes in large quantities. Water can be drawn by these pumps from either the city's water supply system or from the harbor, the latter to be used only in emergency. Manhattan has two stations, costing about $240 000 each, exclusive of land, one on the North River front near Gansevoort Market (not far from 13th Street), and the other on the East River shore at the Brooklyn Bridge. Brooklyn has two stations somewhat smaller than those in Manhattan, one on St. Edwards Street near Fort Greene Park and the other on Joralemon Street near the East River. There is also a small station at Coney Island, which can pump 4 500 gal. per min. against 150 lb. pressure.

Each Manhattan station has six pumping units, of an individual capacity somewhat in excess of 3 000 gal. per min., with a pressure of 300 lb. per sq. in. On test, each station has pumped more than 23 000 gal. per min. using the five units which constituted the original installation. Each unit consists of a five-stage centrifugal pump and an electric motor of the induction type. All parts are interchangeable. Each motor is of approximately 1 000 h.p. Electric current for them is obtained from the New York Edison Company, which has six interconnected supply stations, with an aggregate power generating capacity of about 210 000 kw., in Manhattan, and feeders connecting with the Brooklyn Edison Company. In addition, the pumping stations are connected electrically to eighteen sub-stations of the Edison Company, equipped with converters and storage batteries, which constitute a great power reserve. Therefore it is extremely improbable that the high-pressure fire systems will ever be without power or unable to supply water whenever demand is made.

Construction Camps.

In creating its stupendous modern physical structures and mechanisms, the metropolis has not been wholly unmindful of the humanitarian aspects of its engineering activities. Not only have "labor laws" been enacted by the State Legislature in greater or lesser wisdom, but into many contracts engineers and executive officers have written requirements for the better housing of the men, the more complete safeguarding of life and limb, and the sanitary regulation of construction camps, not alone for the benefit of the dwellers therein, but also for the greater protection of the communities affected directly and indirectly.

In constructing the works for its new Catskill water supply, the City has set a high standard in several particulars. Sanitarians, physicians, and surgeons have been engaged to assist the engineers and contractors in caring for the health of the men and guarding from pollution all public and private water supplies. In each of the numerous principal camps have been housed from a few hundred to several thousand human beings, besides hundreds of draft animals. Stables for the animals have been kept at a distance from the quarters for the men. In social classification, occupants of the camps have ranged from common laborers to superintendents and engineers. Many men, of all ranks, have been accompanied by their families. For the latter, separate cottages have been built. In general, the City has provided land for the camps and has insisted that they be built on well-drained, healthful sites, with ample spaces between houses and liberal allowance of air and light for each occupant. All camps have had provisions for sewage and garbage disposal, depending on the size and location. Commonly, garbage and excreta have been incinerated. Ample water supplies of good quality, and fire-fighting facilities, have been required. Physical examinations of employees and applicants have been made in order to detect communicable diseases. Food supplies have been inspected. All large camps have had hospitals, with surgeons and nurses in attendance. Camp City, at Ashokan Reservoir, although temporary, is a completely equipped modern community, having, in addition to the public utilities already alluded to, day and evening schools, a bank, post-office, general store, bakery, streets, electric lights, telephones, churches, Young Men's Christian Association, and an amateur band of music.

As the Catskill Aqueduct, for nearly 10 miles, is located on the Croton catchment area, and crosses the principal reservoir in a deep tunnel, with a shaft on either shore, about 2 000 ft. from the intakes to the two Croton Aqueducts, special sanitary precautions were taken. All camps were surrounded by man-proof fences and illuminated by night, for better control. Filters and chemical treatment were provided for all sewage and for drainage from camp areas, tunnels, and spoil banks; incinerators, of types similar to those devised originally for the United States army, were provided for defecation in the camps, and small shanties with water-tight removable receptacles were placed at convenient points on the works. Garbage was separately incinerated. That these precautions were effective is proven by the prevailing good health in the camps and the absence of epidemics of water-borne diseases in the City and the other communities within the water-sheds of which the operations have been situated. That labor forces, reaching a maximum total of 5 000 men, could have been resident for three years or more in camps on the most important catchment area of the City's water supply, and there employed in heavy excavation and masonry construction, without once causing sanitary troubles, is an achievement worthy of more than passing reference.

The total capital expenditure for water-works has been about $300 000 000, including the portion of the Catskill system now in hand.

Conclusion.

In this relatively young country, still only partly developed, and with many of its earlier constructions of temporary character, its engineers and architects, in all the branches of these constructive professions, have constantly great tasks to perform. Nowhere are more works of noteworthy magnitude concentrated than within 100 miles from New York City as a center. It is no exaggeration to state that, at all times during the past few years, private, public, and semi-public undertakings, aggregating $1 000 000 000, have been in various stages of progress within this area. The promise for the immediate future is for a continuance of these achievements and activities. The forces which have made New York continue in operation, and new forces are contributing to the City's further expansion. All these engineering achievements and activities of this great young City grew from the humble beginning at the southerly tip of Manhattan Island,

Fort New Amsterdam. Most of the modern greatness of the Metropolis has been created within the memory of men not yet 40 years old, the parents of some of whom can well remember carrying lanterns when going to "evening meeting" up to 14th Street, and others of whom once pastured their cows where Central Park now is, whose homes and churches have been supplanted by many-storied towering hives of commerce and industry.

ACKNOWLEDGMENTS.

Like the engineering achievements of New York City, this paper is the result of co-operation, and it gives the compiler pleasure to acknowledge his indebtedness. Much of the material was collected by Robert Ridgway, Frederick C. Noble, Arthur S. Tuttle, Members, Am. Soc. C. E., and Julian P. W. Richmond, Assoc. M. Am. Soc. C. E. Information and views were generously contributed by many of the city departments and their officials; by several public utility corporations; by Alfred Noble, Past-President, Am. Soc. C. E., Chief Engineer of the East River tunnel work for the Pennsylvania Railroad; George A. Harwood, M. Am. Soc. C. E., Chief Engineer of the Electric Zone Improvements of the New York Central and Hudson River Railroad Company; C. M. Jacobs and J. V. Davies, Members, Am. Soc. C. E., Engineers for the North River tunnels of the Pennsylvania Railroad, and the Hudson and Manhattan tunnels; George H. Pegram, M. Am. Soc. C. E., Chief Engineer, Interborough Rapid Transit Company; Alfred Craven, M. Am. Soc. C. E., Chief Engineer, and Mr. Louis D. Fouquet, Engineer, Sewer Division, Public Service Commission; Alexander Johnson, Assoc. M. Am. Soc. C. E., Chief Engineer, Bridge Department; J. Waldo Smith, M. Am. Soc. C. E., Chief Engineer, Board of Water Supply; George A. Soper, M. Am. Soc. C. E., President, and Kenneth Allen, M. Am. Soc. C. E., Chief Engineer, Metropolitan Sewerage Commission; I. M. de Varona, M. Am. Soc. C. E., Chief Engineer, and William W. Brush, M. Am. Soc. C. E., Deputy Chief Engineer, Department of Water Supply, Gas, and Electricity; George W. Tillson, M. Am. Soc. C. E., Consulting Engineer, Borough of Brooklyn; Edwin J. Fort, M. Am. Soc. C. E., Chief Engineer, Bureau of Sewers, Brooklyn; B. F. Cresson, Jr., M. Am. Soc. C. E., First Deputy Commissioner, and S. W. Hoag, Jr., M. Am. Soc. C. E., Deputy Chief Engineer, Department of Docks and Ferries;

Paper No. 1275

THE ELEVATION OF THE TRACKS OF THE PHILADELPHIA GERMANTOWN AND NORRISTOWN RAILROAD, PHILADELPHIA, PA.*

By Samuel Tobias Wagner, M. Am. Soc. C. E.

With Discussion by Messrs. J. P. Snow, E. W. Lewis, Charles Rufus Harte, George S. Webster, and Samuel Tobias Wagner.

It is the purpose of this paper to present the more interesting features of the work of abolishing grade crossings on the line of the Philadelphia, Germantown, and Norristown Railroad, a leased line of the Philadelphia and Reading Railway, in the City of Philadelphia, between Green Street and the Richmond Branch Crossing near Wayne Junction.

The Philadelphia and Reading Railway enters the heart of the City of Philadelphia, to the Reading Terminal at Twelfth and Market Streets, by two principal routes:

First.—From the main line on the Schuylkill River through the Subway on Pennsylvania Avenue.

Second.—From Wayne Junction *via* private right of way and Ninth Street.

The avoidance of grade crossings on the first line has been described in the *Transactions*.† It is the purpose of this paper to describe the second, which has recently been completed.

* Presented at the meeting of June 4th, 1913.

† *Transactions*, Am. Soc. C. E., Vol. XLIV, p. 1; and Vol. XLVIII, p. 470.

Both these lines are part of the Philadelphia Division of the Philadelphia and Reading Railway.

The tracks, at the time work was started, were elevated from the Reading Terminal as far north as Green Street, where a descent was made to the street level at Fairmount Avenue. From this point to Wayne Junction, a distance of 4.3 miles, there existed in 1906 no less than 28 grade crossings, some of them being very dangerous.

The Philadelphia, Germantown, and Norristown Railroad was built in 1833, at which time the major part of the territory traversed was open fields. As the City grew and new streets were opened, new grade crossings were being constantly created, and conditions became very bad on account of very heavy and rapid train movements over the line.

Previous to 1900 the exceptionally bad crossings existing at Columbia Avenue and Broad Street were abolished, under a city ordinance of December 26th, 1890, which authorized the construction of the Reading Terminal. In both these cases the street grades were raised and the highways carried over the railroad.

Prior to 1906 a number of studies looking toward the abolishment of these grade crossings were made, both by the City and the Railway Company, all being based on the elevation of the tracks as the best and most economical method of accomplishing the desired end. The total estimated cost of the work was as follows:

Green to Broad Streets	$5 779 740
Seventeenth Street to Richmond Branch	1 880 000
Total	$7 659 740

LEGISLATION.

Between 1903 and 1906 a number of conferences were held between the Mayor of the City and the management of the Railway Company for the purpose of reaching an agreement as to the general plan to be followed and the division of cost of the work. At first it was the intention to do away with the grade crossings only between Green and Broad Streets, but, as the work developed, the section north of Broad Street was included, by mutual consent.

After considerable discussion, a form of ordinance authorizing the Mayor to enter into an agreement with the Railway Company for the

work was introduced into Councils and, after discussion in that body, was finally agreed to by both interests, passed by Councils on October 4th, 1906, and approved by the Mayor on October 13th, 1906. This ordinance also included the abolishment of certain grade crossings on the Richmond Branch of the same railway between Somerset and Richmond Streets, which work will not be described here.

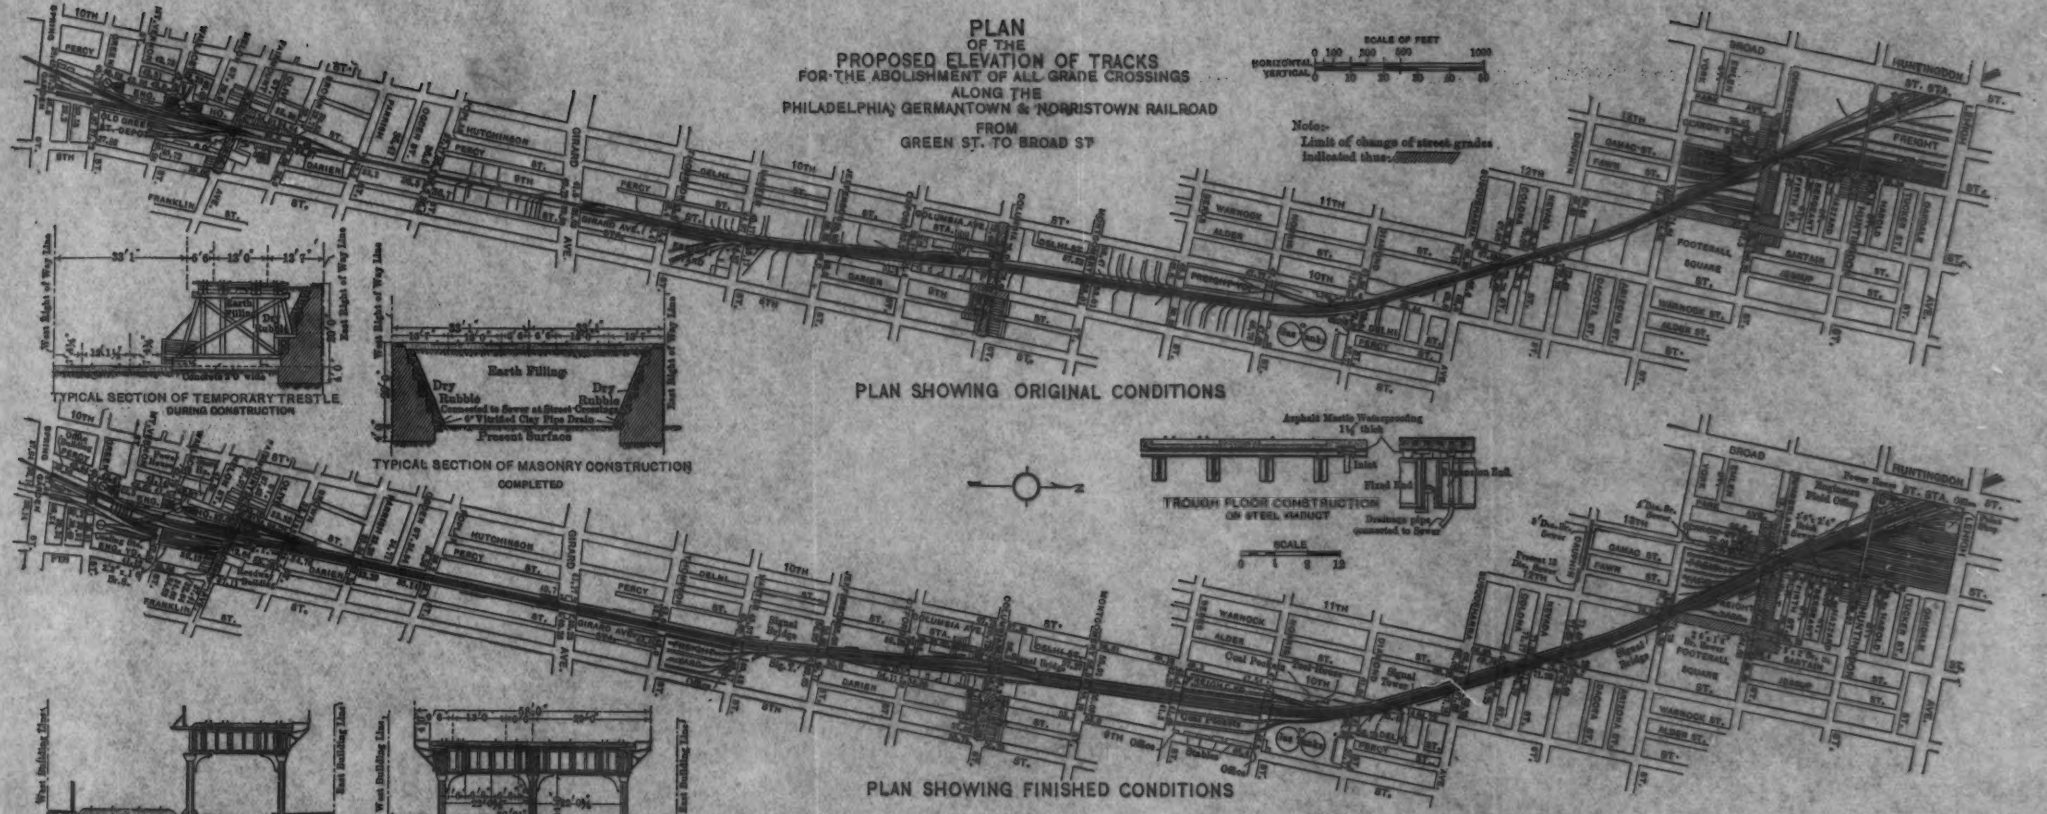
On March 28th, 1907, the agreement authorized by Councils was formally signed by the proper officials of the City and the Railway Company. This agreement, among other things, provided, as follows:

1st. The legal authority for the City to revise the city plans, on account of the changes of grade of the streets, etc.

2d. Authorization of the city officials to prepare plans, specifications, and contracts for the changes of grade of the street, and the opening of new streets, said plans and contracts to be approved by the Railway Company.

3d. Authorization of the Railway Company to prepare plans and contracts for the work of raising its tracks, with the bridges and all other appurtenances, said plans and contracts to be approved by the City.

4th. Authorization of both the City and the Railway Company to employ engineers and inspectors; also to provide for emergency work in the maintenance of railroad and highway travel, not covered by contract, by force account on the part of the Railway Company and the City.



5th. Division of the cost equally between the Railway and the City as long as the Railway Company does not increase its facilities over and above what it had at the time of passage of the ordinance; all other additional expenses incurred by the Railway Company to be at its sole expense. The cost of the work to be equally divided includes all consequential damages caused by the change of street grades.

6th. For the proper disposal (and proper credit to both parties) of all old material or real estate purchased and not used.

7th. That the representatives of the City and the Railway Company shall be, respectively, the Director of the Department of Public Works and the Chief Engineer.

PLAN
OF THE
PROPOSED ELEVATION OF TRACKS
FOR THE ABOLISHMENT OF ALL GRADE CROSSINGS
ALONG THE
PHILADELPHIA, GERMANTOWN & NORRISTOWN RAILROAD
FROM
GREEN ST. TO BROAD ST

General Description.

The following is a general description of the work: Beginning at Green Street, to which point from the south the tracks had already been elevated, they run level at an elevation of 57.44 to a point near Brown Street. A slight hump is placed in this profile to cross the engine passageway in the Green Street Yard. As far as Brown Street, the four main tracks are carried on fill between concrete retaining walls with steel plate-girder bridges crossing the engine passageway and Fairmount Avenue at four different levels. At Fairmount Avenue the grade of the street was lowered so as to allow 14 ft. beneath the bridges leading to the engine yard on the east and west sides of the main tracks. A new locomotive coaling station, with a storage capacity of 2 000 tons, is located in the east yard.

At Brown Street the tracks are over the bed of Ninth Street and are carried on a four-track, steel viaduct with plate-girder spans, generally 50 ft. long, supported by transverse girders and three lines of columns, and, in turn, supporting a solid steel floor, which is waterproofed. This viaduct is on a grade of 0.5%, and is on a tangent as far as Master Street. At Girard Avenue a new elevated station is supported over the street.

Between Thompson and Master Streets, and Eighth and Ninth Streets, the old freight yard is raised to the new level with a ramp approach from Eighth and Master Streets.

At Jefferson Street the tracks are supported on earth fill with third-class, masonry retaining walls and concrete abutments, and this type of construction continues to the end of the line at the Richmond Branch Crossing. At Jefferson Street the line leaves Ninth Street and occupies its own right of way. This right of way, 66 ft. in width, formerly extended as far south as Girard Avenue, but, under the ordinance authorizing the work, it was released to the City for street purposes beneath the viaduct.

The 0.5% grade extends about to Oxford Street, where the tracks are level at an elevation of 74.5, to a point near Montgomery Street.

Between Oxford Street and Columbia Avenue is the Columbia Avenue Station, having island platforms with stairways leading to the main waiting- and baggage-rooms at the southwest corner of Ninth Street and Columbia Avenue.

The tracks cross Berks and Norris Streets on concrete arches, replacing old iron plate-girder bridges which formerly carried the low-level tracks over these streets.

Between Berks and Norris Streets on the west side is a freight yard raised nearly to the new level, with a ramp approach parallel to Tenth Street, and on the east side, on property of the Railway Company, there are two large commercial coal yards. At the northeast corner of Tenth and Norris Streets there is a smaller coal yard.

Between Berks and Norris Streets the tracks ascend on a 0.7% grade to the summit at York Street and then descend on a 1% grade to Broad Street, where the old level is reached.

Between Norris and Cumberland Streets there are five tracks crossing a large number of streets, at very acute angles, on steel bridges of plate-girder type with solid water-proofed floors. Between York and Cumberland Streets there are two elevated freight yards, and north of Cumberland Street there is a car-cleaning yard on the east side.

Between Broad Street and a point near Seventeenth and Indiana Streets no work was required, as there were no grade crossings in this territory.

From Seventeenth and Indiana Streets to Tioga Street, the grade is 1.06%, and there are five tracks as far as Westmoreland Street and four north of that point. In order to obtain the 1.06% grade, it was necessary to raise a truss bridge of the Philadelphia, Germantown, and Chestnut Hill Railroad (Pennsylvania System) about 4 ft. This was done at a cost of $18 384.47.

The new elevation required changes in the grades of Allegheny Avenue, Westmoreland Street, Ontario Street, and Hunting Park Avenue, and slight changes at Atlantic and Venango Streets. The changes at Allegheny Avenue and Westmoreland and Ontario Streets necessitated those in a number of other streets shown on the general plans, Plates LXVI and LXVII.

New stations were constructed at Tioga and Nicetown, and a coal yard of the Railway Company was reconstructed at Hunting Park Avenue.

Preparation of Plans and Contracts.

Plans and specifications for the various contracts were duly prepared for the work by the Railway Company and the City, and were

TRACK ELEVATION, PHILADELPHIA, PA.

submitted for approval to the other interest before asking for bids. All work was advertised publicly, and awards were made to the lowest bidder.

Division Into Contracts.

In the summer of 1906, it was decided to divide the work into contracts so that it could be attacked from the greatest number of points at one time, and so that, as far as possible, the work requiring special skill could be separated in order to reduce the number of contracts to a minimum. All track work was done by Railway Company's forces on what were known as emergency orders.

Tables 1 and 2 show the contracts into which the work was divided. All numbers from 1 to 100 were executed by the Railway Company; those above 100 by the City.

Emergency Orders.

The ordinance provided that in case of emergency work in maintaining railroad or highway travel, and in other cases where necessary—not covered by contract—either the Railway Company or the City should have authority to employ laborers, hire machinery, and purchase materials to perform such work. Such work, when jointly agreed upon, constituted what was known as an emergency order. On the part of the Railway Company, these orders generally applied to the construction of temporary and permanent tracks, the work being done by the Operating Department; and on the part of the City to work connected with the maintenance of underground municipal structures. They were also used for keeping account of numerous minor additional betterment items desired by the Railway Company during the progress of the work, and paid for entirely by them. All labor on pay rolls was carefully checked, and all prices of materials were approved prior to purchase.

Temporary Yards.

Besides the heavy passenger business conducted over the line which was to be elevated, involving about 467 train movements in 24 hours, the Railway Company operated freight yards at Eighth and Master, Tenth and Berks, and Thirteenth and Huntingdon Streets, and a locomotive coaling station and engine repair yard at Ninth and Green Streets.

TABLE 1.—LIST OF CONTRACTS WITH RAILWAY COMPANY.

In order to provide for the car load freight business of the freight yards during construction, a temporary freight yard was constructed on property of the Railway Company at Nineteenth Street, capable of holding 163 cars, and a temporary engine yard at Wayne Junction. Work on the freight yard was begun in October, 1907, and finished on May 30th, 1908. The total cost of grading, drainage, and paving, exclusive of the track work, was $40 380.40. Work on the engine yard was begun on January 7th, and finished on June 30th, 1908. The total cost of grading, drainage, engine house, coaling station, water tanks, ash pits, etc., exclusive of the track work, was $46 501.60.

On the completion of the elevation of the tracks, the City was credited with the amounts which it had paid for the construction of these yards, less an amount agreed on, representing the depreciation of the tracks, in the case of the freight yard, and of the tracks and buildings, in the case of the engine yard.

Sewers.

In August, 1907, work was begun, practically at the same time, on the construction of by far the majority of the sewer work connected with the change in grades of the streets. The work is described very briefly under the following contracts:

Contract No. 101.—Sewer on Thirteenth Street from Dauphin to Cumberland: This was required to drain the depression caused by the lowering of the intersection at Thirteenth and Cumberland Streets.

Contract No. 102.—Clearfield Street east of Sixteenth; Sixteenth Street from Clearfield Street to Allegheny Avenue, and on Allegheny Avenue to Seventeenth Street: This was the outlet section of the main system for draining the depressed streets in the Tioga District, extending as far north as Nicetown Station.

Contract No. 103.—Allegheny Avenue from Seventeenth Street to Nineteenth Street, and Nineteenth Street from Allegheny Avenue to Westmoreland: This is the second section of the main sewers for draining the Tioga District.

Contract No. 104.—On Nineteenth Street from Westmoreland to Venango, and on Venango from Nineteenth to Twentieth: This is the third section of the main system for draining the depressed streets in the Tioga District.

Contract No. 105.—On Venango Street from Twentieth to Twenty-first, on Twenty-first Street from Venango to Blabon, on Blabon from Twenty-first Street to Hunting Park Avenue; on Hunting Park Avenue from Blabon to the railroad: This is the last section of the main sewers in the Tioga District, and taps the depression on Hunting Park Avenue under the railroad.

The sizes, costs, and other data in reference to the sewers built under Contracts 101 to 105 are shown in Table 3.

In addition to these, sewers were constructed in conjunction with Contracts Nos. 108, 109, 110, and 111, covering the smaller sewers in connection with the work of lowering the streets along the whole line of the work. Table 3 contains a summary of the entire cost of the sewer work, including inlets, connections, etc., and showing for each contract the length of the sewers and the total cost of the sewer work.

The construction of these sewers presented no unusual features. The work was executed in accordance with the standard plans and specifications of the Department of Public Works, Bureau of Surveys, of the City of Philadelphia.

Method of Construction.

The general character of the construction consists: First, of masonry walls and fill, between Green and Brown Streets, between Jefferson and Broad, and between Seventeenth and Indiana and the Richmond Branch, with steel bridges over the streets, carrying four and five tracks, respectively; and, second, a four-track steel viaduct over Ninth Street between Brown and Jefferson Streets.

Work was begun between Columbia Avenue and Broad Street in January, 1907, by diverting the temporary travel to two temporary tracks located as closely as possible to the west side of the 66-ft. right of way. The retaining walls on the east side, with the eastern halves of the bridge abutments, were next built, and a temporary trestle for two tracks was constructed alongside of them; and approximately one-half of the permanent bridges were erected, so that two tracks on the new high level could be placed in operation. Access to this high level was made by the permanent 1% grade from Broad Street and a temporary 2.5% grade from Columbia Avenue to Norris Street. Crib-work was placed along the western edge of the trestle to a height of about 8 ft., and as much fill as possible was made between the crib

and the wall around the trestle before travel was placed on the trestle. On the completion of the temporary tracks on the high level, schedule travel was transferred to them and abandoned on the low level. The western retaining walls and the rest of the abutments were then completed with the fill and the remainder of the bridges. The fill was generally made by carting in from the cross streets before the abutments were finished, and completed after the abutments were built by raising it over them with a clam-shell bucket and derrick. The permanent tracks were then laid on the new fill on the west side, and schedule travel was transferred to them; the temporary tracks on the trestle were removed; the ties, guard-rails, and stringers of the trestle were taken out for use at other points; the fill was completed, and the permanent tracks were laid in their final position. This same method was followed at all other points where masonry and fill construction was used, except that, in the Tioga District, between Seventeenth Street and the Richmond Branch, the method was reversed, the work being started on the west side first.

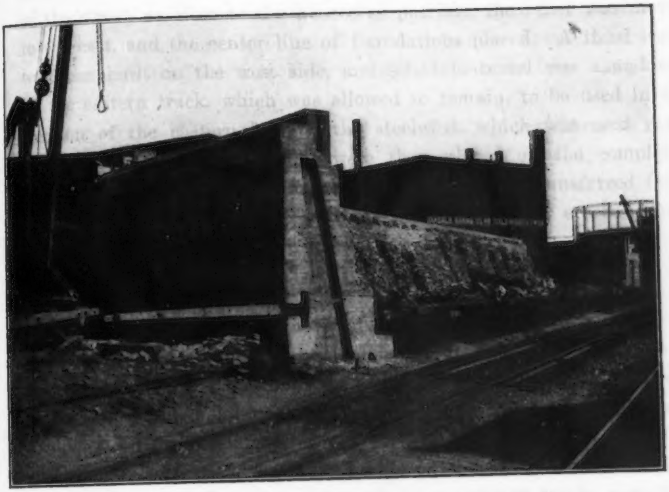
* Does not include cost of inlets or similar details.

In the construction of the steel viaduct between Brown and Jefferson Streets, the foundations for the two outside lines of columns were constructed with the two tracks carrying schedule travel in the



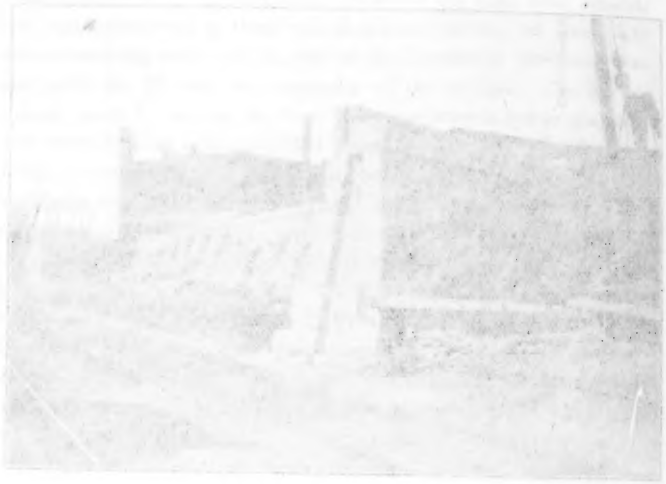


FIG. 2.—ABUTMENT AND DRY STONE PACKING, EAST SIDE.

FIG. 3.—ERECTING BRIDGES, EAST SIDE.

center of the 70-ft. street. One track was then placed on the west side of the street, as close to the houses as possible, the other was moved to the east, and the center line of foundations placed. A third track was then built on the west side, and schedule travel was abandoned on the eastern track, which was allowed to remain, to be used in the erection of the eastern half of the steelwork which was next completed. Two permanent tracks were then placed on the completed eastern half of the viaduct, and schedule travel was transferred from the low to the high level. The western side was then erected, completed, and the remaining two tracks were laid.

Temporary Tracks.

Before beginning work, the Railway Company had two tracks on which schedule trains were operated between Green and Cumberland Streets and four tracks from that point to Wayne Junction. There were also two additional tracks used for siding purposes between Girard Avenue and Cumberland Street.

From the time that the main tracks on the street level were disturbed for construction purposes, until the permanent tracks were laid on the high level, all the charges and maintenance were considered as temporary tracks. The instructions of the management were that there must be at all times two tracks in proper condition to operate schedule trains. Only enough material was ordered to carry out the necessary transfers of traffic and to replace that which was not fit for relaying as the tracks were taken up and moved. The general method for providing for temporary traffic has already been described, and it is fair to say that, owing to the care exercised by the contractors, engineers, and the Operating Department, there was no interference with schedule traffic.

Retaining Walls and Abutments.

The part of the construction with masonry walls and fill consisted generally of retaining walls on each side of the 66-ft. right of way, with vertical faces on the lines. It was absolutely necessary to place these walls vertically on the right-of-way lines between Columbia Avenue and Broad Street, as the plans provided for five tracks with 13-ft. centers in this territory, and the same construction was used at other points. As private property adjoined the right of way, there was not room to erect forms for concrete work without trespassing, and large

rubble masonry was indicated and used. Where retaining walls faced on streets, they were built of 1:3:6 concrete with granolithic washed faces and scored with horizontal lines. The same construction was used for bridge abutments. The typical retaining wall was as shown by Fig. 5.

The rubble work (known as third-class masonry) was built under the following specification, the mortar being of 1:3 Portland cement, the stone being bedded in mortar, and the vertical joints grouted with 1:3 grout:

"Third-class masonry shall be formed of approved quarry stone of good shape and good flat beds. No stone shall be used in the face of the walls less than 6 in. thick, or less than 12 in. in their least horizontal dimensions.

"Headers shall generally form at least one-fifth of the faces and backs of the walls, with a similar proportion throughout the mass when they do not interlock, and the face stones shall be well scabbled or otherwise worked, so that they may set close, and chinking with small stones be avoided.

"In walls, 5 ft. thick or less, the stones used shall average from 6 to 8 cu. ft. in volume, and the length of the headers shall be equal to two-thirds of the thickness of the wall; in walls more than 5 ft. in thickness, the stones used shall average 12 cu. ft. in volume, and the headers shall not be less than 4 ft. long. Generally, no stones shall be used having a less volume than 4 cu. ft., except for filling the interstices between the larger stones.

"In no case shall stones be used having a greater height or build than 30 in., and these stones must bond the joints above and below at least 18 in.; in all other cases the smaller stone used must bond the joints above and below at least 10 in.

"The stones in the foundation shall generally not be less than 10 in. in thickness, and contain not less than 10 sq. ft. of surface. The foundation shall consist of 1:3:6 concrete if so directed by the Chief Engineer."

The concrete used was of two kinds, 1:2:4 in bridge seats, pedestal blocks, etc., and 1:3:6 for main walls, foundations, copings, etc. The important and specially interesting points in the concrete specifications were as follows: Stone to be run of crusher, from ¼ in. to 1½ in. Sand graded from fine to coarse from ¼ in. down. Preference for machine mixing with cubical box type. Consistency to be such that when dumped in place, concrete will not require much tamping, but not wet enough to cause the mortar to

DIAGRAM SHOWING CONSTRUCTION OF MASONRY SECTION

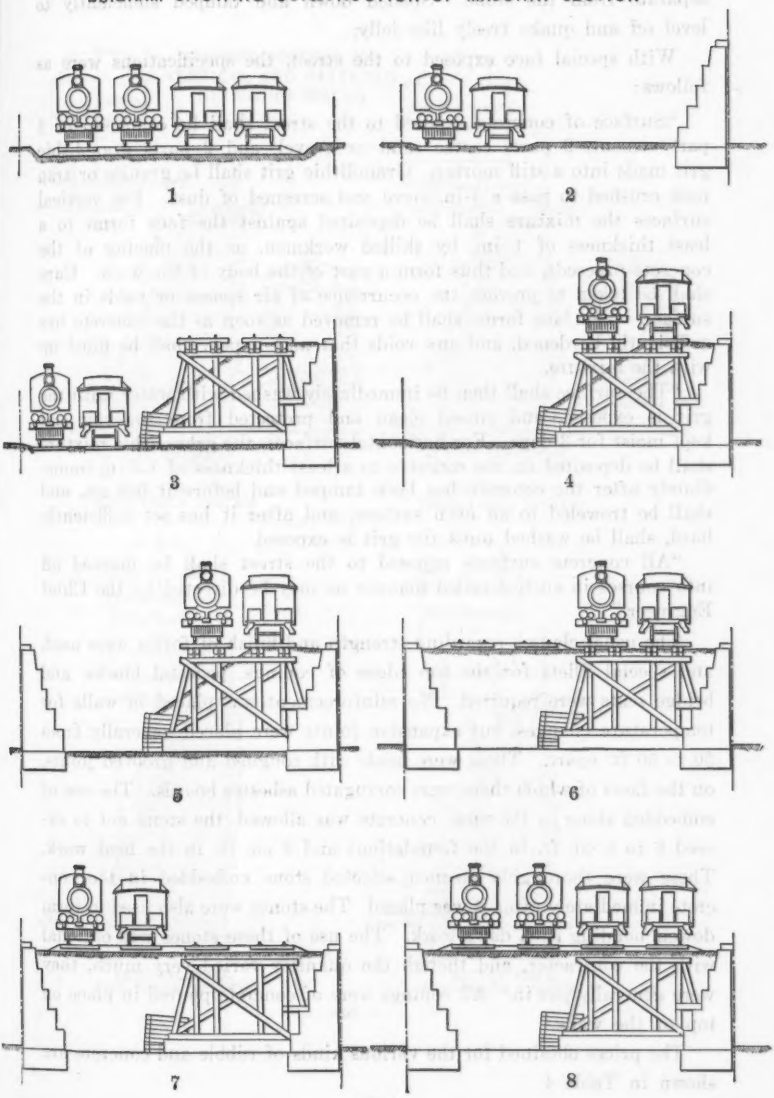

FIG. 4.

separate from the stone. Spaded down and tamped sufficiently to level off and quake freely like jelly.

With special face exposed to the street, the specifications were as follows:

"Surface of concrete exposed to the street shall be composed of 1 part cement, 2 parts coarse sand or gravel, and 2 parts granolithic grit made into a stiff mortar. Granolithic grit shall be granite or trap rock crushed to pass a ¼-in. sieve and screened of dust. For vertical surfaces the mixture shall be deposited against the face forms to a least thickness of 1 in., by skilled workmen, as the placing of the concrete proceeds, and thus form a part of the body of the work. Care shall be taken to prevent the occurrence of air spaces or voids in the surface. The face forms shall be removed as soon as the concrete has sufficiently hardened, and any voids that may appear shall be filled up with the mixture.

"The surface shall then be immediately washed with water until the grit is exposed, and rinsed clean and protected from the sun and kept moist for 3 days. For horizontal surfaces, the granolithic mixture shall be deposited on the concrete to a least thickness of 1.5 in. immediately after the concrete has been tamped and before it has set, and shall be troweled to an even surface, and after it has set sufficiently hard, shall be washed until the grit is exposed.

"All concrete surfaces exposed to the street shall be marked off into courses in such detailed manner as may be directed by the Chief Engineer."

The usual clauses regarding strength and finish of forms were used, and special fillets for the top edges of copings, pedestal blocks, and bridge seats were required. No reinforcement was placed in walls for temperature changes, but expansion joints were placed generally from 30 to 50 ft. apart. These were made with tongued and grooved joints, on the faces of which there were corrugated asbestos boards. The use of embedded stone in the mass concrete was allowed, the stone not to exceed 6 to 8 cu. ft. in the foundations and 2 cu. ft. in the neat work. These were thoroughly cleaned selected stone embedded in the concrete immediately after it was placed. The stones were also used to form dowels bonding each day's work. The use of these stones was optional with the contractor, and though the quantity varied very much, they were generally put in. All copings were of concrete poured in place on top of the walls.

The prices obtained for the various kinds of rubble and concrete are shown in Table 4.

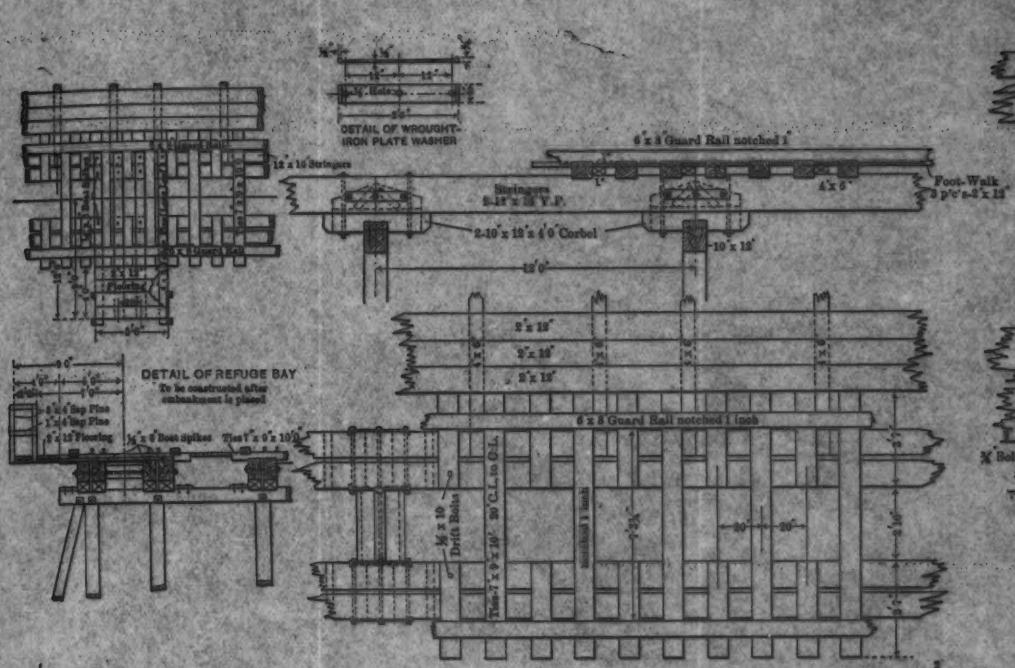
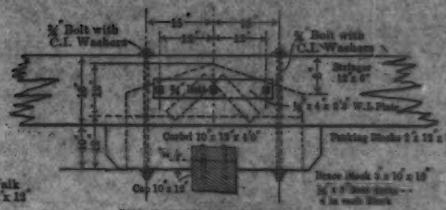
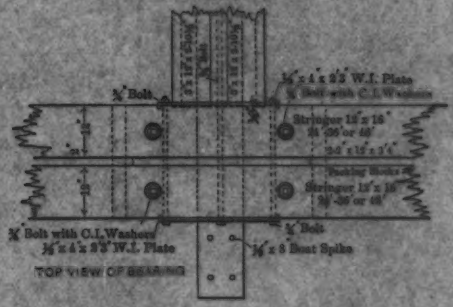
Drainage Back of Walls.



On account of the walls facing immediately on private property, or on the streets, it was decided to carry the drainage back of them, a step farther than the usual practice, in order to guard as far as possible from leakage through them to adjoining property or to the street, and the entire back of each wall, up to the subgrade of the tracks, was filled with a minimum thickness of dry-stone packing, the stone being from $\frac{1}{2}$ to 2 cu. ft. in volume, and placed by hand after the walls were finished and before the embankment was placed. As the third-class masonry walls were built, their backs were thoroughly dashed with 1 : 3 cement mortar. At the bottom of the dry-stone packing, 6-in. vitrified clay pipes with open joints were laid, with grades of about 1%, leading to the cross streets and there connected to the sewers. This drainage has proved very effective.



Temporary Trestle and Crib.



In the sections of the work constructed with masonry and fill, it was necessary to support two tracks between the bridges on trestle and then fill in as much as possible, using a crib about 8 ft. high with its face 5 ft. from the nearest running rail. The temporary trestle was built on concrete footings so as to reduce the settlement to a minimum and prevent wedging at the top in order to maintain proper track surface. It was constructed for two tracks in accordance with the general design shown on Plate LXVIII.

Long-leaf pine was used in the ties, guard-rails, and stringers, and these were all recovered when the fill was entirely completed and before the permanent track was laid. The caps, sills, posts, and bracing were of short-leaf pine, and remained buried in the fill.

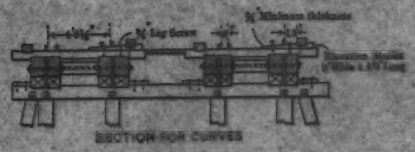


PLATE LXVIII.
TRANS. AM. SOC. CIV. ENGRS.
VOL. LXXVI, No. 1275.
WAGNER ON
TRACK ELEVATION, PHILADELPHIA, PA.

DETAILS OF TRESTLE
FOUR-TRACK SYSTEM

The prices paid for this work are shown in Table 5, and included everything above the concrete footings ready to lay track.

TABLE 5.

Contract numbers	1	4	5	7	9	10
Long-leaf yellow pine, per 1 000 ft. b. m.	$43.00	$44.50	$40.00	$43.00	$44.50	$42.00
Short-leaf yellow pine, " 1 000 " "	41.00	38.00	36.00	41.00	37.00	38.00
Wrought iron or steel, per pound	0.03	0.03	0.04	0.03	0.03	0.03

The average height of the double-track trestle was about 17 ft., and its average cost per linear foot was about $18.50, exclusive of the concrete footings.

The cribwork was covered by the following specifications:

"Where cribwork is required, it shall cover all temporary lumber work with the necessary filling and tamping required to retain slopes along partly made embankments or at other places, as may be directed.

"The lumber used in cribwork shall be placed as shown on the plans. It shall consist of second-hand lumber which is sufficiently sound to hold the drift-bolts.

"As the lumber is laid and drift-bolted, the embankment shall be filled in and thoroughly rammed. This work shall be paid for at the item price given in the proposal for cribwork per 1 000 ft. board measure, which price shall include all drift-bolts and the placing and ramming of the necessary embankment within the crib."

The prices obtained for the cribwork were as follows:

Contract numbers	1	4	5	7	9	10
Cribwork per 1 000 ft. b. m.	$15.00	$15.00	$20.00	$24.00	$25.00	$20.00

EMBANKMENT.

Embankments were built as soon as the footings for the temporary trestle were begun, and all excavated material from the foundations of walls and abutments was placed around them and in the crib, payment being made for excavation only. On the completion of the sections of the trestle between streets, the crib was carried up to its full height, embankment material was delivered on the cross streets, raised over the abutments with derrick and clam-shell buckets, and the fill completed around the trestle to its finished lines.

In some cases where excavation was available from the depressed streets, the trestle was planked, and the street grading contractor hauled the excavated material over it, and dumped it as part of his cost of excavation. With the exception of this, all material going

into embankments was furnished from outside the work and placed by the contractor at fixed prices, measurement being made on carts or wagons on delivery, each wagon load being measured by a representative of the contractor and an inspector who checked at the close of each day's work.

After schedule travel was placed on the temporary trestle, the remainder of the fill was made with teams hauling in from the adjoining streets, and after the abutments were completed the remaining material was raised over the abutment, as was done on the other side.

All material for embankment was inspected carefully and no ashes, cinders, or perishable material were allowed. Nearly all of it came from various building operations throughout the city.

The prices paid for embankment, delivered and placed by the contractor, were as follows:

Contract numbers..	1	4	5	7	9	10	12	14	32
Embankment.....	$0.20	$0.14	$0.45	$0.52	$0.10	$0.15	$0.10	$0.45	$0.175

BRIDGES.

All the bridges on the improvement carried railroad tracks, there being not a single highway bridge. Wherever possible, they were of deck construction, and, where through girders were required, the top of the girder was kept as low as possible, or the distance between tracks was spread to 14 ft.—the standard being 13 ft. All bridges were of the plate-girder type with solid steel floors either of built-up troughs or buckle-plates. The top of the steel on the floors was protected in all cases by some kind of water-proofing described later. Generally, all spans crossing streets had columns on the curb lines. The underside clearance over the streets established by ordinance was 14 ft. All masonry for supporting the steelwork was executed under separate contracts, the bridge contracts, however, covering all water-proofing and painting ready for the ballast.

The design of all the bridges was complicated seriously by the fact that they had to be planned so as to be erected in two sections, in order to carry travel on the high level on one side while the other side was under construction. This was specially difficult where the skews of the street crossings were great, and, in two cases, it was necessary to erect part of the steel over travel on the low level. The problem of water-proofing was also made more difficult on account of the provision for the double erection and the necessary joint.

*Part of these bridges occupied by passenger station platforms.

At two points only was it possible to construct concrete arches. These will be described separately.

The designs and specifications were of the Philadelphia and Reading standard, which generally provide for a live load about equivalent to Cooper's E-55.

The dead weights assumed for the design of the ballasted floors were as follows, all in pounds per cubic foot: Ballast, 120; concrete, 140; asphalt, 90; lumber, 54.

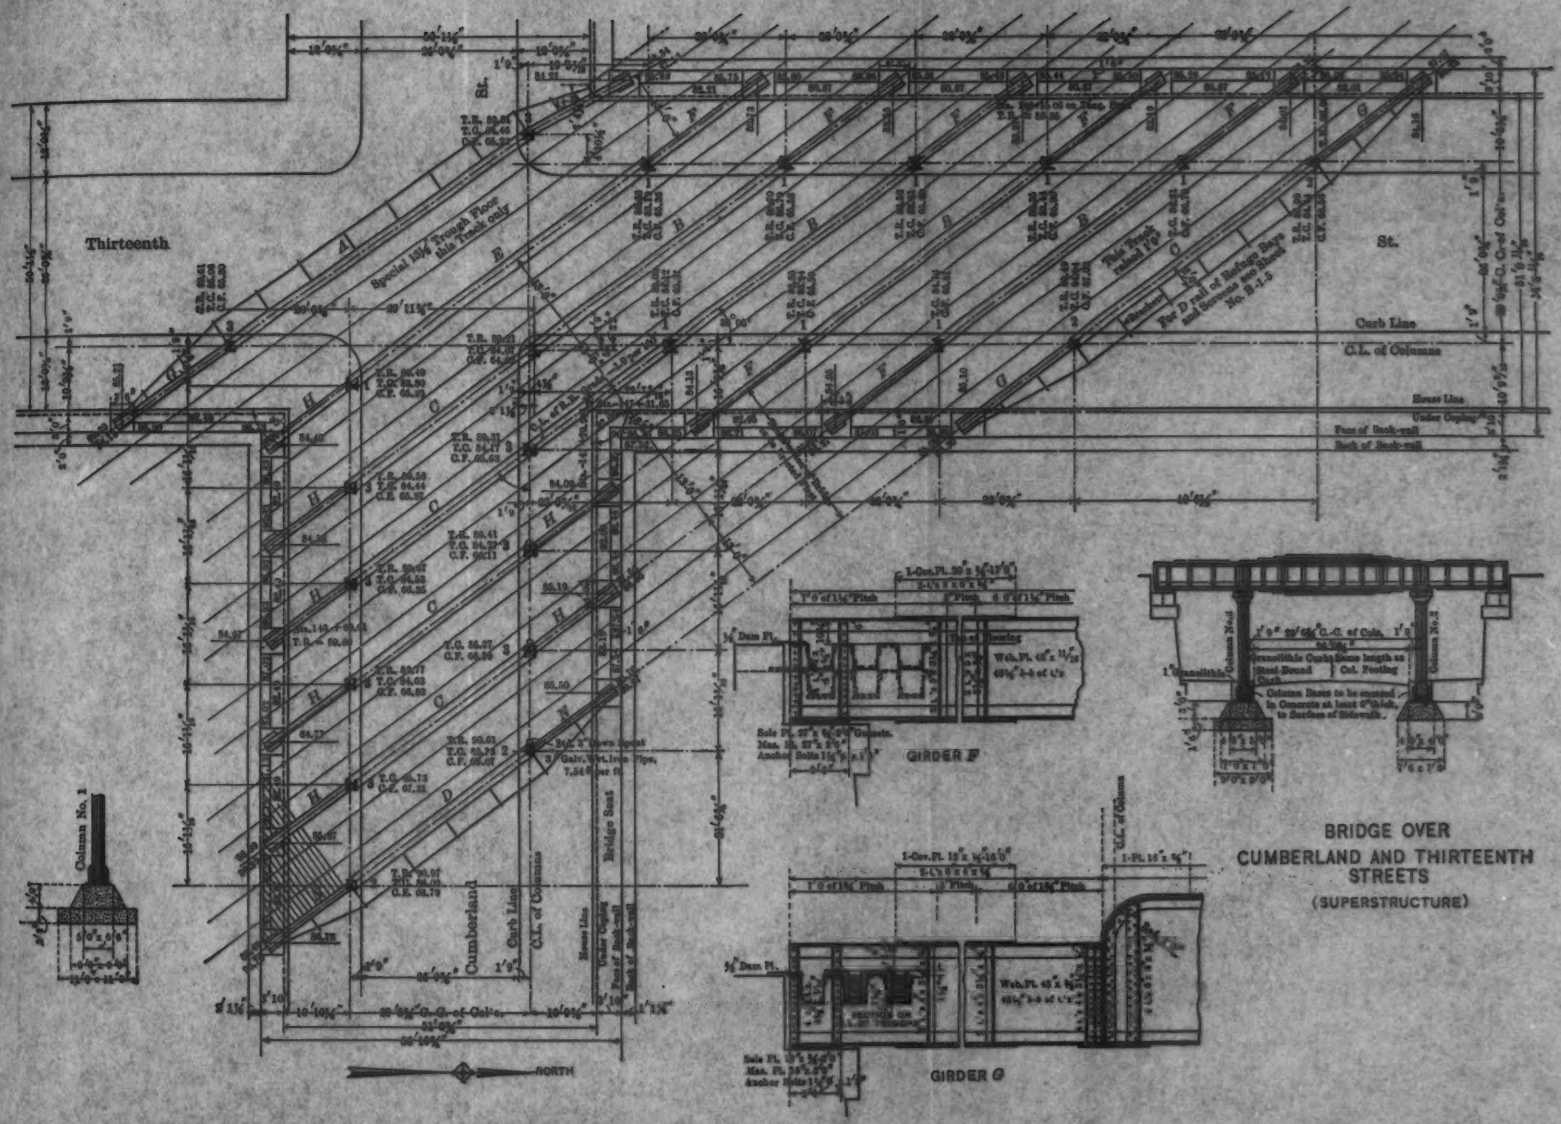
The impact was by the following formula:

$$I = S \frac{300}{L + 300}$$

I = amount to be added to live-load stress;
S = calculated live-load stress;
L = length, in feet, of the loading which produces maximum stress in the member.

Unit stress = 15 000 lb. per sq. in., in tension.
In compression, 15 000 reduced.

All steel was to be made by the open-hearth process, with a desired ultimate strength of 60 000 lb. for structural steel and 50 000 lb. for rivets; minimum elongation in 8 in. $= \frac{1\,500\,000}{\text{ultimate tensile strength}}$.



Very few of the bridges were distinctly of deck construction, on account of the lack of sufficient head-room, caused by the usual close clearances in grade-crossing work, where the procedure seems to be to squeeze the bridge construction out of existence. Where deck construction was impossible, half through spans were resorted to, with the top flange of the girders as close to the rail level as possible. In a number of cases it was necessary—especially on that part of the structure carrying five tracks—to introduce a deep transverse floor, so as to provide for necessary cross-overs in the tracks. The general type of one of the two styles of construction is shown on Plate LXIX.

Table 6 shows the general data regarding the bridges on four different contracts, and, in examining them, the conditions under which they were designed and the peculiar locations of many of them must be considered.

All columns located on the sidewalks were required by the City authorities to have their base-plates far enough below the surface of the street to show only the main section of the column. All gussets were to be below the surface. The masonry contractors built the floorings up to the level of the base-plates, the bridge contractors, after setting the columns and lining up the steel work, encased the entire base of the columns in concrete which formed part of the surface of the sidewalk and a section of the curb.

Most of the bridges were erected with the usual derrick car, either by jacking it up to the high level, as was necessary in one case, or by

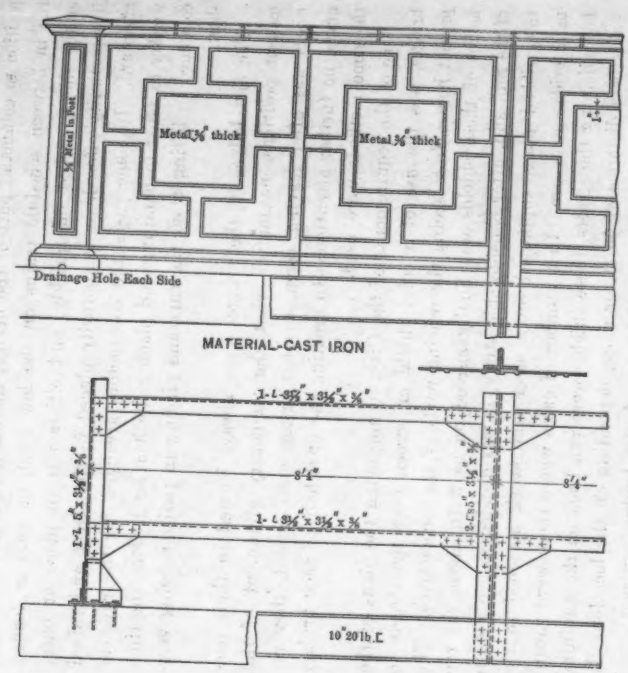
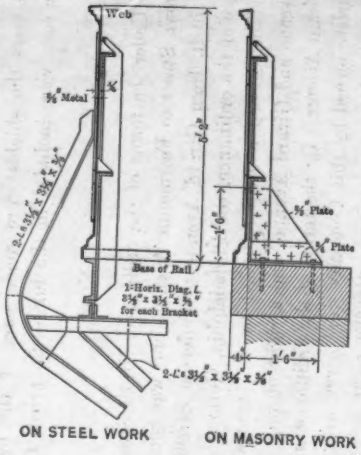
BRIDGE OVER
CUMBERLAND AND THIRTEENTH
STREETS
(SUPERSTRUCTURE)



running it in on the completed high-level approach, in others. When in position to command part of the bridge, the main steel members were run in between schedule trains on the low level, on cars as loaded at the shops, picked off quickly, and either put in place at once, if opportunity offered, or temporarily placed in the street and raised afterward. In some cases the contractors arranged for the railroad wrecker to assist in handling and placing the heavier girders, the time consumed in lifting from the cars and placing in position being very short.



The first halves of the bridges were always located in their permanent positions, no matter what the temporary alignment of the tracks was after leaving them, so that, when once placed, they required no further attention. In erecting the final half of each bridge, the same methods were used.

One of the requirements of the City, in approving the plans of the bridges, was the use of a solid shield or screen over the streets to prevent horses from seeing the moving parts of the locomotives. The height of these shields was finally agreed on as 5 ft. above the top of the rail, and, after considerable study, it was decided to use a cast-iron, ribbed plate, supported on a steel framework attached to the main bridge structure. In a number of cases where there were vacant lots adjoining the streets, these shields were run back on the retaining walls for a distance of 50 ft. or more, depending on the location. In all cases the shields were made part of the bridge contracts, and the costs were included in the lump-sum prices for the bridges.

Viaduct.

Under the terms of the ordinance, Ninth Street was vacated from Brown Street to Fairmount Avenue, and was opened to its full width of 70 ft. from Girard Avenue to Jefferson Street. Prior to the passage of the ordinance, the Philadelphia, Germantown, and Norristown Railroad owned a strip occupied by two tracks between Fairmount Avenue and Girard Avenue, and a right of way, 66 ft. wide, north of Girard Avenue. By the terms of the ordinance, all rights on the street surface owned by this Company were given over to the City, and the Railroad Company retained only the right to enter on the street at all times for renewals or repairs. The ordinance provided for a four-track steel viaduct through this territory, with a paved street

BRIDGE SHIELDS

FIG. 8.

beneath. The Railway Company paid the entire cost of the additional structure for the two extra tracks where it originally had but two.

The structure as built is a four-track steel viaduct supported on three lines of columns, just inside each curb line and in the center of the street. The columns support transverse girders joined over the center column, which in turn carry eight lines of longitudinal

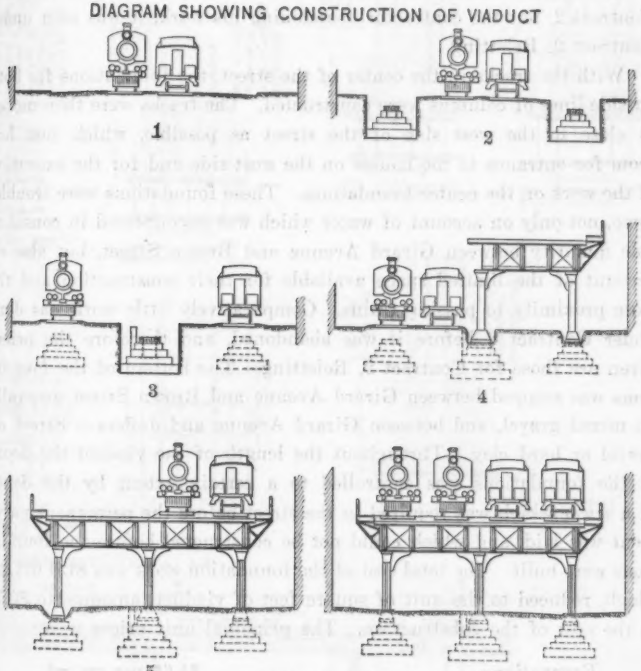


FIG. 9.

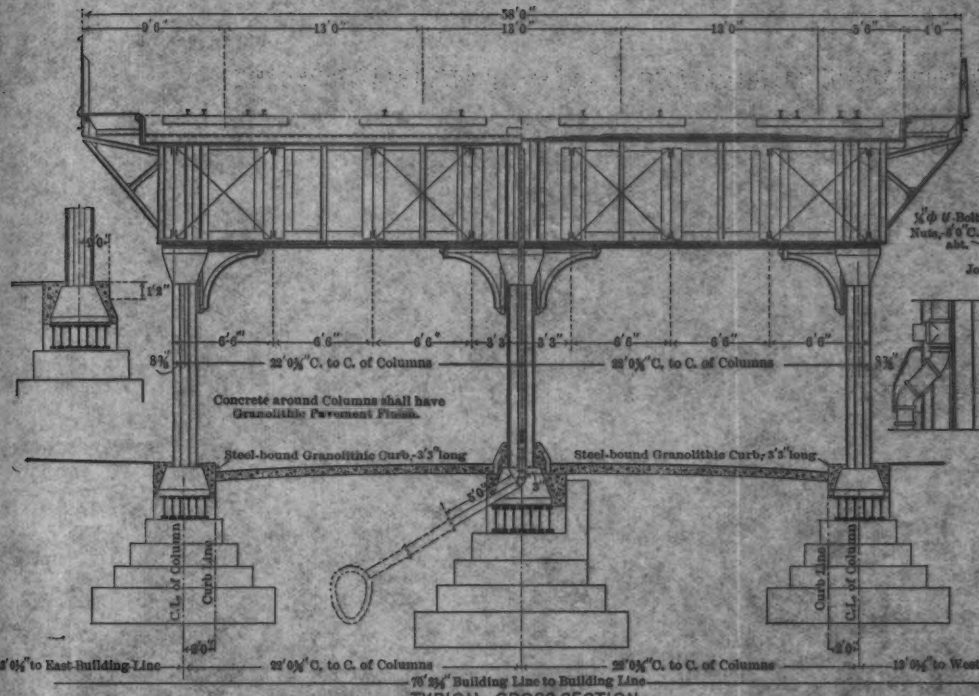
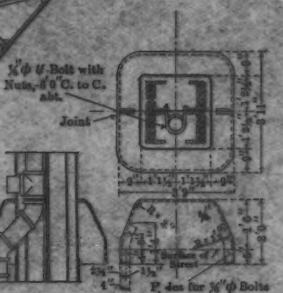
girders, spaced 6 ft. 6 in. on centers, and framing into the transverse girders. On the longitudinal girders, and at right angles to them, is a solid floor of 6-in. steel Z-bars and plates, which is cut longitudinally, at about the center of the street, to allow the viaduct to be erected in halves. This floor has its troughs filled with concrete and is covered with 1.5 in. of asphalt mastic in turn supporting the ballast and stand-



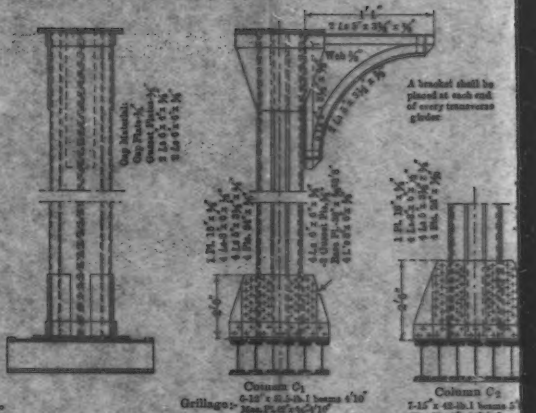
ard track. Sidewalks 4 ft. wide are carried on brackets on both sides outside of the dam plates. These have open floors with ½-in. open joints. The structure is designed to allow cross-overs to be placed in the tracks at any point, and the outside line of longitudinal girders is made of the same section as the others, so as to make it readily possible to provide in the future for siding connections.

The foundations for the columns of the viaduct were started under Contract 2, but the contractor abandoning his work, it was relet under Contract 2, Reletting.



With the tracks in the center of the street, the foundations for both outside lines of columns were constructed. The tracks were then moved as close to the west side of the street as possible, which just left room for entrance to the houses on the west side and for the execution of the work on the center foundations. These foundations were troublesome, not only on account of water which was encountered in considerable quantity between Girard Avenue and Brown Street, but also on account of the limited space available for their construction and the close proximity to passing trains. Comparatively little work was done under Contract 2 before it was abandoned, and therefore the prices given are those for Contract 2, Reletting. The bottom of the foundations was stopped between Girard Avenue and Brown Street generally on mixed gravel, and between Girard Avenue and Jefferson Street on gravel or hard clay. Throughout the length of the viaduct the depth of the foundations was controlled to a certain extent by the depth of a sewer which was required in the street before the permanent pavement was laid, and which could not be constructed before the foundations were built. The total cost of the foundation work was $151 631.20, which, reduced to the unit of square feet of viaduct, amounts to $0.76 as the cost of the substructure. The principal unit prices were:

Excavation	$1.65 per cu. yd.
1:3:6 concrete	5.50 " " "



After the completion of the foundations, the eastern half of the viaduct was erected, starting from Brown Street and working north. On account of the very close proximity to passing travel, the erection was a matter requiring the most careful consideration, and the manner adopted was one for which the contractors should receive much credit. On account of the condition of the work at the ends of the

STEEL VIADUCT

TYPICAL CROSS-SECTION

COLUMNS AND FLOOR.

(SUPERSTRUCTURE)

viaduct, a considerable time elapsed between the erection of the first half and the completion of the whole structure. All steel for both sections was brought to the work on the street level, and the rate of progress, which under average conditions was 3 spans per day, was very good. Better time in erection would have been made but for the expansion-joint detail requiring riveting at the transverse girders before other spans could be raised.

In the layout of the viaduct, a standard span of 50 ft. was adopted, and this was used wherever possible, the odd span being placed adjacent to street intersections, which were always special.

On account of the light grades on the viaduct, and the expansion joints at intervals of about 150 ft., it was difficult to arrange for drainage. Low places were provided with cast-iron inlet boxes, to which 6-in. wrought-iron pipes were attached, following down the column and connecting directly with the sewer.

The method of erection of the viaduct planned by the McClintic-Marshall Construction Company was based on:

First. The determination of a method that would come as nearly as possible to being absolutely safe for the passage of trains; and

Second. Economy of time and money.

The method proposed, approved, and adopted was the use of a steel cantilever traveler running on top of the erected viaduct, the erection being accomplished with the aid of two 15-ton traveling electric cranes with one intermediate bridge carrying four 12-ton hoists. The traveler had been remodeled from a steel cantilever traveler previously used for viaduct erection, a few of the truss members having to be reinforced, and an entirely new system of top construction made. The total weight of structural steel in the traveler was 150 tons. The power used was alternating current furnished by the Philadelphia Electric Company, which established connections where convenient, approximately 800 ft. apart. Four heavily insulated flexible wire cables were connected at these stations, and these cables were carried on a reel suspended from the rear of the traveler, the reel being paid out as the traveler advanced, and rewound when new connection was established. The traveler was erected and taken down with a heavy locomotive crane, which also erected enough of the viaduct to provide a platform on which to build the traveler and on which to start work.

This locomotive crane also erected the portion of the viaduct, wider than four tracks, between Brown and Parrish Streets. A 50-ft. boom placed on the front end of the traveler erected the extra width of steel between Master and Jefferson Streets. On the second half, it was necessary to run the traveler on a slight curve between Master and Jefferson Streets, and there was no difficulty in accomplishing this. The traveler had a 70-ft. anchor arm and a 120-ft. cantilever arm. When moving ahead, the cranes were at the extreme rear end of the traveler, thus helping to furnish counterweight against overturning. The traveler was moved with the aid of a heavy hoisting engine placed on a platform on the rear of the traveler, and a single set of double wire-cable falls moved it with ease. The reaction on the wheels at the main point of support, when moving, was very heavy, being 272 000 lb. on the heavier side. After the traveler was moved ahead, and before the crane could move to pick up any load, the columns or front post extension in front of the traveler had to find a bearing on blocking previously placed on the street at the point to which it was being moved. The actual moving, including knocking out the blocking, the moving itself, and the reblocking, did not take more than 15 or 20 min., that is, 15 or 20 min. after picking up iron in one position the traveler could be moved ahead and be ready to pick up iron for a new span; in general, two spans, or about 100 ft., being erected for each move.

The structural steel was shipped from the contractor's Pottstown plant, being loaded on cars in the exact order in which it was wanted, so that, when delivered to the traveler, the first car received contained the longitudinal girders, the next car contained the transverse girders, columns, and cross-frames for the girders, and the third car contained the trough floor, railing, etc., all for the span being erected. These cars were delivered on an abandoned track directly under the work to be erected—the track being approximately midway between the two lines of columns on which the work was being placed. As the material was unloaded the empty cars were dropped down under the viaduct already erected, the overhead clearance permitting this, though in many cases it would not permit a loaded car to pass beneath the viaduct.

The method of erecting in detail was as follows: The rear electric crane would pick up a longitudinal girder and hang it on one of the chain hoists carried on the trolley on the intermediate bridge. The

rear end of the girder would be connected immediately to the transverse girder of the previous bent before the electric crane cut loose—thus the rear electric crane would set the four longitudinal girders. Meantime, the forward electric crane would erect the two columns and pick up the transverse girder preparatory to connecting it to the longitudinal girders being erected. The transverse girder would be brought in against the ends of the longitudinal girders and set on top of columns, there being in general about 2 in. play between the tops of the longitudinal girders and the top flange of the transverse girder, thus not requiring the longitudinal to be hung at the precise height. The four chain hoists supporting the forward ends of the longitudinal girders would then be slacked off, one man to each chain hoist, so that the girders would be seated on the longitudinal girders and the fitting-up bolts entered. The forward crane would then pick up the cross-frames and place them on the longitudinal girders just erected, when both cranes would place the frames in position. The forward crane would then pick up the trough floor, while the rear crane attended to moving ahead any timbers required for the track, these having been snaked ahead with line from the hoisting engine. When handling the 61-ft. girders across Girard Avenue, one crane was used on each end of the girder, this being also necessary on a few of the other special girders. The use of the intermediate bridge, carrying the four chain hoists, obviated the use of temporary bents on which to set the longitudinal girders, and, in addition, was much better, as it readily gave movement in all three directions, as desired, as the bridge was carried on the trucks on the crane runway beams, and each hoist was hung from a trolley running on the bottom flange of an I, and the chain hoists themselves permitted the small vertical movement required for adjustment with little labor.

In general, three spans were raised per day, requiring gangs working ordinarily 6 hours. Where there were four spans, without encountering expansion joints, these were raised in less than 7 hours. In one day it was impossible to raise more steel than between two expansion joints, as the longitudinal girders had to be riveted, as explained previously.

The general figures of interest in connection with the viaduct were as follows:

The contract price was $772 000, including everything from the top

of the concrete footings to the ballast. This included all drainage, water-proofing, and steel grillages for the top of the footings.

Total weight of steel	30 010 000 lb.
Floor area of viaduct	197 300 sq. ft.
Weight of steel per square foot	152 lb.
Cost of water-proofing per square foot	$0.24
Total cost of work per square foot	$3.91

CONCRETE ARCHES.

There were only two points on the line where arches over the streets were possible, namely, at Berks and Norris Streets, the streets being 50 ft. wide and the bridges carrying five tracks at Berks and six tracks at Norris Street. These arches were of concrete, and, like all the other bridges, were constructed in two sections longitudinally, and were water-proofed. The general dimensions were as follows:

Berks Street:	Span	50 ft.
	Rise	10 ft. 9⅝ in.
	Thickness at crown	3 ft.
	Width	65 ft. 8 in.
Norris Street:	Span	50 ft.
	Rise	11 ft. 1⅛ in.
	Thickness at crown	3 ft.
	Width	82 ft. 7 in.

At Berks Street, five layers of Genasco Positive Seal Felt in Genasco Compound were used for water-proofing, protected with a layer of 1:3 cement mortar 1 in. thick. At Norris Street, there was used 1.5 in. of asphalt mastic, made by mixing 1 part of Barber Asphalt Company's Compound No. 483 with 4 parts of sand and screenings. This was laid in two ¾-in. layers, each, breaking joints. The compound had the following properties: Bitumen soluble in CS_2, 97%; not more than 0.5% volatile at a temperature of 350° Fahr. for 5 hours; does not flow at 212° Fahr. nor become brittle at — 15° Fahr.; not acted on by H_2SO_4 in 7 hours (25% solution). The water-proofing of both these bridges has been very satisfactory. It cost as follows:

Berks Street	23 cents per sq. ft.
Norris Street	30 " " " "

The prices for the concrete in the arches were as follows:

1:2:4 concrete in arch ring, including centers	$7.50	per cu. yd.
1:3:6 concrete in copings	6.75	" " "
1:3:6 concrete in abutments—street finish	6.70	" " "
1:3:6 concrete in foundations	6.00	" " "

Water-Proofing Bridges and Viaduct.

All the bridges and the viaduct cross City streets or are over stations, as is the case at Columbia Avenue, and it was very desirable that they should be impervious to water, not only for the protection of the public, but also for the preservation of the metal. In a large number of cases, the elevation of the curbs of the streets beneath, and the profile of the tracks above, was fixed within such close limits as to make it difficult to provide proper water-proofing details. The writer believes that one of the most important features of water-proofing design is to get the water away from the structures as fast as possible, and, where the grades of the track are light, this is difficult without using up valuable head-room.

In the first bridges designed and erected, where trough floors were required, the whole of the upper surface of the metal was covered with 1.5 in. of asphalt mastic, applied in two layers to the vertical and horizontal surfaces of the steel floor. This was sloped in the troughs to carry the water to a nipple passing through the steel floor emptying into a wrought-iron trough beneath the floor, and then to down-spouts to the street gutters. If the structure was a deck bridge, the steelwork was first leveled up with Portland cement concrete, made of ¾-in. stone and mixed 1:3:6, on which was placed five layers of "Hydrex" or similar water-proofing felt, laid in asphalt compound and protected with a course of hard brick laid flat in the compound. After laying the brick, the compound was poured in the joints and mopped over their tops. The drainage from this type of water-proofing was taken over the back-walls and through the dry packing, already described, to the sewers in the streets. The nipple proved to be a somewhat troublesome detail, and it was difficult to get it tight, the water frequently finding its way around it. These bridges also developed some leaks along the main girders, due to the separation of the mastic from the girder webs; but the leaks were bad in only a few cases, and have been largely corrected by mopping hot pure asphalt on the

mastic along the girder webs, spreading burlap over it, and then applying another mopping of asphalt. The deck bridges with the felt and compound are much tighter.

The second lot of bridges designed and erected differed from the foregoing in that the troughs were filled with cement concrete to the top of the rivet heads, and a smooth coat of asphalt mastic, 1.5 in. thick, was put on in two layers and haunched up against the girder webs and under a flashing angle riveted to the webs. The same method was used on the viaduct. The drainage on the bridges is to one or both ends, and over the back-walls, depending on the grades. On the viaduct, it is to cast-iron inlet boxes and thence through wrought-iron down-spouts to the street level, and in vitrified clay pipes to the sewer. These bridges have generally been tight, except in a few cases where there has been a separation of the mastic from the flashing angles and webs, and these defects have been remedied by cutting out the cracks, filling them with hot pure asphalt, and finally covering them with burlap mopped with asphalt, as previously described. On a portion of the viaduct, the mastic cracked badly on the haunching, and required considerable repairing. This, it is believed, was due to the improper proportioning of the ingredients, as it occurred when the work was first started. In several other cases, leaks have occurred where it was necessary during construction to push the work irrespective of the weather conditions, and in other places where it was difficult to make a good joint between old and new work. It was found to be very difficult to clean properly the surfaces on which either the new compound or the new mastic was added, and it is thoroughly believed that without adequate cleaning and drying it is impossible to bond surfaces with any asphaltic water-proofing material. The necessity of using an asphalt material which has a very low brittle point and a sufficiently high melting point simply to prevent running in hot weather, has been apparent in this work, and is indicated especially for similar work where the structure is subject to vibration. Recent work has also shown the necessity of using a joint, between the asphalt mastic and the metalwork of the structure, consisting of a pocket of pure elastic asphalt.

The estimated costs of the water-proofing were obtained by a careful analysis of the lump-sum figures for the bridges, and show a

FIG. 13.

The specifications for this work may be briefly abstracted as follows:

"Wherever called for on the plans, the decks of the bridges shall be protected as follows:

"First.—By placing 1:3:6 concrete, ¾-in. stone or gravel, troweled on top, as shown on the plans. The cement concrete thus placed shall be allowed to dry thoroughly so as to prevent the formation of steam when the asphalt mastic is applied. All vertical surfaces of concrete or steel shall be prepared by first painting with the asphalt hereafter described, melted and diluted with 62° Baumé naphtha to the proper consistency. The paint shall not be applied to horizontal surfaces except where specially directed.

"Second.—The cement concrete thus prepared shall be water-proofed with asphalt mastic equal in quality, for the intended pur-

pose, as to ingredients used and resistence to water, to the following specifications, and be approved as such:

"Neufchatel, Seyssel, or Sicilian rock mastic... 60 parts.
"Clean sharp grit and sand to pass a sieve of
8 meshes per inch..... 30 "
"Refined Bermudez or Trinidad asphalt..... 10 "

"These proportions shall be varied where required by special conditions on the work.

"The mixture shall be made at the site of the work, and heated to a temperature of from 250 to 300° Fahr., and stirred until all the ingredients are thoroughly incorporated. It shall then be spread and thoroughly worked, to free it from voids, and ironed to a smooth surface with hot smoothing irons, if so directed. All mastic shall be applied to the work in two coats, making the total thickness shown on the plans. The coats shall break joints, and the mastic shall be distributed evenly. Where the thickness of the water-proofing materials is less than 2.25 in., the full thickness shall be made up of asphalt mastic.

"Great care shall be taken around expansion joints, drain pipes, and other similar places, and the methods to be followed shall be as specified on the plans or as directed by the Chief Engineer.

"The cost of the water-proofing specified herein shall be included in the lump-sum prices for the bridges."

The asphalt mastic used on this work was prepared from Sicilian Natural Rock Mastic, which averaged from 13 to 16% of bitumen soluble in carbon bisulphide.

Passenger Stations.

Four passenger stations required rebuilding on account of the elevation of the tracks, namely, Girard Avenue Central, Columbia Avenue, Tioga, and Nicetown. As all have been built considerably larger than the old stations, the greater part of the cost has been borne by the Railway Company, the City simply paying one-half of what it would have cost to raise to the new track level structures with the accommodations of those existing at the time the work was started.

Girard Avenue Central.—The four-track viaduct, with its straight alignment at this point, made it possible to provide platforms only on the two outside or local tracks, the station buildings on each side being erected on a steel structure over the bed of Girard Avenue supported by columns on the curb lines. The lengths of the platforms at this point are controlled by existing industrial sidings, and, un-

fortunately, are not as long as desired. This station had very deep foundations for the columns, they being in the bed of an old creek, and cost $54 602.40, the entire cost being assumed by the Railway Company, as the old building was very small.

Columbia Avenue.—This station is an important one, as all trains on the main line and to New York stop there. The tracks cross the street at about the elevation of the old street, making a very severe change of grade. A number of studies were made for the new station, involving very different schemes, all of which, however, included the spreading of the tracks so as to place island platforms between the north- and south-bound tracks, and in so doing entailed the purchase of additional right of way. It was finally decided to purchase a lot at the southwest corner of Ninth and Columbia Avenues, and place on it the main waiting- and baggage-rooms, locating the other necessary facilities beneath the tracks, which are carried on a steel structure for this purpose.

The main building has a frontage of 170 ft. on the south side of Columbia Avenue, 150 ft. on the west side of Ninth Street, and 150 ft. on the east side of Hutchinson Street. The exterior walls are of gray brick with granite base, and Indiana limestone and terra cotta trimmings. The passageway to the trains and the stairways to the elevated platforms are lined with white enameled brick. The interior is designed with complete accommodations for handling heavy traffic. The main waiting-room is 52 ft. by 79 ft., and is 35 ft. high, with polished Italian marble wainscot 9 ft. high. The floors are of marble terraza with marble panels. A ticket office, smoking-room, men's toilet, barber shop, women's waiting-room, telegraph and telephone service, news stands, baggage- and express-rooms, are also provided.

The two platforms on the high level are 800 ft. long. They are of concrete with concrete curbs on the earth-filled portion and with concrete curbs with asphalt mastic over the steel portion. They are covered with heavy sheds of the umbrella type. The entrance stairways to the platforms are from a passageway at right angles to and beneath the track, and between the main waiting-room and the baggage-room. This passageway can be reached from the main waiting-room or from either Ninth or Hutchinson Streets directly. There are exit stairways from each platform, with turnstiles. These lead to Columbia Avenue and also to Oxford Street.

WAGNER ON
TRACK ELEVATION, PHILADELPHIA, PA.

COLUMBIA AVENUE STATION

HUTCHINSON STREET ELEVATION

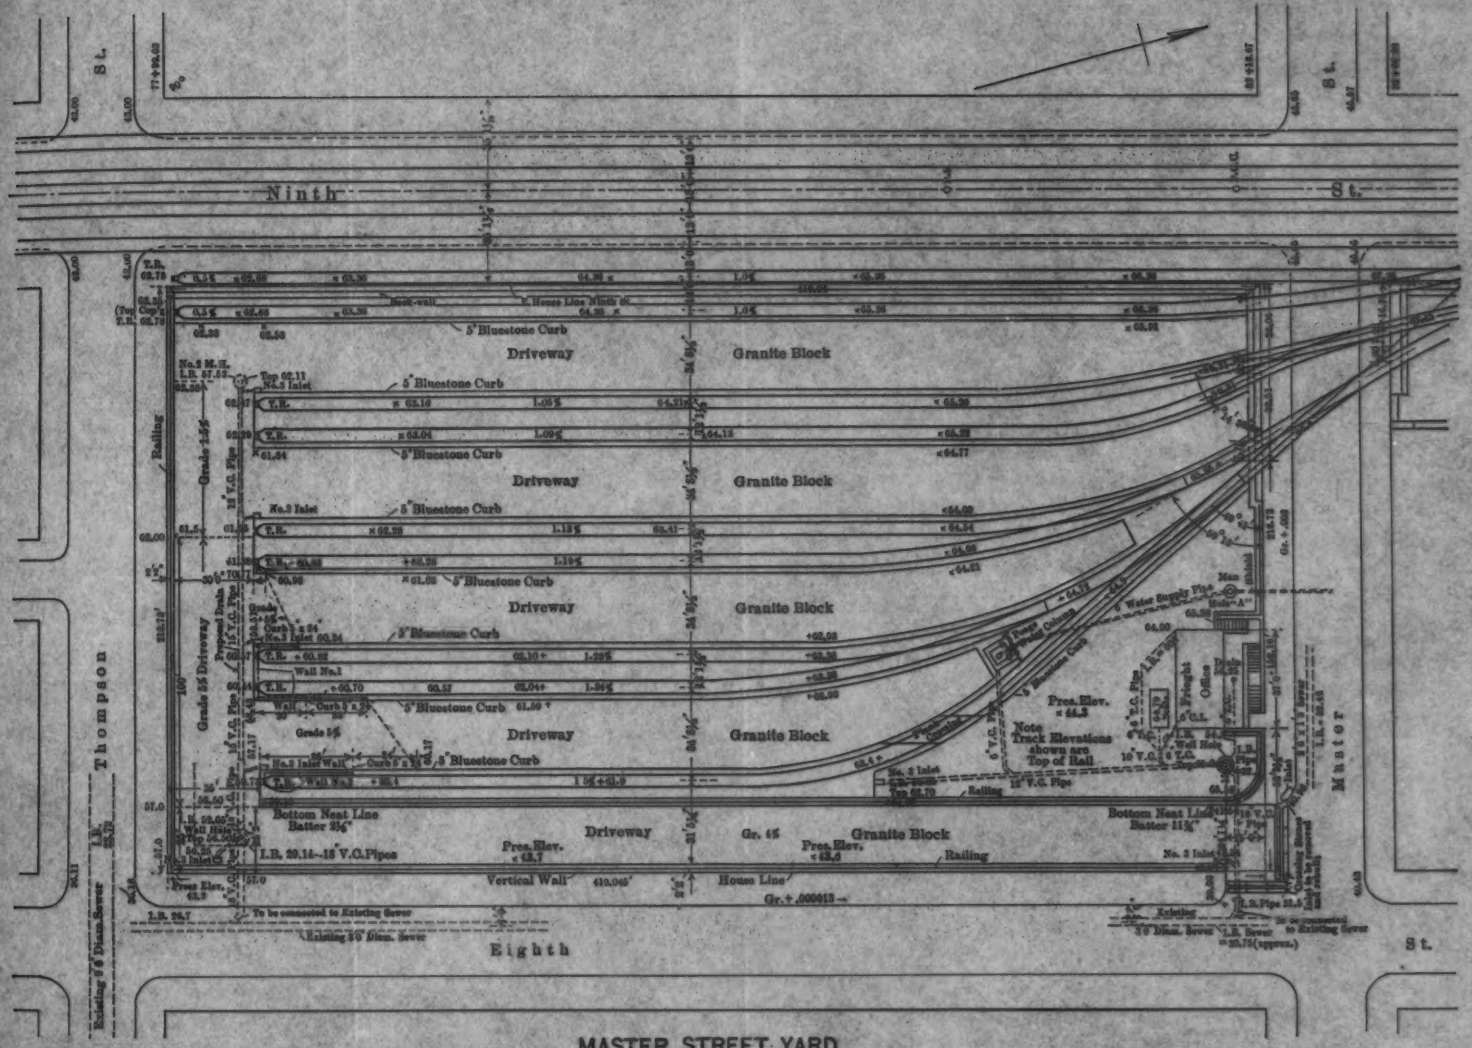
There are two baggage elevators on each platform, and they are located so as to be accessible from the passageway previously referred to. They are of the hydraulic-plunger type, the pumps being operated by a 20-h.p. electric motor. The cars are 5 ft. 10 in. by 15 ft. 9 in., and the vertical lift is about 17 ft. 6 in. Each elevator has a capacity of 4 000 lb. in addition to its own weight, and travels at the rate of 100 ft. per min., with an average load of 2 500 lb. and with a maintained water pressure of 160 lb.

On the abandonment of the old station, a temporary building was erected on the street level at Oxford Street. This was used while travel was on the low level, and also when it was on the high level on the east side. Access to it at this stage was maintained by a stairway from Oxford Street and a temporary baggage lift between Oxford Street and Columbia Avenue. On the completion of the main waiting- and baggage-rooms, the temporary buildings were removed, and all travel was handled from the east platform until all four tracks were placed in service. The cost of the station building, platforms, shelters, etc., was $217 134.15.

Engine "Rocket".—Facing on the passageway to the trains, in the Columbia Avenue Station, there is an inclosed room, electrically lighted, in which the Engine "Rocket" rests on the original stone ties, cast-iron chairs, and wrought-iron rails which were recovered from the excavations made along the line of the elevated work, and which constituted the original roadbed of the Philadelphia, Germantown, and Norristown Railroad. A large number of the ties were found, a few of the chairs, and only a small quantity of the rails.

The "Rocket" was one of a number ordered by the Philadelphia and Reading Railroad in 1836 from Braithwaite and Millner, of London, England, and was built in 1838. It was delivered at the Port of Philadelphia, and conveyed by canal to the foot of Penn Street, Reading. From this point, it was hauled on its own wheels, through the streets, by horses, and placed on the tracks of the Philadelphia and Reading Railroad at Seventh and Penn Streets, Reading. The railroad was completed at that time between Reading and Norristown. It was placed in passenger service in May, 1838, and was retired in March, 1879, having run 310 164 miles. It was placed on exhibition at the World's Fair at Chicago in 1893, and also at the St. Louis Exposition in 1904. It weighs 8.4 tons.

Tioga and Nicetown.—These two stations may be referred to together, as they are in many respects similar. They are in a semi-suburban section of the City, and are used only for local passenger business. They are one-story buildings above the track level, with an additional story on the street level. The larger station at each point is on the south-bound side, in which is also the ticket office. They are built of brick with terra cotta trimmings, and are neatly finished throughout. The platforms can be reached by several flights of steps or by paths through the station grounds. Electric lifts are provided on both sides of the tracks for baggage and express service, and tunnels connect the north- and south-bound stations beneath the tracks. The elevators have a lifting capacity of 2 000 lb. at a speed of 50 ft. per min. The dimensions of the cars are 5 ft. by 10 ft.



The new station at Tioga, including the grading of the grounds, the cement platforms, and the driveways, cost $62 886.64. That at Nicetown, with similar appurtenances, cost $43 554.57.

While the two tracks on the west side were being elevated, the station buildings on this side were being erected, and when travel was placed on that side, a temporary platform was erected to care for the north-bound business, while the two tracks on the east side and the north-bound station were being completed.

Freight and Car Cleaning Yards.

The Railway Company operated freight yards at Eighth and Master, Tenth and Berks, and Broad and Lehigh Streets, before the elevated work was started, as well as car cleaning yards at Twelfth and York and Thirteenth and Lehigh Streets. The finished general plans provided for the retention of the first two freight yards and the rearrangement of the other so as to consolidate the car cleaning yards at Broad and Lehigh Streets. The yards between York and Cumberland Streets were designed for freight purposes. All were designed as elevated yards except that for the car cleaning, in which there was but slight change in grade. A number of studies were made to determine the best and most economical method of arranging the grades of the tracks in these yards, as well as the grades of the driveway approaches; and the final plans, it is believed, embody the most economical arrangement that could be made. The yards in all cases were thrown entirely out of service during construction. Concrete walls were built on the

PLATE LXXIII.

WAGNER ON
TRACK ELEVATION, PHILADELPHIA, PA.

MASTER STREET YARD
GENERAL PLAN

street lines, the embankments placed to the new level, and all driveways provided with 5-in. bluestone curbs, and paved with granite blocks on a sand base. As a general rule, all ramp driveways leading to the streets had 4% grades, and the maximum grade on the tracks was 3 per cent. All track work was done by Company forces on emergency orders. The contracts for the freight yards were as follows, and show all the cost except the track work:

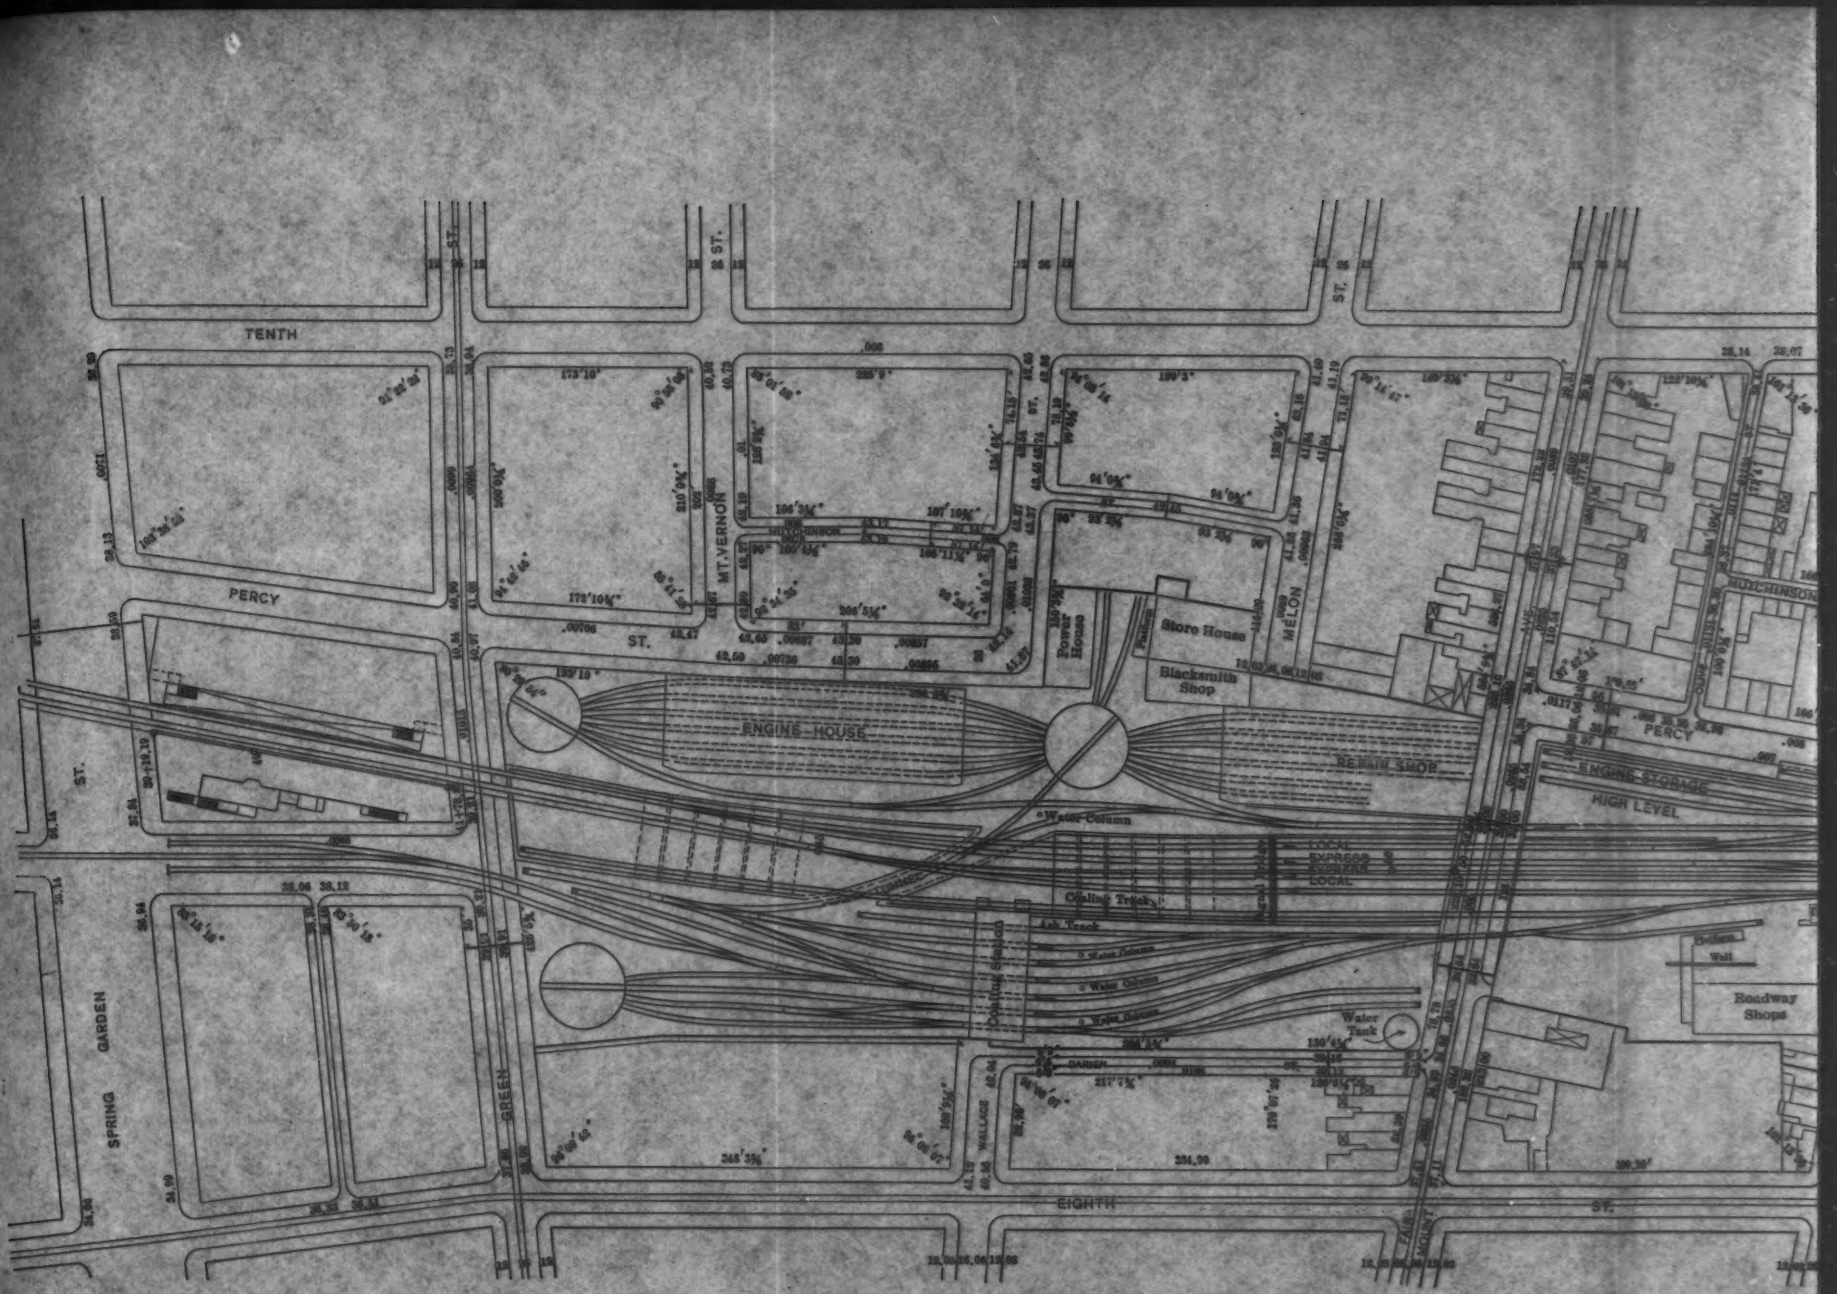
Location.	Total cost.	Car capacity
Master Street	$97 868.30	66
Berks Street	70 350.03	55
York Street Yards	67 059.23	104

Car Cleaning Yard.—This yard has a capacity of 230 passenger cars, and is provided with a service building, a small car repair and paint shop, a power-house building for furnishing steam, air, and lighting, and the yard is equipped with complete piping for the delivery of steam, air, and water to any point. All pipes are placed in creosoted wooden conduits, readily accessible for necessary repairs. The mechanical equipment of the power-house was furnished by the Motive Power Department, and its cost is not included. The entire cost, exclusive of the track work and the mechanical equipment, was $53 326.82.

Green Street Engine Yard.

Practically all the engines operating in the Reading Terminal are cared for in the Green Street Yard. The four main tracks and a track for the delivery of coal to the coaling station run through this yard on an elevated structure of concrete walls and fill. Engines coming from the Terminal run north to about Brown Street and back down a 3% grade on the east side of the yard to the original level beneath the coaling station, where they receive coal, water, and sand, and dump ashes. They then run south, turning if necessary on a 75-ft. turn-table operated by an electric motor, and pass through a tunnel beneath the main tracks to the west side of the yard where they can proceed to the engine-houses for repairs and cleaning, or up a second 3% grade to the high-level storage yard from which they run out on the main tracks and back to the Terminal. Thus all crossing of the main tracks is avoided. There are two turn-tables on the west side of the yard. This arrangement makes four bridges over Fairmount Avenue at different levels. Beginning on the west side, one track for engines leaving

the yard; four main tracks; one coaling track for the coaling station; and one track for engines entering the yard. This arrangement made it unnecessary to raise the whole of the yard, with the engine-houses and turn-table on the west side, to the new elevation, and thus effected a material saving in the cost of the work.



Coal-Pocket Yards.

The Railway Company owns and leases several large coal yards, one on the east side of the tracks between Berks and Norris Streets, and one on the west side at Tenth and Norris Streets. Only the first will be described, the other being similar but smaller.

Originally, the tracks in the yards were about 15 ft. above the street level. Due to the elevation of the main tracks, the difference in level was increased to about 41 ft., and it was decided to construct pocket yards, on account of the great height. There are two double-track pockets, parallel to the main tracks, each with a capacity of 10 000 tons in the pockets. Each is about 46 ft. wide and 500 ft. long. The two pockets are separated by a driveway about 37 ft. wide. The bottoms of the pockets are about 10 ft. above the paved surface of the yards, thus allowing delivery teams to be driven under them and loaded through chutes.

The type of construction was determined only after very careful study. Designs were made for all steel, reinforced concrete, and all wood, and the costs were carefully estimated; a number of different combinations were also tried. It was found, finally, that the composite design finally constructed was cheaper, both in first and capitalized cost, than either all steel or reinforced concrete, and as cheap in first cost as all wood. It consists essentially of a covered double-track steel plate-girder viaduct, wooden longitudinal pocket walls, and wooden pocket floors, supported on vertical concrete transverse partition walls of full height, without reinforcement. Each complete pocket is divided into 20 panels by the concrete walls, which are placed at 25-ft. centers. These walls are 46 ft. long, about 3.5 ft. thick at the base, where they rest on footings of reinforced concrete 4 ft. deep, 10 ft. wide, and about 49 ft. long.

Coal is delivered to the pockets by standard-gauge cars on each side of the longitudinal partition, each track being supported by two lines of 30-in. steel plate girders, at 5-ft. centers. The tracks are enclosed by a monitor of frame and corrugated iron with a slag roof.

PLATE LXXIV.
TRANS. AM. SOC. CIV. ENGRS.
VOL. LXXVI, No. 1275.
WAGNER ON
TRACK ELEVATION, PHILADELPHIA, PA.

GREEN STREET YARD
GENERAL ARRANGEMENT

There are about 5 000 cu. yd. of concrete, and 1 244 000 ft. b. m. of lumber in each line of pockets.

The cost of the yard covering the pockets, stables for 114 horses, paving, drainage, etc., was $273 578.29.

The yard at Tenth and Norris Streets, which is of similar construction, but with a total capacity of 1 170 tons, and stable room for 30 horses, cost $42 884.33.

Locomotive Coaling Station.

The original locomotive coaling station and ash-handling plant in the Green Street Yard consisted of a mechanical plant with a wrought-iron frame building supporting a steel-frame coal pocket with a storage capacity of about 400 tons, the coal being dumped into hoppers beneath the tracks and raised into the pocket by Hunt conveyors. It was constructed about 1894. The ashes were raised by a similar arrangement and loaded from small pockets into cars placed beneath. The metal in the framework was almost entirely destroyed by the lomocotive fumes, and the pocket was temporarily shored up when the work of elevating the tracks required its removal to the east side of the yard.

During the construction of the elevated work on the east side, requiring the entire abandonment of that portion of the engine yard, a temporary yard was built at Wayne Junction and kept in service until the new one was constructed.

Bids and detailed general plans were asked for the new station, based on a general plan of the pocket located at right angles to the main tracks and provided with ashes- and sand-handling facilities in addition to the handling of coal. The specifications called for the following essentials in the design to be submitted:

Building.—Foundations of concrete, and all pits below the surface of the ground to be connected with adjacent sewers, or a sump and pumps provided for caring for the drainage. From the level of the tracks up to and including the floor of the pockets, the construction to be of steel protected throughout with concrete; from the floor up, to be of steel protected with concrete, or reinforced concrete containing no exposed metal. The building to cover seven tracks, one for receiving ashes from a pocket above, and six for delivering coal to, or receiving ashes from, engines. Coal to be delivered from a special elevated track to the east of the main tracks, and, at the same level,

to be dumped into hoppers and raised into the pocket. The pockets to be twelve in number, two over each coaling track. The combined storage to be 2 000 tons. Each pocket to be provided with approved chutes, and with steam pipes and valves to thaw the coal when frozen. Ash pits to be arranged so as to enable engines to coal and dump ashes at the same time, and be supplied with water for quenching the ashes. Provision to be made for pockets for storing 250 cu. yd. of ashes. Hoppers with a storage of 8 cu. yd. of dry sand delivered from the high-level coaling track, and the necessary piping to transport the sand by air pressure to the delivery pockets, each of 4 cu. yd. capacity, one over each coaling track.

Machinery.—Duplicate machinery to be provided throughout, and designed for economy in operation and maintenance; also, to be as noiseless as possible. Each coal-handling unit to have a guaranteed capacity of 100 tons per hour. Machinery for handling ashes to have a capacity of 250 cu. yd. in 10 hours from the six coaling tracks.

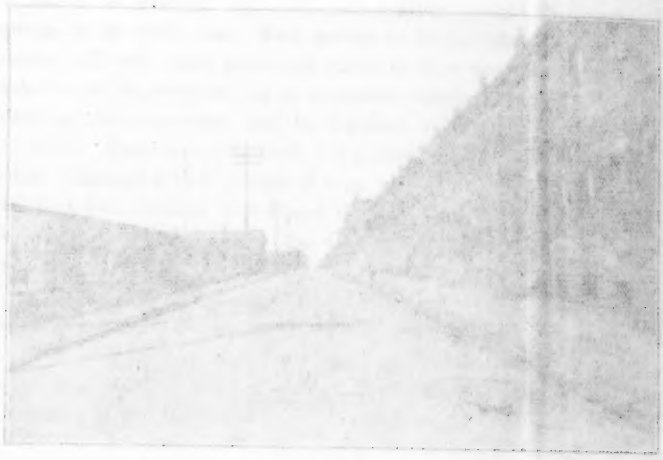
Power.—All power to be electricity, which will be brought to the building by the Railway Company from a power-house on the west side of the yard.

A number of bids were received, based on different methods of handling both coal and ashes, and the contract was finally awarded to the Link Belt Company. The total cost of the work was $96 670.13. The principal items entering into this cost were as follows:

Building, drainage, etc.	$48 090
Coal-handling machinery	22 200
Ashes-handling machinery	8 590
Sand-handling machinery	2 270

The proposals required the bidders to name the following estimated figures, which in the accepted bid were as follows:

Cost of handling coal from cars to locomotive, based on 700 tons in 10 hours	$0.0225	per ton.
Repairs and maintenance on coal-handling machinery	0.007	" "
Cost of handling ashes from pits to cars, based on 250 cu. yd. per 10 hours	0.059	" cu. yd.
Repairs and maintenance, ashes-handling machinery	0.012	" " "



The general arrangement of the plant is shown on Plate LXXV.

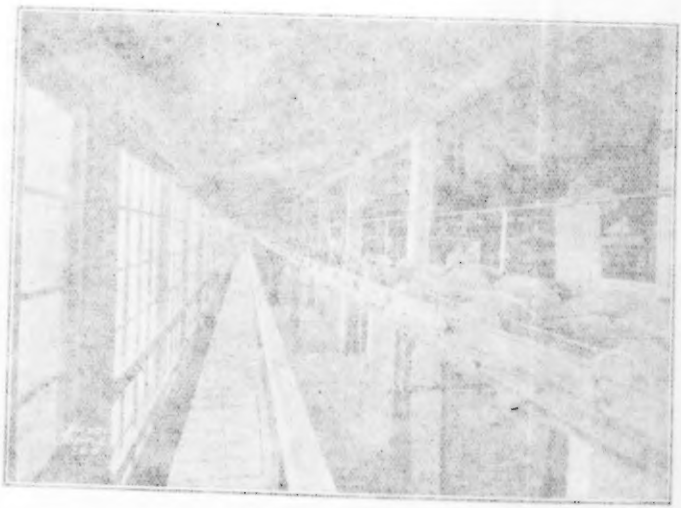

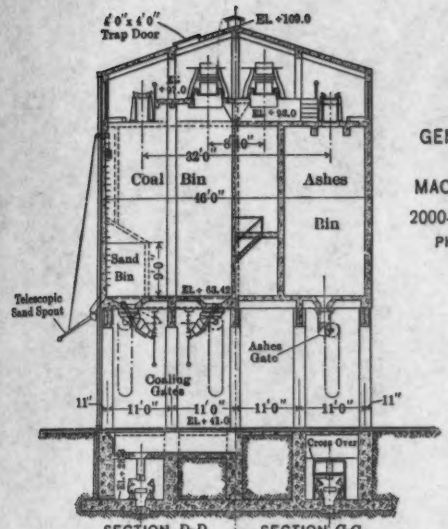

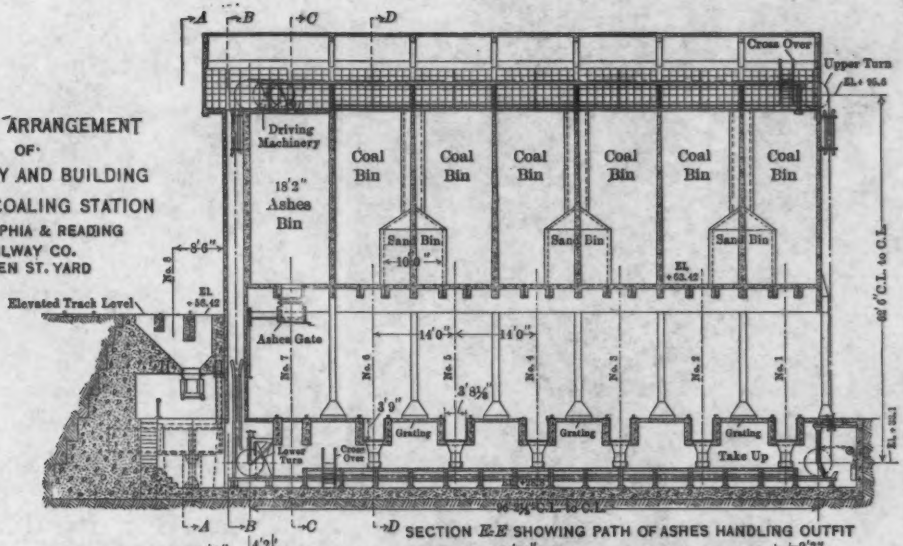

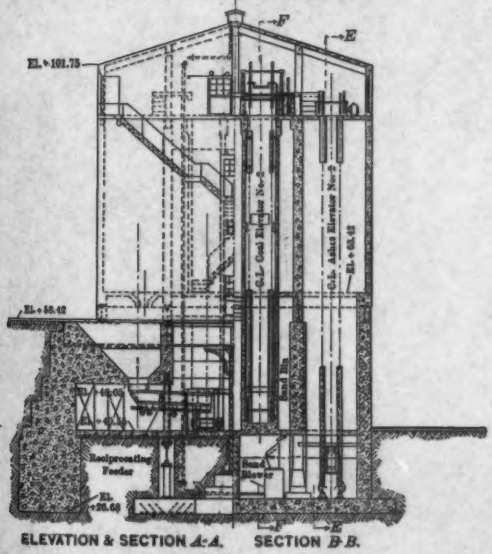

PLATE LXXV.
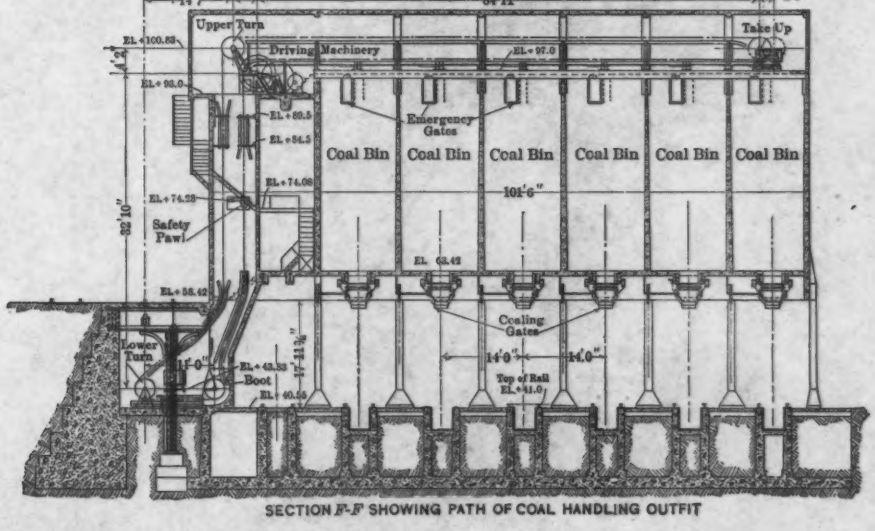
TRANS. AM. SOC. CIV. ENGRS.
VOL. LXXVI, No. 1275.
WAGNER ON
TRACK ELEVATION, PHILADELPHIA, PA.



GENERAL ARRANGEMENT OF MACHINERY AND BUILDING 2000-TON COALING STATION

PHILADELPHIA & READING RAILWAY CO. GREEN ST. YARD

The coal-handling machinery consisted of reciprocating feeders to two Link Belt, gravity-discharge, combined elevators and conveyors. On the horizontal runs the roller chains travel on steel tracks placed on the conveying runs so as to suspend the buckets above the cast-iron trough along which the coal is conveyed. Each machine has a chain speed of 75 ft. per min., and is actuated by a 25-h.p. General Electric motor, the motive power being located in the machinery room.

The fire-boxes of engines are cleaned into concrete brick-lined pits, and scraped through funnel-shaped cast-iron hoppers, with duplex gates and operating valves, to duplex-pivoted overlapping bucket carriers following rectangular paths and discharging into the storage pockets. These buckets are overlapping and of malleable iron, pivotally secured to two strands of heavy malleable-iron roller chain.

Dry sand is delivered from the receiving hopper, through pipes with reinforced bends, under an air pressure of 70 lb. Special chutes lead from the delivery hoppers to the engines, supplying sand by gravity.

The entire foundation of the pockets is of reinforced concrete, and this material is used for the construction above the floor of the pockets, and is properly designed according to the requirements of the Bureau of Building Inspection, City of Philadelphia. The drainage is arranged so as to lead directly to the city sewers.

The high-level delivery track is constructed on a 1% grade, the station being located midway in its length, so that ten loaded coal cars can be placed at the upper end of the grade, dropped by gravity to the hoppers, there unloaded, and dropped out of the way, without reaching the main tracks.

Permanent Tracks.

The main running tracks, previous to starting work, were laid with rails of 90-lb. Am. Soc. C. E. Section, the side tracks and yards with lighter and varying sections. A complete survey and joint inventory was made of all the existing track materials, by representatives of the City and the Railway Company, before the work was started. This was for the purpose of eventually determining the respective shares of each in the cost of the permanent tracks, as the number of tracks on the completed work was in excess of the original number, and in many cases the new tracks were laid with heavier rails and fittings. The City only joined in the cost of replacing the original weight, all

excess being a betterment to the Railway Company and paid for entirely by them. All track details were furnished according to the standard plans and specifications of the Railway Company.

The most interesting details of these specifications are given herewith:

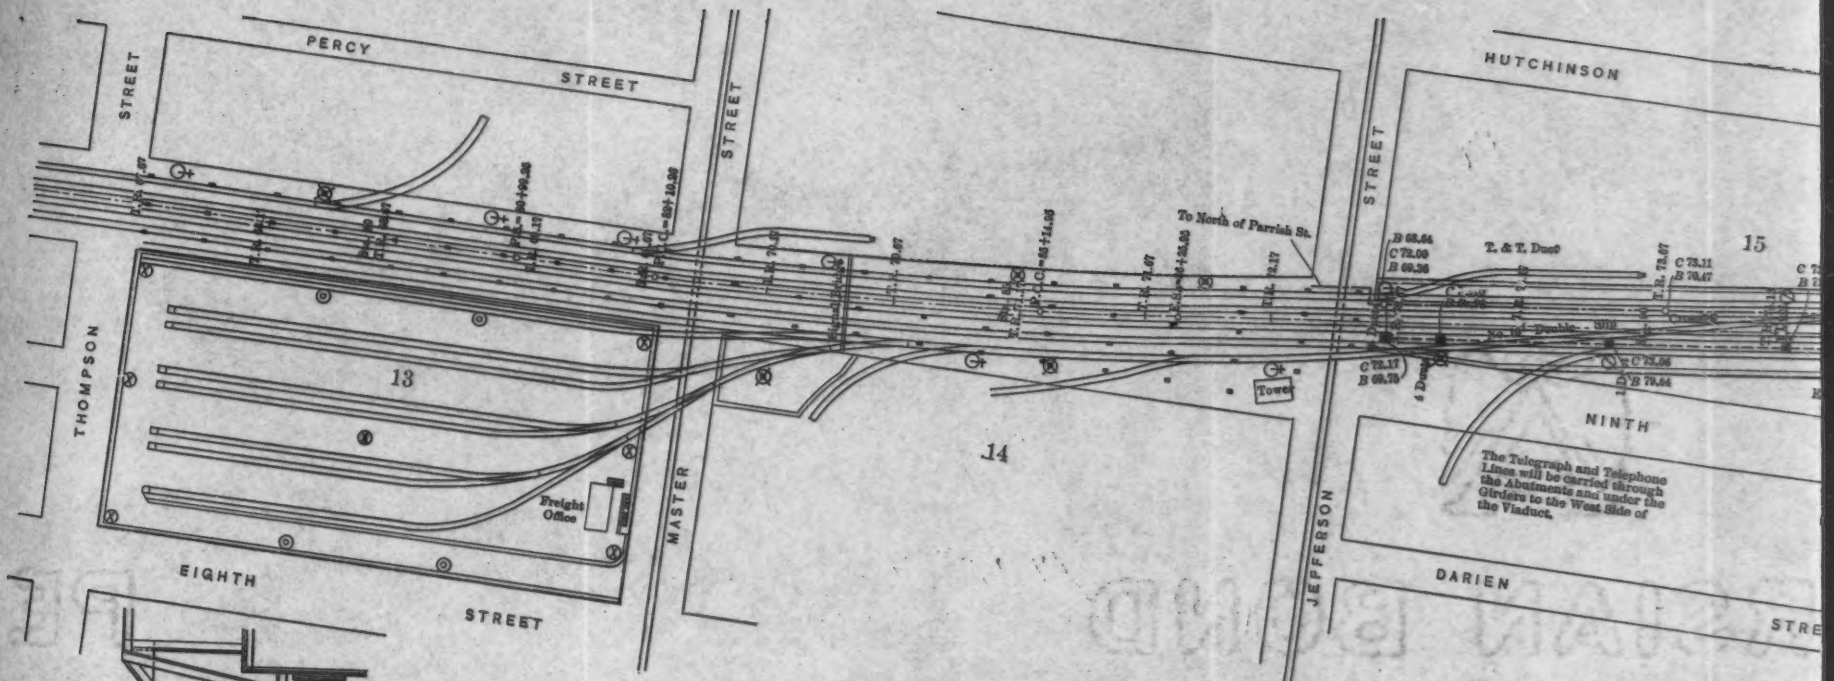
Rails.—90-lb. Am. Soc. C. E. Section. Shrinkage, 6.5 in. in 33 ft. Chemical composition:

Carbon	0.55 to 0.65%, averaging 0.58%
Phosphorus	not to exceed 0.075%
Silicon	not to exceed 0.20%
Manganese	0.90 to 1.15%, with average above 1.00%

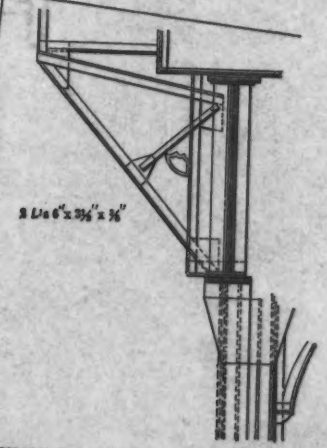
Drop test: 3 ft. between centers of supports; tup, 2 000 lb.; anvil block, 20 000 lb.; striking face of tup, not more than 5 in.; height of drop, 18 ft.

Ties.—First-class ties of white or rock oak. Dimensions, 8 ft. 6 in. long, 7 in. thick, and not less than 7 in. nor more than 14 in. on the narrowest face.

Ballast.—Good, hard, durable, broken trap rock, crushed so that it will not be larger than will pass through a 2.5-in. ring.

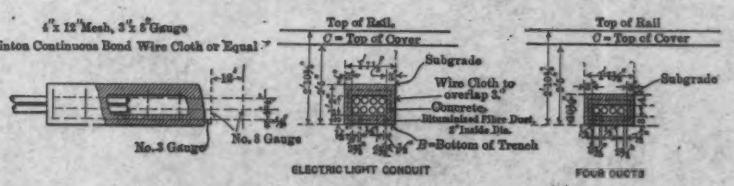


Specials.—100% joint-plates; Verona nut-locks; hard-steel, centered frogs; Wharton guard-rail clamps; Ramapo or Pennsylvania Steel Company switch stands; O'Brien insulated joints.

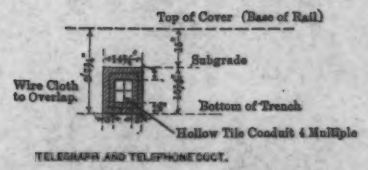


Temporary Signals.

During the changes in the tracks, temporary block signals were erected and maintained throughout the entire length of the line, using old material, as far as possible, and adapting it temporarily to the new conditions. Where lead-outs to the important yards were maintained, or where it was necessary to pass from a two-track to a four-track condition, temporary towers were erected and connected with the necessary switches and signals with manual interlocking. All this was done by Company forces, on emergency orders covering the temporary track work, thus keeping the operation of trains at all times under the control of the Operating Department, and avoiding all possibility of interference with the safe movement of trains.



Permanent Signals.



Before the work of elevation was started, the entire line was equipped with Hall automatic block signals, and two small manual

interlocking plants were located at Fairmount Avenue and Huntingdon Street, respectively, to control the shifting into the yards at these points. After the elevated track plans were completed, it was decided to operate all the switches between Broad and Green Streets affecting the four main tracks from electro-pneumatic interlocking plants, aggregating 98 working levers. These are as follows:

Cumberland Street	11	working levers.
Tenth Street	39	" "
Jefferson Street	21	" "
Brown Street	27	" "
	98	working levers.

The new signaling apparatus was put in by the Union Switch and Signal Company, and embodied the latest practice, such as the following:

1. The auxiliary control of all signals by all switches by means of the duplications of positions of both switches and signals with relays;
2. Approach and route locking;
3. Detector circuits;
4. Federal switch guards.

The high signals are semi-automatic, three-position, lower-quadrant type, with a short "all route" or "call-on" signal beneath, on the same mast. All these signal masts are carried on signal bridges.

The short-arm signal is a two-position signal—horizontal for "stop" and 45° below the horizontal for "caution—proceed." It is used to call trains on past the high signal or signals on the same mast, if, for any reason, the proper high signal cannot be displayed in the "proceed" position, and this "call-on" feature is accomplished by a push-button placed directly under the signal lever. In addition to its "call-on" functions, the short-arm signal governs all the remaining routes, other than the two most important ones controlled by the two high signals above it. The maximum number of high arms on any one mast is two, governing only one route each.

The Federal switch guards are 55 ft. in length, and are placed on every switch, movable-point frog, derail, etc., over the entire territory. The detector circuits are an average of 130 ft. in length.

The route-locking on the various plants is arranged with a releasing feature, whereby all switches in the rear of a train on the route are released as fast as the entire train clears the respective fouling limits of the several switches involved in the route. Thus a route cannot be changed ahead of a train, but may be changed behind one, provided the home signal has been put to the "stop" position. Hand time releases are installed for the release, when necessary, of signal levers affected by the approach locking feature.

Electric lights (incandescent) of ¼-c.p. are applied to all switch levers, this being supplementary to the detector circuit locking. Each light is encased in an iron box with a separate iron cover in which there is a frosted-glass disc. This iron box is directly under the levers, and is at all times in view of the signalman. These indicating lights are normally lighted up, illuminating the small white frosted-glass disc with number thereon corresponding to its respective switch lever number, thus showing the signalman that there is no train on the track circuit governing the switch, and the lever is free to be thrown. The extinction of the light indicates the presence of a train on the switch, and that lever is locked and cannot be thrown.

Approach and home indicators are provided in the tower. The approach indicator is of the disc type, and the home indicator, indicating from the home signal entirely through the interlocking, is of the semaphore type.

The semi-automatic high semaphore signals at the entrance to the interlocking provide the signal aspect for automatic indication through the interlocking block, that is, these signals will assume the "proceed—caution" (45°) position when the interlocking block is unoccupied, and when the track and switches are right for the route governed, and when the signalman throws the signal lever, that is, these signals will go on from the "caution" to the "proceed full speed" (90°) position, if conditions are right for two blocks ahead. They will go automatically to the stop position, after the train has passed them and entered the interlocking block.

The automatic signal aspect at the end of the interlocking block—governing the territory between and up to the next interlocking plant—is a double-head "home" and "distant," normal danger, Hall disc signal. These disc signals are wired in conjunction with the semi-automatic semaphore signals, so that, in all cases, for all kinds of signals, the

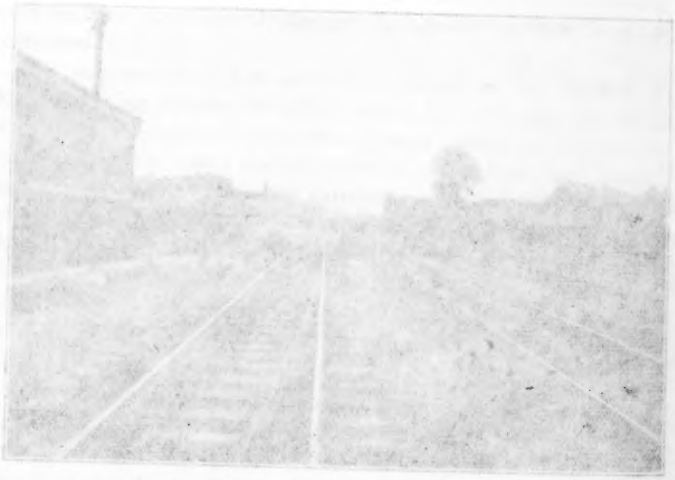

FIG. 31.—WESTMORELAND AND NINETEENTH STREETS BEFORE WORK WAS STARTED.

FIG. 32.—WESTMORELAND AND NINETEENTH STREETS AFTER WORK WAS COMPLETED.

proper home and distant indications are given, and also so that the disc signals through the interlocking will only clear if the proper route, leading to them, is set up.

At Broad Street the new signaling connects up with three-position semi-automatic signals, and with home and distant disc signals, as above explained. The signaling at the Green Street end joins up with two-position normal clear automatic pneumatic semaphore home and distant signals, governing into the Reading Terminal.

Eight iron signal bridges on the elevated carry the signal masts for the high semi-automatic semaphore signals, short-arm signals, and side signals. Table 7 gives the location, number of tracks crossed, and cost of same. At Columbia Avenue Station, where the tracks spread apart on account of the station platforms, there is a two-track signal bridge north of the station carrying signals for the south-bound tracks, and a two-track bridge south of the station with the signals for the north-bound movement. In all cases the clearance from underside of signal bridge to top of rail is 23 ft. 8 in.; and the side clearance from leg of bridge to center line of nearest track is an average of 7 ft.

Throughout the entire territory, between Broad and Green Streets, all switches are interlocked and controlled by machine.

TABLE 7.

Contract No.	Location.	Number of tracks.	Cost.
47	South of Fairmount Avenue	5	$1 684
	North of Poplar Street	4	1 558
	North of Master Street	4	1 444
	North of Oxford Street—two bridges	4	1 489
	North of Columbia Avenue	5	1 595
33	North of Norris Street	8	1 503
	Twelfth and York Streets	5	1 100
	Thirteenth and Cumberland Streets	5	1 174

Power plants, at Huntingdon and Wallace Streets, supply the compressed air (100 lb. per sq. in. at the power-house) to the towers through a 2-in. main air pipe, which is buried 6 in. in the ballast alongside the track. There are reservoirs in the main air pipe for drainage, and also auxiliary reservoirs in the ¾-in. branch pipes between the functions operated and the main air pipe.

Electric current is furnished from the power plant at Huntingdon Street at 650 volts and 25 amperes (D. C.) for charging the necessary storage batteries at the various interlocking towers.

The charging wire, etc., and all signal wires and cables, are laid in trunking on top, at the side, and between the tracks of the elevated structure. There is a main switch-board and rheostat at the power house at Huntingdon Street controlling the current for the charging of the storage batteries, and also a switch-board at each plant for the control of charging and discharging. These switch-boards at the several plants are wired so that, if desired, all the batteries at all four plants can be charged in a series at one time, or, on the other hand, any battery or batteries desired can be cut off from charge and put on discharge.

Electricity is used for the lighting of all signals, towers, etc. The signal lanterns are specially designed, each containing two 2-c.p. incandescent electric lights, and, for emergency use, an oil fount, wick, etc. The high-tension (1 100 volts, A. C.) wire for the electric lighting is carried in a separate conduit from the trunking used for the signal wires, and this current, by means of transformers on the ground at each signal group, is stepped down and changed to 110 volts (D. C.) for the signal lamps. Separate trunking is also run for these 110-volt wires.

Communication between the towers is provided for by train describer and telephones. These train describers consist of sending and receiving instruments for each track, and the description of traffic is accomplished by the signalman pressing certain numbered buttons (according to code) on the sending instrument for a certain track. This action appears on a corresponding receiving instrument at the next tower, giving full information to this signalman of coming train movement.

The signal tower at Cumberland Street is set back from the center line of the track 10 ft., and is a brick building, three stories from the street—two stories above the elevated structure. It has brick facings and an overhanging tile roof. The inside dimensions are 21 ft. 9 in. by 11 ft. 8 in. The machine is in the top story; on the track level are the relay racks and relays and the storage batteries. On the street level the room is used for the signal maintainer and for the furnace.

The tower at Tenth Street is the largest of the four. It is triangular in plan, with the hypotenuse running parallel with the railroad. The arrangement of the rooms is similar to that at Cumberland Street.

The tower at Jefferson Street is built on the viaduct and back

10 ft. from the center line of the track. It is a copper-sheathed, steel structure, with overhanging tile roof. The inside dimensions are 26 ft. by 11 ft. It is two stories high.

The tower at Brown Street is set back from the center line of the track 9 ft. It is of brick, two stories high, and similar to that at Cumberland Street. The inside dimensions are 25 ft. 10 in. by 11 ft. 3 in. In this tower is placed a temporary six-lever frame machine, with four working levers to take care of the converging of the new four-track line into the old two-track line at Green Street. This will be removed when the four-tracking is completed into the Reading Terminal.

The cost of the signal towers was as follows:

Location.	Cost.
Cumberland Street	$3 990
Tenth Street	5 990
Jefferson Street	4 114
Brown Street	3 760

The entire cost of the interlocking work, exclusive of the signal towers and bridges, was $127 462.90.

Locomotive Water Supply.

On account of the changed conditions in the Green Street Engine Yard, it was necessary to lay new pipe lines, making connections with the existing water tanks on the west side of the yard; furnish and erect three new 12-in. Poage automatic water columns; re-erect an old 8-in. column on the west of the main tracks; and construct the pits and drainage to the city sewers. The total cost of this work was $6 107.27.

Changing Grades of City Streets.

All the plans for the necessary changes to the city streets were prepared by the Bureau of Surveys and approved by the Railway Company. The work was divided into five contracts.

The work under these contracts included the underpinning of the adjoining buildings, where the changes in the streets affected their foundations; the excavation between house lines to the new street level; the renewal and reconstruction of all gas and water mains, electrical conduits, and other underground structures; provision for temporary access to all buildings, and the repaving of driveways and

sidewalks. It also covered the necessary adjustments and repaving of streets, where there was no change of grade, but where the previous existence of the tracks of the railroad and their removal made such adjustments necessary. It also covered the construction of the smaller sewers, the work on which could be deferred until the streets were excavated. The work covered was generally as shown in Table 8.

TABLE 8.

Contract No.	Description.	Cost.
108.....	Changes of grade, Fairmount Avenue and other adjoining streets; paving Ninth Street from Brown to Jefferson Streets; changes of grade on Columbia Avenue and adjoining streets.....	$122 833.27
109.....	Adjustments of streets, Berks to York Streets; changes of grade of Cumberland, Thirteenth and adjoining streets.....	110 756.42
110.....	Changes of grade on Allegheny Avenue, Westmoreland, Ontario and adjoining streets affected.....	134 338.60
111.....	Changes of grade of Hunting Park Avenue and adjustments of all streets from Tioga Street to Richmond Branch.....	43 125.00
115.....	Adjustments on Montgomery Street.....	2 185.75
	Total.....	$413 239.04

The principal prices and the quantities of the most important items are given in Table 9.

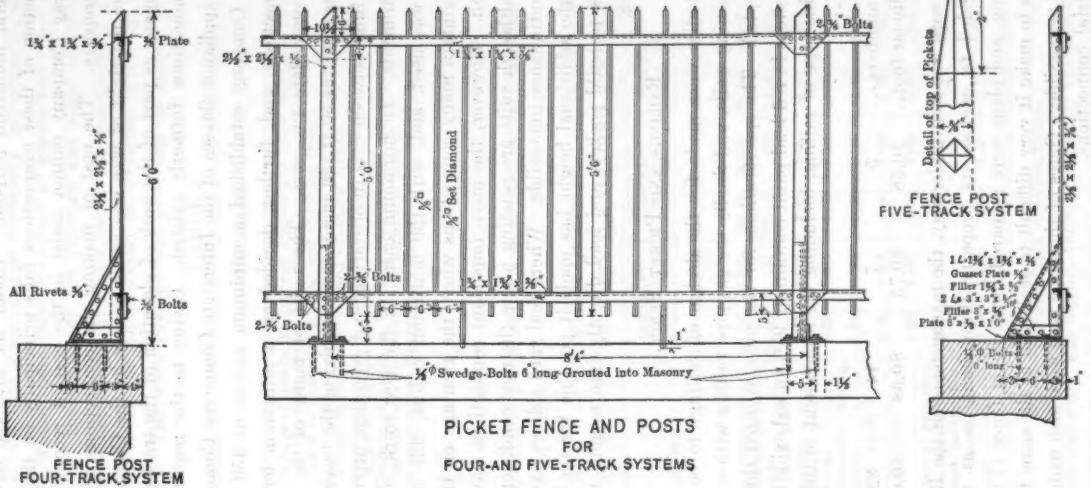
INDUSTRIAL CONNECTIONS.

Before the work was begun, there were many industrial connections to the existing tracks, leading to coal yards of retail dealers, to factories,



and for general industrial purposes. Under the law, the burden of the reconstruction of these connections falls principally on the owner, as the Railway Company cannot assist in the cost of reconstruction on private property. The cost of making the connections from the main tracks to the right of way was borne jointly by the City and the Railway Company as part of the work of elevation of the tracks, where industrial connections formerly existed. Owing to the requirements of the safety appliance clauses of the Interstate Commerce Commission, the Railway Company established a minimum radius of 150 ft. for the new connections, and, further, decided on a minimum length of siding to accommodate two cars. The radii of many of the former sidings was as small as 50 ft., in many cases requiring the insertion of special extra links between cars in operating, and even then attended by frequent derailments. In minimum cases, in the new work, a No. 4 curved frog was used, and, with the minimum radius, this made it possible to maintain many connections where the frontage on the railroad was small. However, the more important connections have been maintained, although suits are pending where the new conditions have made their continuance impossible. Where coal yard sidings have been reconnected, the additional height has made it possible for the owners in many cases to build pockets and load directly into wagons without extra handling.

Railings and Picket Fence.

Careful studies were made for the design of railings to be placed along the retaining walls, and finally the gas-pipe railing with cast-iron posts was adopted. The specifications for the pipe required that it be dipped at the shops in red lead paint containing 95% of red oxide of lead. The cost of this type of railing, including the attachment to the walls, was as follows:

Contract numbers...	5	7	14	32
Cost per linear foot..	$0.58	$0.75	$0.58	$0.68

After the work was well under way, the management of the Railway Company decided to enclose its property throughout, so as to prevent trespassing, and plans were prepared for a picket fence (Fig. 33), designed so as to make it very difficult to scale and at the same time be as economical as possible. Gates of the same type were also required at all the industrial connections.

PICKET FENCE AND POSTS
FOR
FOUR-AND FIVE-TRACK SYSTEMS

FIG. 33.

All the gas-pipe railing which had been furnished was stored and used on other contracts where the walls required merely protection for railway operatives, and were not on property lines.

Most of the picket fence was furnished under Contract No. 36, but prices were obtained in a number of other contracts. These prices included the priming with red lead and the erection and painting with two coats of standard Philadelphia and Reading paint. The prices were as follows:

Contract numbers ...	3	4	6	9	10	12	36
Fence per linear foot.	$1.21	$1.15	$0.90	$1.15	$1.15	$1.50	$1.05

The work under Contract No. 36 included a number of iron gates for the entrances of the various freight yards, an item of $2 580 for raising the Huntingdon Street foot bridge, and 8 819 ft. of picket fence.

The result of placing the picket fences has been a complete shutting out of trespassers from the tracks, as the only approach to them is from the freight yards or stations.

Telegraph and Telephone.

Before the elevation of the tracks, the telegraph and telephone system was carried on pole lines throughout the entire extent of the work. In addition to the wires of the Railway Company, those of the Western Union Telegraph Company (operated under a lease) had to be cared for.

As overhead wires during construction would have required constant changing, and would have been much in the way, it was decided to remove all through wires entirely from the line. Accordingly, arrangements were made to carry them in cables through city conduits to Thirty-first Street and Girard Avenue, and thence in a temporary cable attached to the existing pole line along the main line to West Falls, and thence by the Richmond Branch to Wayne Junction. The wires to yards and stations required for operation were carried through the city streets, by leased attachments on poles of private corporations, to the several yards and stations, and in a few cases along the line during construction in underground temporary trunking. The Railway Company elected to place these wires underground permanently on the solid elevated structure, by cables in vitrified clay ducts surrounded with concrete and in cables attached to the steel viaduct between Brown and Jefferson Streets. As the City was not willing to do more than join in the cost of an overhead pole line, it was

decided to have the Railway Company arrange and pay for the permanent installation, the City to join only in the cost of replacing an overhead pole line. In crossing the bridges, the cables are either carried beneath the steelwork, passing through openings provided in the back walls or above the floor carried through the haunching against the girders through bituminized fiber conduits laid in the concrete. Concrete manholes with steel covers are located at such intervals as the drawing of the cables makes necessary. The laying of the ducts and the drawing of the cables was done by Company forces, after travel was on the tracks and as soon as the fill was sufficiently consolidated.

Permanent Electric Lighting.

The original lighting of the line and the stations was by no means complete. The stations and yards were lighted either by gas or electricity, provided by outside corporations. The lighting of the new work is complete, not only in the yards and at the stations, but also along the entire line, the current being furnished by the power-houses of the Company at Wallace and Huntingdon Streets. The wires are carried from the power-houses along the line in ducts of bituminized fiber, laid in concrete on the masonry and fill sections, and by overhead poles attached to the steel viaduct. As this work was an entire betterment, it was carried out by Company forces in conjunction with the Motive Power Department, and the entire cost borne by the Railway Company.

General Data.

Total number of grade crossings abolished	28
Total number of bridges, not including viaduct	28
Length of four-track viaduct, in feet	3 365
Square feet of bridges, including viaduct	352 400
Total weight of structural steel in bridges and viaduct, in tons	27 180
Number of signal bridges	11
Third-class masonry in retaining walls, in cubic yards	67 500
Concrete masonry in abutments and walls, in cubic yards	151 800
Barrels of cement used	231 800
Embankment, in cubic yards	430 400
Lumber in temporary trestle, in thousands of feet	4 322
Number of contracts	47
Number of emergency orders	52

Station and other buildings	16
Miles of single track, permanent	30.1
Number of reconstructed industrial connections	46
Miles of telegraph and telephone conduit	3.8
Miles of electric light conduit	3.2
Excavation for changes in street grades, in cubic yards	139 620
Total length of sewers, in feet	17 835
Street driveway paving, all kinds, in square yards	73 192
Street sidewalk paving, all kinds, in square yards	31 120
Plans prepared by Railway and approved by City	347
Plans prepared by City and approved by Railway	50
Total number of plans prepared by Railway Company	3 200

PRINCIPAL CONSTRUCTION DATES.

July 6th, 1907. Work begun on Engineer's office, Huntingdon Street.

October 2d, 1907. Work begun on temporary freight yard, Nineteenth and Indiana.

August , 1907. Work begun on sewer contracts.

Between Berks and Broad Streets.

November , 1907. Work begun on temporary tracks, low level.

January 15th, 1908. Work begun on retaining walls, etc., east side.

January 30th, 1909. Two temporary tracks in service, high level, east side.

November 27th, 1909. Two permanent tracks in service, high level, west side.

January 4th, 1911. Schedule trains on all four tracks.

Between Seventeenth and Indiana and Richmond Branch.

October 4th, 1909. Work begun on walls, west side.

October 22d, 1910. Two temporary tracks in service, west side, high level.

June 4th, 1911. Full schedule travel over whole section.

Between Green and Berks Streets.

June 2d, 1909. Work begun on foundations for viaduct.

January 1st, 1911. Two tracks in service on east side, high level, on viaduct and trestle. All grade crossings gone.

December 17th, 1911. Full schedule travel on all tracks.

ACKNOWLEDGMENT.

The ordinance authorizing the work provided that it be carried out by the Chief Engineer of the Philadelphia and Reading Railway Company and the Director of the Department of Public Works of the City of Philadelphia. The original plans were signed on March 28th, 1907, by William Hunter, M. Am. Soc. C. E., as Chief Engineer of the Railway Company, and Mr. John R. Hathaway, as Director of the Department of Public Works; also by Theodore Voorhees, M. Am. Soc. C. E., Vice-President of the Railway Company, and George S. Webster, M. Am. Soc. C. E., Chief Engineer, Bureau of Surveys, City of Philadelphia. Since that time the same officials of the Railway Company have continued in office, while the Directors serving the City have been Messrs. George R. Stearns, Harry A. Mackey, and Morris L. Cooke. Mr. George F. Baer has been President of the Railway Company, and the Mayors of the City have been, the Hon. John Weaver, the Hon. John E. Reyburn, and the Hon. Rudolph Blankenburg.

The engineering work, in the preparation of the plans and specifications, as well as the work of construction, was carried out by the Railway Company under the direction of William Hunter, M. Am. Soc. C. E., as Chief Engineer, with the writer and Messrs. E. Chamberlain and Charles H. Hitchcock as Assistant Engineers; and by the City under the direction of George S. Webster, M. Am. Soc. C. E., as Chief Engineer, Bureau of Surveys, by Mr. James W. Phillips as Assistant Engineer in charge, and Assistant Engineers D. Jones Lucas, M. Am. Soc. C. E., Silas G. Griffith, H. T. Shelley, Arthur G. Singer, and Charles H. Stevens.

During the entire time, all bridge plans were passed upon by W. B. Riegner, M. Am. Soc. C. E., Engineer of Bridges, Philadelphia and Reading Railway, and George E. Datesman, M. Am. Soc. C. E., was Principal Assistant Engineer, Bureau of Surveys.

The Operating Department of the Railway Company rendered most valuable assistance throughout the entire work. Mr. Agnew T. Dice, General Manager, and the following officers of the Philadelphia Division, J. B. Warrington, Superintendent; H. C. Smith, M. Am. Soc. C. E., Division Engineer; Geo. W. Snook, Supervisor; and J. E. Peters and H. Mansfield, Trainmasters.

To Mr. A. H. Yocum, Signal Engineer, and to Mr. David S. Gendell,

Engineer of Erection, McClintic-Marshall Construction Company, the writer desires to express his appreciation for assistance in the preparation of details of this paper.

To all these gentlemen, the writer begs to acknowledge kind assistance, advice, and courtesy rendered at all times, and to his superior officers for permission to present the data contained in this paper.

DISCUSSION

Mr. Snow. J. P. SNOW, M. AM. SOC. C. E.—It will be of interest to learn from the author if the scheme for this work was decreed by some public board, as is customary in some of our States, or by agreement between the City and the Railroad; also, if all matters of detail, like handling telegraph wires, which it is stated the City would not help pay for, were settled on in the original agreement or decided on as the work proceeded; also, if the Railroad was compelled to pay one-half the total cost of widening streets, where that was done.

In connection with building the temporary trestle, would it not have been entirely safe to have used timber sills resting directly on the street surface, and much cheaper than to build concrete footings? Where there was any question of the bearing value of the ground, cross-planks could have been placed under the sills. Apparently, this trestle was built along the street, the surface of which must have been well compacted and probably much better able to sustain loads than the soil beneath. The load per square foot under a simple sill would not much exceed 5 tons per sq. ft., and, with 30-in. cross-planks under the sills, it would reduce to about 2 tons, which is a safe load on very ordinary soil.

For temporary work, it is good practice to use timber in contact with the ground, and oftentimes the top crust of soil is capable of carrying a greater concentrated load than the material below.

Mr. Lewis. E. W. LEWIS, M. AM. SOC. C. E.—The speaker would like to ask Mr. Wagner how near the original estimate the total cost of the work has proved to be, if he is permitted to give the figures. Some railroad corporations are averse to giving out any figures of actual cost of improvements, and the speaker does not wish to place the author in an embarrassing position. The cost of extensive improvements, in a number of cases which have come under the speaker's observation, has largely exceeded the estimates, in some cases as much as 100 per cent. It is a matter of considerable interest, particularly to those engineers directly involved, to have a comparison between the estimated and the ultimate actual cost.

Mr. Harte. CHARLES RUFUS HARTE, M. AM. SOC. C. E.—It would be interesting to know the details of the drainage system of those bridges in which the troughs were filled with concrete.

On the Boston elevation of the New York, New Haven and Hartford Railroad, hollow trough bridges, similar to those described in this paper, were used to a considerable extent, and, as in Mr. Wagner's case, there was quite a little difficulty in the matter of drainage.

Each trough had a drainage hole in which a copper thimble was expanded. Not only was it very difficult to keep this thimble tight,

but other and entirely unexpected troubles developed. The thimbles were intended to discharge into a copper trough running parallel with the street, which in turn emptied through leaders into the sewer. The trough was suspended from the bridge by wires attached to the centers of spanners over the top of the trough, and in the first installation these spanners were highest in the center. Condensed moisture gathered on the steel, ran down the wires to the spanner and then, instead of decently dropping into the trough, flowed on top of the spanner and over the edge of the trough and then dropped into the street. It was remarkable how often this occurred, and on what valuable clothing the water managed to fall. Until the cause was located and the trouble corrected by depressing the spanner at the center below the level of the ends, the Claims Department was kept busy with complaints. Mr. Harte.

GEORGE S. WEBSTER, M. AM. SOC. C. E. (by letter).—During the past twenty-five years, grade crossings in the City of Philadelphia have been abolished by the co-operation of the City with the railroad companies. Mr. Webster.

An Act of the General Assembly of the State of Pennsylvania, approved June 9th, 1874, authorizes cities and towns of the State to enter into contracts with railroad companies, whereby the lines of railroads may be relocated, reconstructed, or elevated, with the view of abolishing grade crossings and furnishing better railroad service.

Under authority of this general act, city ordinances are passed, authorizing the mayor to enter into such contracts with railroad companies on whose lines it is desired to abolish grade crossings. These ordinances are not general, but apply to the particular line of railroad on which the work is to be undertaken.

The Department of Public Works conducts the negotiations with the railroad companies, prepares the ordinances, in co-operation with the same, has charge of the preparation of plans and contracts for changes of streets and other municipal work, and exercises the right of general supervision and inspection of all construction.

There is no absolute rule which can be laid down as to the best solution in matters of the depression or elevation of railroad lines. It will depend on the physical condition and the character of improvement of the section through which the line passes.

In the abolishment of grade crossings in Philadelphia the method adopted in every case has been one which seemed to suit best the particular problems under consideration.

Practically all the passenger-carrying lines have been elevated or depressed, the exception being branch lines carrying purely local traffic. The lines of the Philadelphia and Reading Railway Company and the Pennsylvania Railroad Company enter their terminal stations over elevated tracks. The Baltimore and Ohio Railroad Company enters its station by tracks depressed below the streets.

Mr. Webster.

Generally, the elevation of the tracks is preferred by the railroad companies, but the depression is somewhat more to the advantage of the City, as the railroad is practically concealed, though the nuisance caused by smoke is greater than with an elevated line.

As a rule, the noise from a depressed line is much less than from an elevated line, and where the streets pass below the railroad there is more temptation for the commission of nuisances than where the streets pass overhead in the open.

The method which seems to affect property most seriously is that which involves a partial elevation of the tracks and a partial depression of the streets, in which cases the adjoining property is damaged to a considerable extent by the change of grade of streets, and a long time usually elapses before these properties recover their value and desirability.

The State of Pennsylvania does not contribute to work of this kind. It has been the general practice for the city and the railway company interested to pay equal proportions of the cost, although this is not an invariable rule. In only one instance has the street railway company contributed.

The work of abolishing grade crossings in Philadelphia commenced about 1887, and since that time three grade crossings of important railway lines have been abolished and about one hundred and twenty street and railway grade crossings have been eliminated.

The first ordinance authorizing the abolishment of grade crossings was approved on March 29th, 1887. This provided for the gradual abolishment of grade crossings and the opening of new streets along the New York Division of the Pennsylvania Railroad, in the northeastern section of the city. The Railroad Company elevated its tracks approximately 9 ft., and the grades of the streets were depressed a like amount, so as to permit of the construction of undergrade bridges. The Railroad Company paid the cost of changing the elevation of the tracks, the construction of the bridges, and all work incident thereto within its right of way. The City graded the street approaches to the bridges and paid the damages to property due to the change of street grades. The work has extended over a considerable period of years, and is not yet entirely completed, therefore the ultimate cost to the City or the railway companies has not been determined, but when the agreement was entered into it was estimated that the cost of the work would be approximately equally divided.

An ordinance of December 26th, 1890, provided for the construction of the Reading Terminal Railroad to Market Street, by an elevated line from Green Street and the abolishment of grade crossings at Columbia Avenue and at Broad Street and Lehigh Avenue, those streets being carried above the railroad. The Railway Company paid all the cost of these improvements and changes.

Mr. Webster.

An ordinance of February 4th, 1892, provided for the abolishment of grade crossings of the North Pennsylvania Railroad and the Connecting Railway Company, together with four grade crossings of streets, at a cost of $300 000, $200 000 being paid by the City and $100 000 by the Pennsylvania Railroad Company, lessee of the Connecting Railway. The Philadelphia and Reading Railway Company, lessee of the North Pennsylvania Railroad, did not contribute.

In abolishing the grade crossings on Pennsylvania Avenue, under the ordinance of March 17th, 1894,* the railroad was depressed below the streets and carried partly in tunnel. Seventeen grade crossings were abolished, at a cost of $5 487 000, the cost being equally divided between the City and the Railway Company.

Under an ordinance of 1897, thirty grade crossings were abolished on the Philadelphia and Trenton Railroad. In this instance the railroad was elevated in such a manner that street grades were not disturbed. The City contributed $800 101 toward the cost of the work and the Pennsylvania Railroad Company, lessee of the Philadelphia and Trenton Railroad, paid the remainder, amounting to $667 541.60.

An ordinance of 1900 provided for the abolishment of four grade crossings on the line of the Chestnut Hill Branch of the Philadelphia and Reading Railway. In this case the contract price was $216 000. The City appropriated $70 000 and assumed the liability for land damages, which amounted to $82 035.75, making the total cost to the City $152 035.75. The Railway Company paid the remainder, $146 000.

The elevation of the tracks of the Philadelphia, Germantown and Norristown Railroad, authorized by ordinance of October 13th, 1906, which has been described so fully and clearly by Mr. Wagner, involves an expenditure of approximately $7 000 000. The cost of elevating the tracks in order to give the railway company "as good accommodations and as complete and convenient facilities as existed prior to the commencement of the work, for conducting business and operating said railroad," was borne equally by the City and the Railway Company, the Railway Company bearing the expense of all betterments to its line.

The Philadelphia Rapid Transit Company (operating the street passenger railway system of the city) contributed $400 000 to the City as a part of the cost of abolishing grade crossings in this instance.

In the work of abolishing grade crossings described in Mr. Wagner's paper it was necessary in several instances to lower the grade of a number of important streets in order to carry them under the railroad. The properties fronting on these streets were used for both manufacturing and residential purposes, and were of moderately high class; and, as some of the streets were important thoroughfares leading from one populous district to another and carried heavy traffic, the problem

* Described in *Transactions*, Am. Soc. C. E., Vol. XLIV, p. 1, and Vol. XLVIII, p. 470.

Mr. Webster.

of adjusting grades was difficult. It was decided that on all main thoroughfares the gradients should not exceed 3%, and that on minor residential streets steeper grades, generally not exceeding 5%, would be permissible, and on this basis the street grades were established.

Where streets were depressed to carry them under the railroad, a total reconstruction of the sewer system was made necessary. This required the laying of new trunk sewers (in many cases with flat gradients) to distant points where outlets could be obtained. To prevent overflows in these depressions during heavy rain storms, the sizes of the sewers were designed with an ample factor of safety.

The writer heartily endorses Mr. Wagner's statement that one of the most important features in water-proofing is to get the water away from the structure as fast as possible. As all viaducts and bridges carrying the railroad over streets are required to have solid floor construction, it is important, not only for the maintenance of the steelwork, but also for the protection of pedestrians passing under the bridge, that care should be taken to water-proof the structure properly.

The City of Philadelphia has recently reached an amicable understanding with the Pennsylvania Railroad Company and the Baltimore and Ohio Railroad Company for the abolishment of grade crossings and the readjustment of their freight lines in the southern section of the city, the cost of which is estimated to be about $20 000 000, which, under the terms of the tentative agreement, will be paid for approximately one-half by the City and one-half by the Railroad Companies. The City's contribution in this case is predicated upon the Railroad Companies agreeing that the railroad, to be constructed around the southern section of the city, to replace the existing lines, shall form an "Open Gateway" for the entrance of other railroads into the city, on the payment of an equitable share of the costs.

A minimum clearance of 14 ft. is required under all bridges carrying railroads above streets, whether or not occupied by street railroad cars, but it has been found that a greater clearance is desirable on wide avenues, even at an increased cost.

There has been little or no difficulty in obtaining the co-operation of the railroad companies in this work. Negotiations sometimes move slowly, on account of legal and financial obstacles to be overcome, but, as a rule, the companies are as anxious to abolish their grade crossings as the City is to have them do so, and the work has been planned so that both railway and highway travel has been maintained during construction. In all cases the total cost, including land damages, has been less than the engineers' estimates prepared prior to the commencement of the work.

Mr. Wagner.

SAMUEL TOBIAS WAGNER, M. AM. SOC. C. E. (by letter).—Replying to Mr. Snow's questions, the abolition of these grade crossings had been under discussion between the City and the Railway

Company for a number of years prior to the beginning of the work and was the result of a number of conferences terminating in the passing of the ordinance by the City Councils and the signing of the agreement, authorized by the ordinance, by the officials of the City and the Railway Company. During this time the general plan, as finally constructed, was decided on, and the scheme for the division of cost, as well as the necessary legislation required by the City to carry on its part of the work, was perfected. Mr. Wagner.

The ordinance, while general in its scope, covered some points with considerable detail, such as fixing the limits of the four-track viaduct; the main points of the railroad construction in which the City would join; and some specific details of what were to be considered as betterments for the Railway Company, such as the cost of the construction of two tracks of the steel viaduct between Brown Street and Girard Avenue, where the Railway Company had but two tracks prior to beginning work and where it was desired to have four in the completed work. The majority of the cases in which the division of cost had to be determined, was decided on after the work was completely planned and placed under contract. This was done after the most careful preparation of plans and estimates, based on accurate and checked data, as to the dimensions and character of the structures existing before the work was started. Conferences on each subject were held, and the matters decided on were made of final record by the signatures of the Director of the Department of Public Works of the City and the Chief Engineer of the Railway Company, who were the specially designated officials under the terms of the agreement. In this way, before any payments were made on a contract executed by the Railway Company, the amounts to be paid by each interest were definitely determined. As the ordinance did not provide for any betterments to the City, the division of the estimates on the contracts executed by the City was always into two equal shares.

Where streets were widened, the Railway Company paid for one-half of the cost of the widening. This widening was shown on the general plans of the work, which were made part of the original agreement.

The agreement specially provided that the Railway Company could not recover for damages, caused by changes of the grades of streets, to any of its property held prior to the date of the ordinance, and, therefore, whatever amount was necessary to place the property in usable condition was divided equally between the two interests. This work was always done under contract on properly approved plans.

The question of the design of the temporary trestle was one which required much study in order to determine the most economical construction combined with its maintenance under heavy and rapid travel. One of the requirements of the Operating Department was, that there

Mr. Wagner.

should be, at all times, two tracks entirely unobstructed, on which all trains could be run on schedule time. This meant that a perfect track must be maintained, and the primary thought in the design was that of minimum maintenance. As one of the two tracks carried by the trestle was half supported by the masonry wall, and as a portion of it was over a part of the excavation for the foundations, it was considered wise to endeavor to have a specially secure footing for the remainder of the trestle. The section of the work where the trestle was built was formerly occupied by four tracks, 12-ft. centers, on a right of way 66 ft. in width, with drainage ditches on the sides, and was not on a street surface. The bottom of the foundation of the concrete footing was but 12 in. below the old low-level rail, and therefore not down to the original sub-grade. It is believed that any increased cost in the placing of this concrete was more than offset by the saving in maintenance. In one or two cases where the footings were on a fill, and where settlement had occurred, the maintenance of the track by blocking up the stringers was very expensive on account of the continuous traffic.

Mr. Harte's remarks about the water-proofing of the bridges are interesting as being further proof of the perversity of water in finding its own way and not following one which has been provided by the engineer. As already explained, the use of drainage nipples was found to be bad, and the troughs on later designs were entirely filled with concrete and the mastic placed on top. The grades were either toward both ends of the span, or all to one end, depending on the grade of the track. The only difficulty with this method is that if the sub-drainage, behind the back walls, is not good, the water, in case of a heavy rainfall, will back up, and it is difficult to prevent it from working under the apron-plate and down the face of the abutment. Further, it is often difficult to get sufficient grade on even a short span to carry the water off the bridge as rapidly as is desired, especially after the ballast has become dirty. In recent designs, the detail arrangement of the steel above the top of the floor has been made with special reference to the water-proofing, and the principle has been established that it is not wise to allow the water to run off the ends of the span. It should be caught by inlets placed near the ends and carried into the sewers by wrought-iron piping with suitable clean-outs. Intermediate inlets are also provided on the concrete floor, with grades as steep as possible. In these designs the membrane method of water-proofing was adopted as being preferable to the asphalt mastic. In a number of spans of this character just completed, the wisdom of this method seems to be indicated as the results so far have been very good.

It will be noticed that the majority of the bridges described in the paper were water-proofed with a natural rock asphalt mastic, without any protection from the ballast. In spite of what would be

now considered indifferent details, these bridges are giving fairly satisfactory service, and to the writer's knowledge, there has not been a single complaint from any one as to leakage. It is true that they are not all tight, but the average seems to be good. When it is remembered that there are more than 350 000 sq. ft. of bridge surface over streets, or more than 8 acres in all, it is believed that this is a fair record, when the usual ability of the public to complain, is considered. Mr. Wagner.

The question of the proper material for use in the water-proofing of solid floor bridges is a most interesting one, not only on account of the cost involved, and the uncertainty of the durability of the materials, but also because there are two widely different materials in very general use for such work, namely, coal-tar pitch and materials of an asphaltic nature, and it behooves the engineer to use the best. The whole question is also complicated by the proper design of the steelwork for the water-proofing, as well as the workmanlike application of the materials, both of which are of the utmost importance. With careful observation during the past four years no cases have been discovered where the asphalt mastic has been cut into by the ballast in such a manner as to injure it in any way, and considering the large areas involved, there have been very few cases of the mastic cracking on the main surfaces. Where cracks have occurred, they have generally been along the webs of the girders or at the ends of the spans, and even these have been surprisingly few. In new work where the V-shaped wedge of pure, low melting point asphalt has been used along the girders, there has been no cracking or leaking. In asphalt mastic, the writer believes that the use of a ductile, low melting point asphalt as a flux is desirable, and also that the proportions be such as will produce a mastic which is soft rather than one which is hard.

During the summer of 1913, asphalt mastic, made of Val de Travers natural rock, was uncovered on a brick-filled arch carrying a railroad over a street in Philadelphia. The arch had been built by the City in 1892. The mastic was 1 in. thick and placed on cement mortar over the top of the brick. The dry stone packing for drainage was placed immediately on the mastic. Inspection showed that in many cases the stone had cut down into the mastic, but in four openings made at different parts of the bridge, every case of such cutting showed sufficient mastic remaining to give adequate protection. At the end of 21 years of service, the surfaces of this mastic were bright and showed no signs of disintegration of the asphalt. A small sample removed showed surprising ductility and uniformity of the fractured surface.

Replying to the question asked by Mr. Lewis, comparisons between the original estimates of the total cost of any work and the final cost are always interesting, and of great value to the engineer who has much of this kind of work on which to estimate. In this case, it is possible to give but rough figures at the present time, for though

Mr. Wagner. the work of construction is completed, there are a number of suits for damages which are still pending, and until these have been disposed of, final figures cannot be given. It is quite safe to state, however, that the work will be completed well within the original estimated cost of $7 659 740, as at the present time the total expenditures amount to about $6 800 000, and the total amount of the unsettled claims is far less than the difference.

AMERICAN SOCIETY OF CIVIL ENGINEERS
INSTITUTED 1852

TRANSACTIONS

Paper No. 1276

THE INFILTRATION OF GROUND-WATER INTO SEWERS.*

By John N. Brooks, Jun. Am. Soc. C. E.

With Discussion by Messrs. John H. Gregory, Edward S. Rankin, Kenneth Allen, G. L. Christian, E. Kuichling, E. G. Bradbury, Marshall R. Pugh, and John N. Brooks.

An examination of the Index to the *Transactions* of the American Society of Civil Engineers, published recently, shows that the Society has never published a paper on the infiltration of ground-water into sewers. Some recently collected data on the subject are presented in Table 1, and a glance shows that the information is incomplete in most cases, and that there is a wide variation in the form in which it is presented.

The writer, therefore, has attempted to prepare a comprehensive and compact form for the presentation of data on infiltration, and to suggest rational units for the measurement of its quantity.

The factors governing the total quantity of infiltration into a sewer are:

1.—The diameter and length of the sewer.

2.—The material of which the sewer is constructed.

a.—In vitrified pipe sewers, the type of joint used.

b.—In concrete or brick sewers, the type and quantity of water-proofing used.

3.—The skill and care used in laying the sewer.

4.—The character of the materials traversed by the sewer.

5.—The relative positions of the sewer and the ground-water level.

* Presented at the meetings of February 5th and 19th, 1913.

TABLE 1.—DATA ON INFILTRATION OF GROUND-WATER INTO SEWERS.

Item No.	Place.	Diameter of sewer, in inches.	Length of sewer, in miles.	Leakage, in percentage of capacity of sewer.	Leakage per day per mile of sewer, in gallons.	Leakage per day per capita, in gallons.	Total leakage, in gallons, per day.	Remarks.

" 14. Joint Trunk Sewer. Takes in sewers of part of Elizabeth, Roselle Park, part of Newark, West Orange, Summit, etc.

Reference to Table 1 shows that in every case data on some of these factors are missing. As it is evidently impossible to express all these factors in precise terms, it becomes necessary to agree upon terms for their expression, and the writer suggests the following:

For the material of which the sewer is constructed, in the case of pipe sewers, use the term "Vitrified Pipe." In the case of concrete sewers, state the thickness of the wall, the mixture, and whether crushed stone, gravel, or slag was used in the aggregate. For brick sewers, state the thickness of the wall, the quality of the brick, and the bond.

The type of joint is usually easily described. If the joints are of cement, it should be noted whether they are finished with a bevel or flush with the bell of the pipe.

For the type and quantity of water-proofing, if a fabric is used, the percentage of the total length of sewer treated may be stated, together with the number of plys of fabric and the kind of paint. In cases where a water-proofing compound is mixed with the concrete, a statement of the kind and quantity of compound will be sufficient.

For skill and care used in laying, use such terms as "Little," "Ordinary," and "Unusual."

For the character of the materials traversed, use such terms as "Wet," or "Dry," "Rock," "Gravel," "Sand," or "Clay."

For the relative positions of the sewer and the ground-water level, reference may be made to the daily reports of the engineer or inspector; and the length of wet trench reported may be expressed as the percentage of the total length of the trench, assuming that where wet trench is reported the sewer will be below the ground-water level.

The foregoing descriptive terms will inevitably have different shades of meaning for different engineers, but the writer believes that they are sufficiently definite to present the salient features of a sewer described by them with a degree of accuracy sufficient for an intelligent comparison with other sewers.

Reference to Table 1 shows that there is a wide variation in the units chosen for the measurement of the quantity of infiltration, and that none of them is altogether satisfactory. Expressing the quantity

of infiltration as a percentage of the maximum capacity of the sewer is irrational, because the maximum capacity depends in part on the gradient of the sewer, which has no relation whatever to the quantity of infiltration.

Gallons per day per mile of sewer is a useful unit only when the size of the pipe and the length of each size are stated, and in a collecting system with many laterals such a statement becomes decidedly cumbrous.

Gallons per day per capita of tributary population appears to be the favorite measure of the quantity of infiltration, but this unit is entirely irrational, for there is no conceivable relation between the number of people contributing sewage and the quantity of ground-water percolating into a sewer.

The total quantity of infiltration, in gallons per day, is a statement which is evidently entirely useless in making comparisons between systems unlike in diameter and length of conduit.

In view of the unsatisfactory form of the data, and of the units thus far considered, the writer suggests the presentation of such data in the manner shown in Table 2, and the following units for the measurement of the quantity of infiltration. These units are used by Mr. Nicholas S. Hill, Jr., and are believed by the writer to be both simple and rational.

For vitrified pipe sewers, the unit is gallons per day per foot of joint. Table 3 shows the total length of joints per 100 ft. of sewer for the commercial sizes of pipe, for which the total length of joints for any length of sewer is obtained by a single multiplication. Evidently, in a vitrified pipe sewer free from cracks, infiltration can occur only at the joints. An examination of Table 1 shows that sufficient data for the computation of infiltration, in gallons daily per foot of joint, are presented in only four cases, namely, Items 8 and 9, and in two sewers under Item 11. The data for these cases are repeated in Table 2, with the computed infiltration expressed in gallons per day per foot of joint; this is seen to vary from 0.3 to 5.0.

For concrete and brick sewers, the unit is gallons per day per square yard of interior surface. Table 4 shows the interior surface area, in square yards per 100 ft. of sewer, for circular sewers, from 3 ft. 8 in. to 6 ft. in diameter, and a single multiplication gives the interior surface area for any length of sewer. For sewers of egg-

Item 16 of Table 2 gives the results of a test for quantity of infiltration, recently made by the writer, under the direction of Mr. Hill, on a new reinforced concrete trunk sewer. Triangular weirs were set at two points, 47 745 ft. apart, and each weir was provided with an automatic head-recording device, giving a continuous record of change in head, and reading to the nearest $\frac{5}{1000}$ ft. From these records the average head on each weir for a period of one week was computed, by obtaining with the planimeter the area between the curve of change in head and an arbitrary base line,

and dividing by the proper length. From this average head the corresponding average rate of discharge was computed, making allowance for velocity of approach. The average time of flow between the weirs was obtained by the comparison of maxima and minima points on the respective curves showing decided change of head.

The interval or lag between the time of corresponding discharges having been determined as described, the total discharge at the up-stream weir for a period of one week was then subtracted from the total discharge at the down-stream weir during the corresponding period. The difference in discharge thus determined is a very close measure of the quantity of infiltration between the weirs during one week. The conditions for this test were ideal, as no sewage entered the trunk lines between the weirs during the test. The infiltration found was at the rate of 0.8 gal. per day per sq. yd. of interior surface.

A careful inspection of the length of sewer tested revealed no visible cracks, and the work in general appeared to be first-class, but the quantity of infiltration measured appears to be much smaller than may in general be expected in work of this class.

The writer hopes that discussion of this paper may bring out improvements in the form suggested for the presentation of data on the infiltration of ground-water into sewers, as well as additional data on the subject.

He wishes also to acknowledge his indebtedness to Mr. Nicholas S. Hill, Jr., for valuable criticism and suggestion in the preparation of this paper.

DISCUSSION

Mr. Gregory. JOHN H. GREGORY, M. AM. SOC. C. E.—The author has presented a paper on a subject which is of especial interest to engineers who are called on to design, construct, or maintain, a system of sewers or a sewage disposal works. Leaky sewers are objectionable from many standpoints. It is not the intention of the speaker to mention all their objectionable features, but to call attention to one of the most important, that is, the consequent increased cost of construction, maintenance, and operation. Due to the infiltration of ground-water, not only must the sewers be larger than would otherwise be required, but also the sewage disposal works, if the sewage receives treatment before final disposal.

The author has opened a way by which many data on the quantity of ground-water leakage into sewers can be obtained if each engineer having any data on the subject will contribute the same in the form of a brief discussion of this paper. The author will then have material which can be tabulated in concise form in his closing discussion, and should be of much service. The speaker believes that many engineers have some data on this subject, but hardly enough to justify them in writing a paper thereon, and, therefore, have not given the information to the Engineering Profession.

With reference to the author's headings under which such data should be tabulated, the speaker has one or two suggestions to make. It would be desirable to include a column for the date—the year alone is sufficient. The engineer will then know how recent is the information he is examining. There should also be a statement of just how the sewer was constructed; if of sewer pipe, cement pipe, or reinforced concrete pipe, the lengths of the pipes, whether of 2, 2½, or 3-ft. sections, etc. Similarly, with monolithic, or other construction, data should be given as to both horizontal and cross-joints.

The speaker, however, is especially interested in the unit in which the leakage is to be reported. Perhaps the unit most commonly used is gallons per 24 hours per mile of sewer. This is very convenient, but it does not go quite far enough—it takes into account the length of the sewer, but not the diameter. The author presents a unit which has much to commend it, namely, gallons per 24 hours per square yard of inside surface. The unit is a rational one, but, unfortunately, is not a very convenient one to use.

The speaker suggests: gallons per 24 hours per inch of diameter of sewer per mile of sewer. A consideration of this unit will show that it takes into account not only length but diameter. He has used it to record the leakage of water pipes, which have been tested under his direction, and has found it extremely convenient. It also has the

advantage that, in designing a system of sewers, calculations of ground-water leakage can be made very rapidly. Mr. Gregory.

To show the application of this unit, Table 5 is presented. This has been computed from the author's data in Tables 1 and 2.

TABLE 5.—INFILTRATION OF GROUND-WATER INTO SEWERS.

Item No.	Place.	Diameter, in inches.	Length, in feet.	Leakage, in gallons per 24 hours per mile of sewer.	Leakage, in gallons per 24 hours per inch of diameter per mile of sewer.
(1)	(2)	(3)	(4)	(5)	(6)
8	North Brookfield, Mass.	12	1 584	17 000	1 420
9	Rogers Park, Ill.	6	8 976	1 240	210
11	Altoona, Pa.	27	6 336	40 814	1 510
11	" "	30	3 168	86 592	2 890
11	" "	38½	5 016	264 000	6 830
16		3 ft. 8 to 6 ft. 0	47 744	7 280	123
17	Columbus, Ohio.	42	1 744	6 340	151

Item No. 17 in Table 5, gives the result of a leakage test on a 3 ft. 6-in. by 3 ft. 6-in. concrete sewer of horse-shoe section, built under the speaker's direction at Columbus, Ohio, in 1906. The construction of the sewer was in charge of Mr. E. A. Kemmler, Resident Engineer, and the test was made under his immediate direction. This is the speaker's humble contribution to the data which he would like to see tabulated in the author's closing discussion.

It will be seen from Table 5 that the infiltration into the sewers listed varies from 123 to 6 830 gal. per inch of diameter per mile of sewer.

To illustrate the convenience of the unit suggested herein, assume that 300 gal. per 24 hours per inch of diameter per mile of sewer is a reasonable quantity (but the speaker does not care to go on record as stating that this is or is not a reasonable quantity). The leakage into a sewer, say, 18 in. in diameter, would then be 5 400 gal. per 24 hours per mile of sewer, a figure very quickly and easily obtained.

EDWARD S. RANKIN, M. AM. SOC. C. E.—Ten years ago it was the speaker's privilege to listen to a paper on this subject by Mr. A. P. Folwell, before the American Society of Municipal Improvements.* In that paper there was a table giving all the data Mr. Folwell was able to collect; it included gaugings on sixteen sewers. Mr. Brooks gives seventeen gaugings, of which six appear in Mr. Folwell's paper, the net total being twenty-seven. Mr. Rankin.

* "Perviousness of Sewers," *Proceedings*, Am. Soc. Mun. Impvts., 1903.

Mr. Rankin.

Considering only pipe sewers—to which alone this discussion will refer—and omitting those in which the leakage is only expressed in terms of population or percentage of capacity, neither of which units, as pointed out in the paper, has any direct bearing on the question, there remain but nineteen, and even these are so incomplete as to be practically useless in comparing the leakage of the several sewers mentioned.

The speaker is unable to agree with Mr. Brooks that the single unit of gallons per 100 ft. of joint would form an accurate basis for comparison. Although this includes the two factors of length and diameter, it omits the highly important factor of head of ground-water mentioned on the first page of his paper. The speaker would suggest that the true unit of comparison be expressed by the formula, $n\ d^x\ y\ h$, in which n represents the number of joints, d the diameter of the pipe, in inches, and h the head of water above the invert. From the data available, it would seem to be impossible at this time to determine with any degree of accuracy the values of x and y.

Mr. Brooks considers the leakage as directly proportional to the diameter. Alexander Potter, Assoc. M. Am. Soc. C. E., in his report on the Joint Outlet Sewer, states that, from his observation, the leakage varies as the square of the diameter. The speaker is of the opinion that the true value is less than unity, approximating to the square root of the diameter, and that the greater leakage in the larger pipes of a system is due to these pipes being in most cases laid at a lower level, and consequently being under a greater head of ground-water. He is unable to support this opinion by figures, but it is reasonable to suppose that the leakage is not uniform throughout the joint, but is confined largely to the weakest point, the few inches in the extreme bottom, most difficult to make, and practically impossible to inspect. If this theory is correct, the approximate value of the term, d^x, would become:

For an	8-in.	pipe.....	2¾ in.
12	"	"	3½ "
18	"	"	4¼ "
24	"	"	5 "

In regard to the other factor, h, there is abundant evidence to show its importance. In soil which is at all porous, every rain storm creates or increases the head, and the most casual inspection of the flow in most sanitary sewers will reveal a decided difference before and after a heavy rain.

A gauging of about 4 miles of 8 to 15-in. pipe sewer in Newark, in March, when the ground was saturated with melting snow, showed a leakage of 38 000 gal. per mile, while in May only 13 500 gal. were found.

Mr. Rankin.

The diagram, Fig. 1, shows the total annual rainfall, in inches, and the estimated average daily leakage, in gallons per mile, on the Newark sections of the Joint Outlet Sewer for the past eight years. Automatic records are kept of the daily flow, and the leakage was obtained by deducting from the total a quantity equal to 500 gal. for each house connection. This is close to the actual quantity, as found in the dryest section of the sewer.

It will be noted that the curves follow each other, showing clearly the close relationship between leakage and ground-water. In the speaker's opinion, the co-efficient, y, would approximate unity, so that the formula would become $n\,h\,\sqrt{d}$.

Although this formula is believed to be theoretically correct, and is useful in comparing the leakage in existing sewers, yet, for practical purposes in designing new work, the more simple form, expressed in gallons per mile or per acre, is to be preferred.

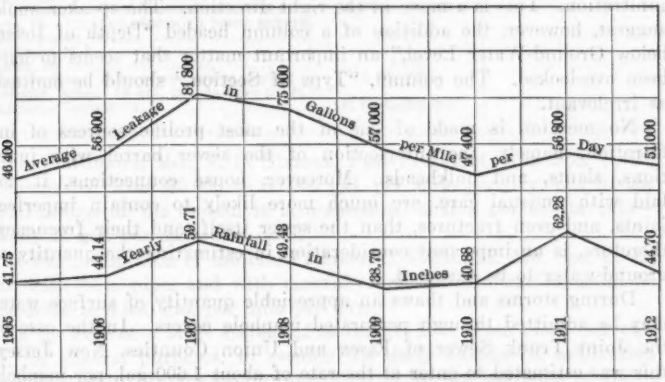

FIG. 1.

Mr. Allen.

KENNETH ALLEN, M. AM. SOC. C. E.—In designing a system of sewers, it is often difficult for the engineer to ascertain what allowance should be made for ground-water. The speaker believes that it is high time that those who have the opportunity to note the conditions affecting the flow due to infiltration do this for the benefit of the Profession.

Data up to the present have been expressed generally in volumes per mile of sewer, or per capita daily, but such all-important elements as head of subsoil water, perviousness of the ground, and the size and character of the sewer itself, are either ignored or stated in such a general way as to be of little value.

Mr. Allen.

There are those who believe that sewers laid in a porous soil, above the level of the ground-water, may be expected to lose an appreciable proportion of their contents by leakage, so that, instead of making an allowance for infiltration, one should more properly make a deduction in the estimated flow due to such leakage. The speaker believes such conditions to be exceptional, and that the ordinary pores left in well-made joints will gradually clog up; thus far, however, there appears to be no consensus of opinion on the subject.

It is desirable to forecast sewage volumes as closely as possible, in order to avoid spending money unnecessarily on sewers which will be too large, on the one hand, and from danger of damage due to backing up of sewage if the sewers are too small, on the other. In any case, excessive infiltration should be prevented, as it not only increases the first cost of the sewers, but, if the sewage is to be pumped or treated, it may increase the annual charges by a very large sum.

In Table 2 the author attempts to standardize the data relative to infiltration. This is a move in the right direction. The speaker would suggest, however, the addition of a column headed "Depth of Invert below Ground-Water Level," an important matter that seems to have been overlooked. The column, "Type of Section," should be omitted, as irrelevant.

No mention is made of one of the most prolific sources of infiltration, namely, the intersection of the sewer barrel with junctions, slants, and bulkheads. Moreover, house connections, if not laid with unusual care, are much more likely to contain imperfect joints, and even fractures, than the sewer itself, and their frequency, therefore, is an important consideration in estimating the quantity of ground-water to be expected.

During storms and thaws an appreciable quantity of surface water may be admitted through perforated manhole covers. In the case of the Joint Trunk Sewer of Essex and Union Counties, New Jersey, this was estimated to enter at the rate of about 1 600 gal. per manhole daily.*

With a system of well-constructed sewers, the initial infiltration is likely to decrease as the pores and crevices in the joints gradually become clogged by silt or deposits of salts, introduced by the ground-water itself or contained in the cement forming the joint. For example, in a pipe sewer recently laid in Batavia, N. Y., with a patent gasket composed of cement and sand placed in pockets of muslin dipped in glue, the infiltration at first was about 1 000 000 gal. per day in 31 miles of sewer, or 32 260 gal. per mile, with the ground-water standing from 3 to 5 ft. above the pipe; but later, after connecting 900 houses with the sewer, this rate fell to about 22 580 gal. per mile.†

* *Engineering News*, February 11th, 1905.

† *Engineering Record*, November 9th, 1912.

Mr. Allen.

The rates of infiltration in Table 6 are abstracted from discussions on the subject by George T. Hammond, M. Am. Soc. C. E., and the speaker,* and may be added to the list given by the author in Table 1.

TABLE 6.

Place.	Rate of Infiltration, in Gallons Per Day.	
	Per mile of sewer.	Per capita.
Alliance, Ohio. 15-in. pipe	195 000	.....
Clinton, Mass.	32 500	62.4
Concord, Mass. 18% of sewers from 0 to 16 ft. below ground-water level	43 000	.....
Framingham, Mass.	31 180	65
Gardner, Mass.	45 875	156
Madison, Wis. Trunk sewer. Dry weather	48 000	.....
Malden, Mass. 60% of sewers in wet ground	50 000	65 to 70
Marlboro, Mass.	59 540	144
Metropolitan (Boston) System, before making connections	40 000	.....
Natick, Mass	77 420 to 100 000	209
New Orleans, La. Good construction. Wet soil.	31 800 to 60 000	.....
Peoria, Ill. Vitrified pipe with brick sewers 15 gal. per sq. ft.	100 000	.....
Providence, R. I.	.....	47
Reading, Pa	5 172	.....
Westboro, Mass. 15-in. sewer in wet ground	1 320 000	.....
Worcester, Mass. 14 gal. per day per sq. ft. of interior brickwork	31 700 to 800 000	.....

For Baltimore, Md., F. P. Stearns, Past-President, Am. Soc. C. E., recommended from 30 000 to 80 000 gal. per mile per day, but in the actual design of the system it is understood that a per capita rate—usually 20 gal. per day—was used.

It was the opinion of the late Freeman C. Coffin, M. Am. Soc. C. E., that, with 6-in. pipe, and with careful work, the infiltration could be kept down to 4 000 gal. per mile per day.

In the case of a large system of sewerage, it is often more convenient, for general purposes, to assume the daily volume of infiltration per square mile. In the preliminary studies for the sewerage of Baltimore, the speaker used, as suggested by the Consulting Engineers, Messrs. Rudolph Hering and Samuel M. Gray, Members, Am. Soc. C. E., the quantity, 100 000 gal. per sq. mile, increased to 750 000 gal. in the low areas bordering the water front.

More recently, in some studies for the Metropolitan Sewerage Commission of New York, the capacity of sewers has been estimated to provide for 450 000 gal. per sq. mile daily in partly developed districts and 1 000 000 gal. per sq. mile in completely built up territory. Assuming 15 miles of sewer per sq. mile in the former case and 25 in the latter gives: for suburban areas, 30 000 gal., and for urban areas 40 000 gal., per mile of sewer.

Mr. Allen.

Assumptions or results in other cities are shown in Table 7.

TABLE 7.

	Infiltration, in gallons per day per square mile.
Louisville, Ky.	1 250 000
New Orleans, La.	1 250 000
Peoria, Ill. (observed)	50 000 to 100 000
San Francisco, Cal. (pipe sewers)	55 300
San Francisco, Cal. (brick sewers)	166 000
Union and Essex Cos., N. J. (observed)	350 000
Washington, D. C. (very wet weather)	620 000
Worcester, Mass.	450 000

The quantity of infiltration, especially for poorly laid brick sewers in a pervious, saturated soil, may be very great. The speaker recalls one case where the water spurted up through the invert of such a sewer in a number of places in jets at least the size of a pencil. On the other hand, concrete sewers may be made practically impervious by the proper proportioning and placing of the ingredients.

Although such sewers will be practically impervious under ordinary heads, it has been thought safer, in some cases, to resort to waterproofing. The first 3 590 ft. of the West Low-Level Interceptor at Baltimore was constructed of concrete with a 4-in. lining of brick. Between the concrete and the brick lining was placed membrane waterproofing consisting of two layers of 10-oz. burlap saturated with asphalt. The sewer varied from 74 to 84 in. in diameter, was provided with numerous house connections aggregating 2 700 ft. in length and was bulkheaded with timber at the upper end. It was laid on a marginal street along the water-front with the invert from 11 to 13 ft. below tide, and included a section of 100 ft. passing just below the bed of a tidal stream. When completed, the infiltration amounted to about 16 000 gal., or 0.223 gal. per sq. ft. of interior surface, per day, probably half of which leaked in around the bulkhead.

With pipe sewers, the only trouble, except with fractures, lies at the joint, and in wet ground such joints should be made with special care. In yielding ground, there should be a special foundation, unless the joint is made of some substance, like bitumen, that will remain to a certain degree plastic. For this purpose, the speaker has used cement, kneaded with tar pitch, with success. About ¼ mile of from 8 to 20-in. pipe laid in this way was tested by filling with water and found practically impervious under a head varying from 3 to 4 ft.

In hard ground, a mixture of sulphur and sand, or "leadite," may be preferred.

Whatever material is used should not be subject to deterioration or be either so plastic as to flow from the joint or so rigid as to crack under the conditions in which it is placed.

Mr. Allen.

The entire subject is one involving so many factors, some of them obscure, that probably nothing closer than a fair approximation for considerable lengths of sewer can ever be hoped for; and, for short lengths, a larger margin for error must be allowed. With a knowledge of the local conditions, however, and more complete data regarding existing sewers, the engineer should be able to avoid any serious error of design due to this cause.

Mr. Christian.

G. L. CHRISTIAN, M. AM. SOC. C. E.—The infiltration of ground-water into a sewer depends on so many variable conditions, none of which is exactly similar in any two sewers, that it would seem to be quite impossible to establish a standard of construction from which to determine definitely the degree of impermeability of any two sewers constructed in exactly similar ground, the depth of the ground-water being the same in both cases. It also makes a great difference whether the sewer is a sanitary one, pure and simple, or is part of a combined system. If the former, it is usually desirable to reduce the infiltration to a minimum, the joints being generally tightly caulked with oakum, then filled with cement mortar, and wound with cheese-cloth to hold the mortar in position until it is well set; spurs with loose covers are the exception, rather than the rule. In a combined system, the ends sought are, in a measure, quite different, part of its province being to lower the ground-water level permanently; the joints in pipe sewers are not caulked, being filled with mortar only. For many years it was the custom in the Borough of The Bronx, New York City, to put in a spur on all sewers every 3 ft., except at block intersections. Some years ago this practice was changed, and the distance is now 6 ft. These spurs have loose vitrified covers, and are capable of lowering the ground-water level permanently, regardless of the impermeability of the concrete or brick, or of the joints in pipe sewers.

The design of a combined system of sewers is based, primarily, on the intensity and duration of the maximum rain storm, or on the average of a series of heavy storms, in a given locality, and it is evident, therefore, that the quantity of ground-water infiltration in such a design is so small that it becomes negligible. As to the skill in doing the work, cementing the joints, mixing and placing the concrete, and the character of the aggregate, etc., if one is to depend on the contractor's opinion, it will be first-class in every particular. On the other hand, if the decision is left to the engineers in charge of the work, there are apt to be as many opinions as there are engineers. The character of the trench, as to whether it is wet or dry, is also a relative term, and is apt to be colored by local conditions, that is, what would be termed a wet trench in a region where ground-water is generally high, might mean something quite different if recorded by an engineer doing work in a region where the ground-water seldom appears in the trenches.

Mr. Christian.

A little more than ten years ago, the Sewerage and Water Board of New Orleans, La., made some careful observations, from which it was found that the actual infiltration into the sewers practically checked previous assumptions—that the quantity of ground-water to be provided for would be equal to 0.003 cu. ft. per sec. per acre, which is equal to 1 250 000 gal. per sq. mile in 24 hours. It might be said, in passing, that the ground-water level in New Orleans is very high, and all the sewers are below it. On the foregoing basis, there would be 32 miles of streets in 1 sq. mile, assuming it to be laid out in blocks 400 ft. long and 200 ft. wide, with streets uniformly 60 ft. wide. The infiltration, therefore, would average 39 000 gal. per mile per 24 hours. This figure is also used by the Borough of Brooklyn, New York City; in the Borough of Queens, the assumption is 75 000 gal. per mile per day. Since these observations were made, New Orleans has built some hundreds of miles of pipe sewers, and as all, or substantially all, of its sewage has to be pumped, it is possible to measure quite accurately the quantity of infiltration. It was the speaker's good fortune to witness the laying of some of the pipe, and he noted that the utmost care was taken to make the work water-tight. It was also noted that spurs were put in on each side, every 30 ft., opposite vacant property, the covers being tightly cemented inside the bell. Notwithstanding the care used, there is still considerable infiltration, the actual quantity being shown in the following extract:

GROUND-WATER FLOW, STATION A.*

Year beginning.	Ground-water per mile of sewer, per day, in gallons.
1907	55 000
1908	53 000
1909	51 000
1910	51 000
1911	48 000
1912	42 000

The author describes a concrete sewer in which the infiltration amounted to 0.8 gal. per day per sq. yd. of interior surface, which amounts to 7 300 gal. per mile per 24 hours. From the speaker's experience with the construction of concrete sewers, he would regard this as rather high, unless there was some leakage at the joints, or where each day's work joins that previously laid; and he suggests that a careful inspection would find that to be true.

In conclusion, it may be said that the design of a system of sanitary sewers in any town is a law unto itself; and, in designing such a system, it is wise to consider that the ground-water may have to be taken care of whether one wants to or not. Indeed, in the early stages

*Twenty-fourth Semi-annual Report of the Sewerage and Water Board of New Orleans, La., p. 100.

of such a system, with only a few connections, and many of the sewered streets sparsely populated, it is often desirable to have many unconnected spurs through which water may enter, in order to assist in flushing the sewer. As the district is built up and the houses one by one are connected with these spurs, the need for the ground-water will cease, the house sewage taking its place. Coincident with the building up of the district, it might be assumed that the paving of streets and of court yards is taking place, which would probably mean a corresponding lowering of the ground-water and a reduction of infiltration into the sewer. Mr. Christian.

E. KUICHLING, M. AM. SOC. C. E.—A number of useful suggestions, in regard to the form in which data pertaining to infiltration should be presented, have been made by the preceding speakers, so that little further remains to be said. The principal factors are the character of the soil, the extent to which it is saturated with ground-water, the elevation of the surface of this water above the top of the sewer, and the manner in which the sewer itself is built. An extensive stratum of sandy or gravelly soil often contains and yields a large volume of water, whereas little is delivered from clayey deposits; and in rocky strata seams are frequently encountered which deliver water very copiously. The quantity of water in the subsoil also varies with the daily and seasonal rainfall and the magnitude of the absorptive territory exposed thereto. It is obvious that much more ground-water will be found in the sandy soil at the bottom of a broad valley than in a similar soil on a narrow ridge. Mr. Kuichling.

One of the benefits usually claimed as resulting from a comprehensive system of sewers in a community is the permanent lowering of the existing ground-water table to the level of the sewers, thereby attaining dry cellars automatically and much less dampness of the air in dwellings. Observation has proved that this claim is well founded, and that in most cases shallow wells, in premises adjacent to streets provided with comparatively deep sewers, become permanently dry, even when the utmost care has been taken to make the sewers water-tight. Various reasons for this occurrence have been given in the case of sewers not equipped with under-drains. A common explanation is that the ground-water escapes by flowing along the smooth exterior surface of the main and lateral sewers and finally reaches the outfall; another one is that much less care is given to the construction of the numerous small lateral sewers, whereby the ground-water is enabled to enter through many defective joints and thus find its way into the well-built main sewer; and a third one is that, in the course of a year or two, many small cracks will develop in the entire sewer system, in consequence of settlements and unavoidable changes of temperature, thereby affording the ground-water access to the interior. Each of

Mr. Kuichling.

these explanations is satisfactory in some measure, but it is more likely that all the causes mentioned combine to accomplish the result.

In former years it was a frequent practice to build sewers with open joints at the bottom to admit the ground-water. An interesting measure of the quantity of such infiltration into an extensive sewer system built in this manner is given by Ernest Adam, Engineer of the Department of Streets, of Newark, N. J., in the discussion of a paper on the subject before the American Society of Municipal Improvements, on October 21st, 1903. He stated that many of the old brick sewers of Newark were made without mortar joints in the bottom, the result being a sewage flow of 48 000 000 gal. per day, though the water supply of the city was only 25 000 000 gal. per day. It may be remarked that in 1903 the population of Newark was about 268 500, and that on December 31st, 1903, the total length of all public and private sewers in that city was 198.7 miles.* The total area of Newark was then 14 976 acres, of which 10 679 acres was dry land surface, the remaining 4 297 acres being tidal meadows and water.† From these figures, it will be found that the stated daily infiltration of 23 000 000 gal. of ground-water into the sewer system of Newark corresponds to average rates of 85.7 gal. per capita, 115 752 gal. per mile of sewer, and 2 154 gal. per acre, or 1 378 401 gal. per sq. mile of dry land surface, per day.

It is reasonable to consider that the soil under and adjacent to inhabited buildings will eventually be drained in some manner, either directly by special systems of tiles, or indirectly by defective joints in the lateral sewer pipes; and it is also fair to assume that in most cases the ground-water thus intercepted will be discharged into the public sewers. The total area of the sewered territory, therefore, becomes a factor that must be taken into account, together with the adjacent uplands which may contribute to the flow of ground-water in the populous districts. In some cases much of the flow from the uplands is intercepted by the highest line of sewer, thereby greatly relieving the saturation of the lower ground; but in most instances the sewers are built in streets which cross the contours more or less at right angles, so that ample space is left between such streets for much of the upland ground-water to flow down to the lower districts and seek an entrance into the sewers there.

Some notion of the quantity of flowing ground-water per unit of tributary area may be gained from measurements of the yield of natural springs which have a well-defined water-shed. Numerous observations of this kind in central Switzerland have shown that the normal minimum yield of such springs is 154 gal. per acre of tributary water-shed per day, when derived from the fine-grained sandstone called

* Annual Report, Board of Street and Water Commissioners, Newark, N. J., 1903, p. 118.
† U. S. Census, Report on Cities, 1905, p. 111.

"molasse"; from four to six times that quantity when derived from moraines; and from eight to ten times that quantity when derived from the gravelly soils of valleys. Similar observations in Germany* indicate a minimum yield ranging from 154 to 924 gal. per acre of tributary water-shed per day; an average yield ranging from 462 to 1 232 gal.; and a maximum yield ranging from 770 to 4 620 gal. and upward, depending on the nature of the subsoil and the distance traversed by the percolating water. These yields from flowing springs may also be compared with the observed dry-season flow of rivers. In the New England and Middle States, the least monthly flow of streams having a drainage area of more than 100 sq. miles usually ranges from 0.10 to 0.25 cu. ft. per sq. mile per sec., which is equivalent to a yield of from 101 to 253 gal. per acre per day. This quantity is less than the aforesaid minimum yield of springs, but it must be remembered that in a considerable portion of a large water-shed the soil is generally unfavorable for absorption and percolation. Mr. Kuichling.

A better estimate of the quantity of ground-water that may reach a system of sewers is afforded by the results of numerous land-drainage experiments in England, France, Germany, and the United States. It was found that the quantity of rainfall which would be absorbed by the soil and percolate to the under-drains varied greatly with the character of the soil, the nature of its surface with regard to plant growth, the season of the year, and the magnitude of the rainfall during one or more days. A few references to such data may be of interest. J. Bailey Denton, a well-known English authority, states† that the maximum discharge measured by him from the under-drains of a large tract of free-soil land at Hinxworth took place in January, and was at the average rate of 0.16 cu. ft. per acre per min., which corresponds to 1 710 U. S. gal. per acre per day; and Charnock's observations, of the discharge of field under-drains at Holmfield during 1842-46, exhibit a maximum rate of 0.24 cu. ft. per acre per min., or 2 585 gal. per acre per day. French authorities, like Hervé-Mangon and Delacroix, state that the system of under-drains should have a capacity to remove a depth of at least 0.24 in. of water per day on the entire area, which corresponds to 6 517 gal. per acre per day. In Germany, the Silesian Agricultural Commission recommended that the under-drains should remove not less than 2 845 gal. per acre per day from low-lying flat areas, and 3 390 gal. from higher flat areas. Other German authorities on land drainage, like Vincent and Perels, advise the removal of 6 983 gal. per acre per day.

In the United States the subject of land drainage has recently been investigated by the Department of Agriculture, and in the re-

* Keilhack, "Grundwasser und Quellenkunde," Berlin, 1912, p. 447.

† "Sanitary Engineering," London, 1883 (?), p. 53.

Mr. Kuichling.

port of such observations in Illinois and Iowa, published in 1908,* it is stated that the tile under-drains of areas ranging from 400 to 1 040 acres of black open loam with a clay subsoil frequently gave a maximum discharge of 0.16 in. of depth in 24 hours, or 4 345 gal. per acre per day; also, that in some cases the under-drains were engorged, and that it would be better to remove a depth of 0.25 in. of water in 24 hours, or 6 788 gal. per acre per day. It may be noted that the lines of lateral drains were here from 100 to 250 ft. apart, and it was recommended that in heavier or more clayey soils they should be placed from 40 to 80 ft. apart.

The foregoing discharges from the under-drains of agricultural land were all carefully measured, and can be regarded as a good indication of the quantity of ground-water to be expected in the outskirts of a city. The figures range from 1 700 to 7 000 gal. per acre per day, or from 1 088 000 to 4 480 000 gal. per sq. mile per day, and relate to surface strata of ground from 3 to 4 ft. thick. It is very probable that much larger quantities would be found at times in strata 8 ft. or more in thickness, corresponding to sewered territory. Larger figures would also be obtained by using the results of the numerous percolation experiments which have been made with lysimeters of small area. The data submitted, however, suffice to show that much water is present in the subsoil after a period of heavy rainfall, and that it will enter the sewers under considerable head if opportunity is offered, as in the aforesaid case of the Newark sewers.

Two very instructive measurements of the infiltration into a system of earthenware pipe sewers were made at Stamford, Conn., a number of years ago. An aggregate of 13.38 miles of such sewers, ranging from 6 to 18 in. in diameter, had been laid in 1888 under the direction of the late Col. George E. Waring, Jr., in a wet gravelly soil under an area of 746 acres, or 1.16 sq. miles, of that city, and the infiltration was measured in May, 1889, when only 215 house connections had been made. The quantity was found to be 885 gal. per acre per day, or 566 400 gal. per sq. mile per day, or 49 340 gal. per mile of pipe per day, on the average. In September, 1892, when 530 house connections had been made, it was measured again by Col. Waring and John Bogart, M. Am. Soc. C. E., and was found to have increased to 1 689 gal. per acre, or 1 080 960 gal. per sq. mile, or 94 170 gal. per mile of pipe per day.† The reason for this large increase is doubtless that numerous joints had become defective, in the course of three years, and thus facilitated the admission of the ground-water.

† *Engineering Record*, 1892, II, p. 247.

Mr. Kuichling.

Numerous other data, not given in Table 1, will be found in two papers* on the subject by Mr. A. P. Folwell and E. D. Rich, M. Am. Soc. C. E. In Mr. Folwell's paper it is stated that in many sewer systems the infiltration is from 50 to 100% of the volume of house wastes; also that in Boston, Mass., Howard A. Carson, M. Am. Soc. C. E., estimated, from extensive measurements of the flow in the main sewerage system in 1889, that the infiltration was at the rate of 45 gal. per head of population per day, and in Malden, Mass., and Providence, R. I., it was, respectively, 65 and 47 gal. per head per day. It is also stated in the same paper that, in a length of about 4 000 ft. of brick sewer in East Orange, N. J., the rate of infiltration was 570 000 gal. per mile per day, while in 21 miles of 8-in. pipe sewer it was only about 9 000 gal. per mile per day; that in Malden, Mass., it was 50 000 gal. per mile per day on the average for 38 miles of sewer, and that, if only the length laid in wet ground were taken into account, it would be 83 000 gal. per mile per day; that in Westboro, Mass., in 1899, the infiltration into 1 950 ft. of 15-in. vitrified pipe sewer was 489 000 gal. per day, or at the rate of 1 320 300 gal. per mile per day, and in another section of the same sewer, 1 060 ft. long, it was at the rate of 610 000 gal. per mile per day; that in New York City the infiltration into a system of 5 miles of sewers, ranging from 8 to 24 in. in diameter, was found to be about 1 300 000 gal. per mile per day; and that, according to a report made in 1900 by X. H. Goodnough, M. Am. Soc. C. E., to the State Board of Health of Massachusetts, about 137 miles of sewers, ranging from 8 to 36 in. in diameter, had recently been constructed in and near Boston, in which the infiltration was at the average rate of 40 000 gal. per mile per day before any buildings had been connected thereto.

In Professor Rich's paper it is stated that in a 20-in. pipe sewer in Canton, Ohio, the infiltration was at the rate of 70 000 gal. per mile per day; and that in a 12-in. pipe sewer in New Bedford, Mass., it was 17 000 gal. per mile per day. These two papers also refer to some of the other data given in Table 1. In describing the sewage works of Fond lu Lac, Wis.,† George S. Pierson, M. Am. Soc. C. E., stated that the soil in which the sewers were laid was a very retentive red clay, and that the infiltration into the new 24-in. vitrified-pipe outlet sewer was carefully measured before the old sewers were connected thereto. This new sewer had been laid below the level of low water in the river, and was a little more than 7 000 ft. long. The infiltration was found to be less than 3.0 cu. ft. per min., and was regarded as very slight. From these figures we obtain in said 24-in. pipe a rate of 24 370 gal. per mile per day.

* *Engineering Record*, November 7th, 1903, p. 564, and October 1st, 1910, p. 377, respectively.

† *Engineering News*, May 22d, 1902, p. 411.

Mr. Kuichling.

In Table 2, Item No. 16, the author gives the average rate of infiltration into a reinforced concrete trunk sewer, 47 744 ft. long and ranging from 3.67 to 6.00 ft. in diameter, as being 0.8 gal. per day per sq. yd. of inside surface. This information is interesting, but it should be supplemented by naming the locality and describing the nature of the subsoil along the route. It would also have been useful if the author had stated explicitly that the aggregate interior surface of that sewer was 82 123 sq. yd., and that the measured infiltration was about 65 700 gal. per day, or at an average rate of 7 266 gal. per mile per day, which he leaves his readers to ascertain. In comparison with the other observations cited herein, this rate of infiltration is extremely low, and indicates either great water-tightness of the concrete, or an unusually dry subsoil at the time of measurement.

Reference was made in the foregoing to the probable increase in the quantity of infiltration in the course of time. This is to be expected, as small settlements of a sewer usually occur in soft ground, whereby cracks are produced. In the case of large pipes, such cracks are often due to the rapid settlement of the back-fill after a thorough saturation with water. The speaker has seen many miles of pipe sewer laid truly to line and grade originally, and has found them after ten or more years showing numerous irregularities of both line and grade, as well as many fractures. The same is also true of large brick and concrete sewers. In structures of this kind in wet ground, few have ever been built that did not exhibit considerable infiltration in the outset, and it is not likely that they became tighter subsequently if the external head of water remained unchanged. Cracks are likewise formed by the unavoidable contraction of the material when the temperature is lowered for a long period. It must be presumed, therefore, that the infiltration into old sewers will be greater than into new ones, other external conditions remaining the same.

The subject is important, notwithstanding that it has been treated very briefly in most textbooks on sewerage. It becomes specially prominent in a separate system when the sewage has to be pumped or treated in disposal works, and much of the initial capacity of the pipes is taken up by infiltering ground-water. It is hoped, therefore, that the author will succeed in eliciting and arranging in convenient form many additional trustworthy data. The proposition to estimate the infiltration by the square yard of interior surface is good, but it will probably be more convenient to express it in terms of per foot of diameter and a length of 100 ft., or even 1 000 ft. In any event, the nature of the subsoil and the height of the ground-water surface above the top of the sewer should be given, together with the date of the observation, and a brief description of the construction, and its age.

E. G. BRADBURY, M. AM. SOC. C. E. (by letter).—A sewer which does not carry a much larger flow during heavy rains than in dry weather is an exception, and, as the maximum flow must be provided for in the design, it is important that information regarding leakage should state the weather conditions. Probably most of the data on systems in use are based on the difference between the storm flow and that of dry periods. There is danger, however, of obtaining misleading figures from observations of leakage in new sewers, or in sewers without connections, when the ground-water is comparatively low, for they may show nothing more than the quantity of water which can make its way through the soil to the sewer. This should be borne in mind in comparing gaugings of leakage in the same sewer at different dates. Mr. Bradbury.

Under average conditions, few sewers are built which fail to permit the entrance of ground-water as fast as it can get to them, except during a heavy rain. This is demonstrated by the fact that water is seldom encountered in making connections to public sewers; it is also shown by the usual great increase of leakage coincident with storm conditions.

Unless the tightness of the work, rather than the imperviousness of the soil, is the controlling factor in the quantity of leakage, the size of the sewer evidently makes no difference. As this is seldom the case, it is not strange that there has been great difficulty in establishing any relation between diameter and leakage.

The writer has become convinced, much against his will, that, in the average location, with the ordinary method of making cement joints in pipe sewers, even with the most thorough supervision and careful inspection, the ground-water level immediately along the line of the sewer is invariably lowered to the level of the pipe, sloping upward from it at a gradient depending on the porosity of the soil, the surface topography, and other conditions. Under these circumstances, the original height of the ground-water enters into the problem of leakage only as it affects the flow toward the sewer.

It is seldom possible to determine without great effort the actual head on a sewer under working conditions. The writer believes that if data were limited to observations in time of heavy storm, when the tightness of the sewer is really put to test, something more remotely suggestive of a relation between size and leakage than has yet been produced, might result, although the surreptitious connection of roof drains, the inflow at manholes, and other possible means for the entrance of surface water, render this one of the most difficult subjects on which to obtain reliable information.

In the consideration of disposal plant design, it is necessary to have in mind both the ordinary infiltration, which is a function of soil

Mr. Bradbury.

and ground-water conditions, and the leakage in time of storm, which is governed more directly by the tightness of the construction. The one will cause a continuous flow, usually of small consequence, and the other an occasional heavy discharge which may overtax the capacity of piping, weirs, etc., and perhaps derange seriously the operation of tanks and filters. If the writer's views are correct, it is of course entirely fruitless to attempt to reduce normal infiltration to terms of diameter of pipe; but it should be possible, as already suggested, to establish some general relation which would be of value in estimating the maximum leakage during storm periods.

Mr. Pugh.

MARSHALL R. PUGH, M. AM. SOC. C. E. (by letter.)—The information contributed as a result of this timely paper is most interesting; and, in the hope that it may give the author material which will be of use in his closing discussion, the writer submits some observations made by him recently at Ocean Grove, N. J. South of Asbury Park is Neptune Township, the eastern part of which, known as Ocean Grove, is owned by the Camp Meeting Association. West of this are West Grove and Bradley Park, the greater part of which are included in what is known as "Sewer District No. 1." About a year after the construction of the sewerage system, the writer was retained to design sewage disposal works. The infiltration was so important a factor that a number of observations were made in the effort to determine it, and though the results are discordant in one or two particulars, it is thought that this is due chiefly to the impossibility of determining accurately the sewage flow as distinguished from the infiltration flow, other than by an estimate based on the houses sewered; there is also the great probability that one portion of the system is badly blocked up by sand, as will be noted later.

The system is divided into two parts, joining at a pumping station, which is being supplanted by a gravity outfall now under construction. The lengths and sizes of the sewers are shown in Table 8.

TABLE 8.

Item.	Length of north section, in feet.	Length of south section, in feet.	Length of entire system, in feet.	Remarks.

10-in. " " "	.....	1 000	1 000	Pipe in 3-ft. lengths, with cement joints.
8-in. " " "	13 325	23 460	36 785	
4-in. laterals	2 300	5 140	7 440	Two laterals or Y's every 50 ft. Soil wet, sandy loam.
Total pipe	17 150	33 000	50 150	
Brick manholes	36	72	108	

It will be noted that the number of linear feet of joint in the total length of the 4, 10, and 12-in. pipes, in both the north and south

sections of the system, corresponds so closely to the number of linear feet of joint in an equal length of 8-in. pipe, that, for all practical purposes, the system may be considered as consisting of the following: Mr. Pugh.

North section	3.25	miles of	8-in.	pipe.
South section	6.25	"	"	"
Entire system	9.50	"	"	"

The sewers are laid in a soil consisting partly of sandy loam and partly of sandy clay, or clayey sand, underlaid by gravel, and at times there may be a head of from 3 to 5 ft. of water on the pipes at the lower end of the system, and from 1 to 2 ft. at the upper end. The pipes are in 3-ft. lengths, with the ordinary cement joint, and have a slant or lateral on each side about every 50 ft. They were probably laid with only very ordinary care, and about 76 of the manholes were not brought quite up to street grade, being from 4 to 12 in. too low, and 9 of them still have temporary wooden covers. Some of the manholes were very leaky, and two of them had powerful jets of water shooting through the sides.

As nearly as could be ascertained, the infiltration at times was approximately 900 000 gal. per day, and the house sewage, with the few connections as yet made to the system, amounts to about 50 000 gal. per day, divided fairly equally between the two sections. A sewage ejector which was placed at the pumping station has been discontinued, and, during construction, a temporary pumping plant has been erected. From the records of this plant the following details have been obtained. The rainfall data are given in Table 9, and show what an all-important factor is the precipitation.

TABLE 9.—MONTHLY AVERAGES OF PRECIPITATION.

Month. 1912.	Total, in inches.	Greatest in 24 hours, in inches.	Total snow fall unmelted, in inches.
April	4.41	1.06	....
May	6.47	3.21	....
June	1.12	0.70	....

September	3.46	1.42	....
October	6.95	3.12	....
November	3.82	2.27	....
December	5.49	1.94	11.2

Table 10 shows the infiltration in the entire system, in a dry time, before any attempt had been made to diminish the ground-water flow into the pipes.

Table 11 shows the results after the tops of 76 manholes had been raised, and the leaky ones had been made tight.

Mr. Pugh.

At the time the repairs were made, the south section was disconnected, and Table 12 gives the infiltration in the north section alone. The much higher infiltration per mile in the north section may be due to the fact that a large part of the south section is in territory which is not built up, and there is reason to believe that a great many stoppages are caused by sand which is washed in at the manholes (the tops of 50 being below the grade of the streets), thus blocking off the escape of the ground-water through the sewers.

Then, too, the outlet of the north section is about 2 ft. lower than that of the south section, and is under a greater head of water. A part of the north section, also, runs through filled-in land which was formerly a swamp.

FIG. 2.

Mr. Pugh. It will be noted that the infiltration shown in Table 12 was for a somewhat drier time than that in Table 11.

TABLE 12.—INFILTRATION IN NORTH SECTION AFTER REPAIRS, AND IN A DRY PERIOD.

Date. 1912.	Precipitation, in inches.	Hours of pumping.	Gallons pumped.	Approximate infiltration, in gallons per day.	Infiltration, in gallons per day per mile of sewer.	Infiltration, in gallons per day per inch diameter of pipe per mile of sewer.
Oct. 8.....	....	4.45	72 000	47 000	14 461	1 808
9.....	....	4.40	74 600	49 600	15 261	1 907
10.....	....	4.45	72 000	47 000	14 461	1 808
11.....	0.76	5.0	80 000	55 000	16 930	2 116
12.....	0.01	4.40	74 600	49 600	15 261	1 907
13.....	....	4.30	73 300	48 300	14 861	1 857
14.....	....	4.40	74 600	49 600	15 261	1 907
15.....	....	4.45	72 000	47 000	14 461	1 808

It is obvious that there cannot be more infiltration in the north section than in the entire system; which shows that the estimated sewage flow is open to suspicion, and, in all likelihood, is not properly proportioned between the two sections. The fact that the total pumpage only fell off from 94 700 to 72 000 when two-thirds of the system was cut out, showed, however, the general correctness of the higher infiltration figures in the north section.

The latter part of October was wet, and the flows shown in Table 13 clearly demonstrate the effect of the rise in the ground-water in winter. Mr. Pugh.

At first sight it appears strange that the 0.86 in. of precipitation on December 24th did not show in the sewer flow, but it is easily accounted for, as it consisted of a 10-in. fall of snow, on frozen ground, followed on the 27th by a cold rain, which increased the flow somewhat. On the 29th there was a thaw, and a heavy downpour on the 30th, the result being at once visible. The cause of the increase on December 16th is difficult to explain.

Fig. 2 shows graphically the precipitation, and the infiltration, in gallons per day per mile of sewer, and in gallons per day per inch of diameter of pipe per mile of sewer.

These units appeal to the writer as the most convenient and satisfactory for general use, although the latter is open to the serious objection that manholes, slants, and laterals are frequently as numerous on the smaller sewers as on the larger ones, and they undoubtedly are responsible for much leakage.

JOHN N. BROOKS, JUN. AM. SOC. C. E. (by letter).—In Table 14, which is a summary of the data presented in the discussion of this paper, the writer has included all the sewers mentioned, where sufficient data were given to permit of expressing the infiltration in gallons per mile of sewer. Four sewers in Table 1, for which the infiltration was stated only as a percentage of the total capacity of the sewer, have been omitted. Mr. Brooks.

The writer has examined the original sources of the data presented and has checked the figures in Table 14 with the original statements.

From the very complete data on the sewers of Ocean Grove, N. J., presented by Mr. Pugh, the writer has selected the quantities given in Tables 12 and 13 as representative results, and the figures in Table 14 for the Ocean Grove sewers are averages of the quantities in those tables.

In order to reduce Table 14 to a convenient size, certain abbreviations have been used, as noted at the bottom of that table.

In Columns 15, 16, and 17 the quantity of infiltration is expressed in three units.

In Column 15 it is given in gallons per 24 hours per foot of joint. This is the rational unit for pipe sewers, as suggested in the paper.

In Column 16 it is expressed in gallons per 24 hours per inch of diameter per mile of sewer. This unit is suggested by Mr. Gregory, as an improvement on that proposed by the writer for concrete and brick sewers. The writer accepts Mr. Gregory's unit as rational and convenient for both pipe and concrete or brick sewers. In examining the figures in Column 16 it should be borne in mind that though this

Mr. Brooks.

unit gives a fair comparison between the infiltration in two sewers of similar type, vitrified pipe or concrete, it does not give a fair comparison between sewers of different types, because the entire length of a concrete sewer is porous, and, in a pipe sewer, infiltration is supposed to take place only at the joints.

In Table 5 Mr. Gregory computes the quantity of infiltration expressed in this unit for seven sewers, two of which (Items 11 and 17)

H. S. = Horse shoe, R. = Rectangular, B. = Brick, C. = Concrete, V. P. = Vitrified pipe, C. = Clay.

Mr. Brooks.

ter of an equivalent circle in computing the quantity of infiltration, we have, for the Altoona sewer, 5 390 gal. per day per inch of diameter per mile of sewer, and 120 for the Columbus sewer, instead of 6 830 and 151, as computed by Mr. Gregory.

In Column 17 the infiltration is given in gallons per 24 hours per mile of sewer. This unit is retained as the most useful in cases where insufficient data are presented for the use of the preceding units.

Mr. Allen calls attention to the fact that in a collecting system a large proportion of the infiltration will come from laterals. An attempt has been made to recognize this factor by the addition of Column 11 in Table 14, stating the size and spacing of laterals.

In an impervious soil it may happen that a sewer, however carefully built, will be sufficiently porous to admit ground-water as fast as the soil can carry it. That is to say, the infiltration will be limited, not by the imperviousness of the sewer, but by the quantity of ground-water transmitted to it by the surrounding soil. Mr. Bradbury states that this is usually the case. In such a case the infiltration must be estimated as equal to the ground-water flow, data on which are presented by Messrs. Kuichling and Christian.

The data presented by Mr. Rankin, for the Joint Outlet Sewer, in Newark, and by Mr. Pugh, for the sewers of Ocean Grove, N. J., show that the quantity of infiltration follows closely the rainfall, indicating the direct dependence of the quantity of infiltration on the head of ground-water. The greatly increased infiltration into the Ocean Grove sewers in winter with a high ground-water level, as compared with that of the same sewers in summer, illustrates the same point.

The divergence of opinion among engineers as to the quantity of infiltration to be expected is well illustrated by a comparison of the comments of Mr. Christian and Mr. Kuichling on the infiltration reported by the writer for the Bronx Valley Sewer. Mr. Kuichling says:

"In comparison with the other observations cited herein, this rate of infiltration [0.8 gal. per day per sq. yd. of interior surface] is extremely low, and indicates either great water-tightness of the concrete, or an unusually dry subsoil at the time of measurement."

Mr. Christian says:

"From the speaker's experience with the construction of concrete sewers, he would regard this [infiltration] as rather high, unless there was some leakage at the joints, or where each day's work joins that previously laid; and he suggests that a careful inspection would find that to be true."

As noted in the paper, such an inspection was made, and no leakage was observed; and, further, the subsoil could not have been "unusually dry" because the sewer for its entire length lay beside, and, for a considerable portion of its length, directly beneath, a flowing stream. The low infiltration, therefore, is apparently due to tight concrete.

Mr. Brooks.

The data collected in Table 14 indicate that the quantity of infiltration is dependent on so many conditions, and may vary between such wide limits under apparently similar conditions, that the estimate of this flow in a sewer to be constructed, is a matter calling for the exercise of judgment enlightened by experience, rather than an attempt to apply a mathematical formula.

Paper No. 1277

FREMANTLE GRAVING DOCK: STEEL DAM CONSTRUCTION FOR NORTH WALL.*

By Joshua Fielden Ramsbotham, Assoc. M. Am. Soc. C. E.

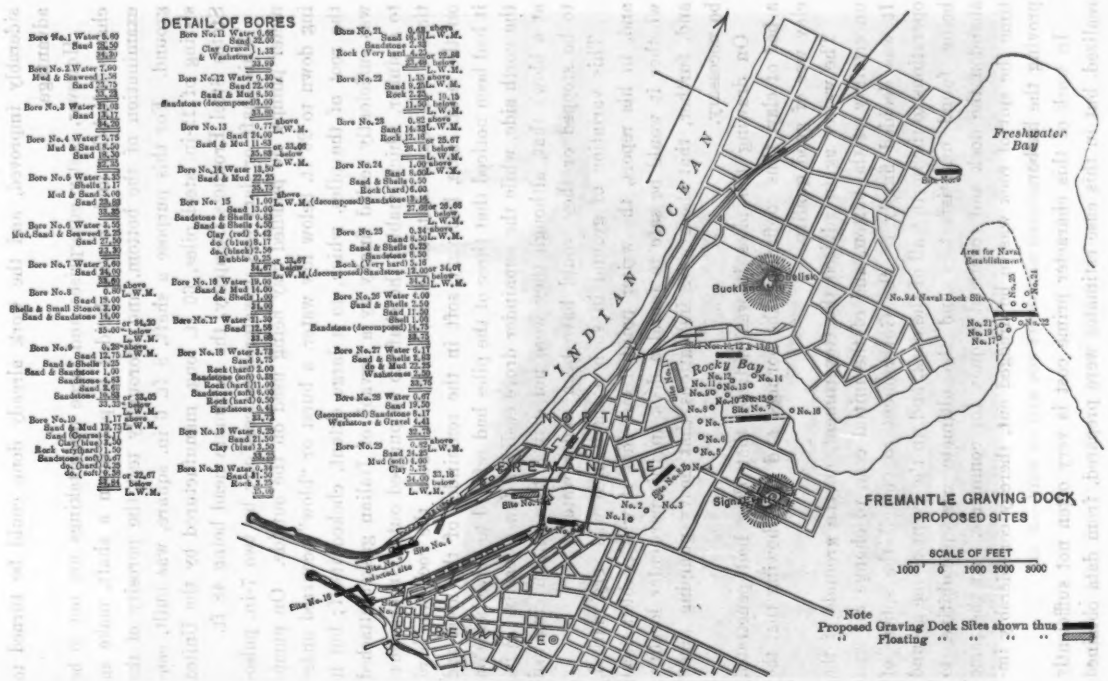
With Discussion by Messrs. A. R. Archer, Herbert E. Bellamy, and Joshua Fielden Ramsbotham.

Toward the end of 1910, the writer was appointed by the Western Australian Government to design and carry out departmentally the Fremantle Graving Dock, the construction of which was in hand under the Engineer-in-Chief of the Public Works Department, Mr. James Thompson. When the writer took charge, an area had been dredged for the dock to a depth of 49 ft. below low-water mark, the ordinary rise of tide being about 3 ft. 6 in. and extraordinary tides rising only 6 ft. The tidal rise and fall are irregular and intermittent, and, to a large extent, depend on the direction of the wind.

The whole policy of future work depended on the core borings, which had been taken previous to the writer's appointment. From these 73 core borings (two typical bores are shown on Fig. 3) it will be noted that the ground consisted generally of a calcareous sandstone containing pockets of sand, with a bed of clay at a lower level.

After careful consideration and examination of the dredged spoil, the writer advised the Engineer-in-Chief to recommend the Government to abandon the site. From the plan, Fig. 1, it will be noted that by doing this, the entrance and fairway to the harbor would be con-

* Presented at the meeting of April 2d, 1913.



DETAIL OF BORES
Bore No.1 Water 5.99

FIG. 1.

siderably improved, and the work already done could be turned to advantage.

However, costly enterprises and large undertakings are not to be changed lightly, and it was decided to put down a shaft, make an examination of the bottom, and thoroughly test the porosity of the ground. For this purpose a shaft, 8 ft. 6 in. square, was built, consisting of 12-in. steel piles, 60 ft. long, manufactured by the United States Steel Products Company, the minimum head being 48 ft.

This shaft or dam was unwatered successfully by two 7-in. pulsometer pumps, no puddled clay being used on the outside. On pumping down to 26 ft. below low water, a burst or "blow" occurred under the root of the piles, which, to a large extent, choked itself; but it was sufficiently sealed finally by a "swab" of Italian gasket attached to a sinker, which enabled the shaft to be pumped out. On examination it was found that, at 48 ft. below low water, the rock was hard on the north side, but very soft in the remainder of the area, and it had been noticed that three of the piles had refused to drive home on the north side, while the remainder drove easily, a few so easily (1½ in. at a blow) that, although they were not driven to a set, driving had to be stopped or they would have been under water.

This variation of ground in such a small area was very marked, and, in his report, the writer pointed out that it was problematical whether it would be safe to found a dock in this particular locality, and, further, that there were indications that heavy pumping would be necessary.

On drawing the piles it was noticed that they had penetrated a bed of clay, thus confirming the borings, and also showing that the clay was of good quality.

The writer again advised the Government, on the grounds of the uncertainty of the bottom and of the initial cost, to change the site. It was decided finally by the Government to curtail the sphere of operations to the north wall of the dock, and, in the event of the ground being found unsatisfactory and the ultimate cost prohibitive, to abandon the dock and construct a quay for commerce. At the same time the spit of rock was to be dredged out, thereby considerably improving the harbor.

In work of this character prime cost is very often not sufficiently realized. but in this case estimates were prepared, from data obtained

FIG. 2.—VIEW OF DAM FOR FREMANTLE GRAVING DOCK.

from similar work, accounting for every item except pumping, which, considering that it was deemed impossible to ascertain, was left as an unknown quantity, with the intimation that the cost would be excessive. From the borings it will be seen that the material in which the piles were driven consisted of a hard limestone cap, coral, clay, and sandstone, the limestone cap being particularly hard in a portion of the pumping station, where a total of 60 ft. of driving had to be done, or, in other words, each pile had to be driven 60 ft. into the ground.

Public tenders were called for, and the lowest, that of the United States Steel Products Company, was accepted.

It is worthy of record that, in driving one of the steel piles, a 45-lb. per yd. steel rail was cut into two pieces, one section being found subsequently on excavating within the dam.

From a driving point of view, these piles are admirable, as the cross-sectional area, or displacement, is small compared with the covering area of the face of the pile, it being very much like driving a knife into a pat of butter, and yet, although whippy, with care very few piles were damaged; and, further, in shipping 1 900 piles, 60 ft. long, from the United States to Western Australia, not one was damaged, and only two were damaged in handling for driving. In handling from the steamer it was found best to have 8 by 3½-in. fishplates of Oregon pine, 10 ft. long, with a sling chain around them, placed 20 ft. from one end.

In handling, preparatory to driving, a single piece of 7 by 3-in. Oregon pine, 8 ft. long, was found best, and was slung one-third from one end.

Design of Dam.—The design of the dam, to a large extent, was assisted by the results attained in the small trial shaft. The object was to have as few sets of timber as possible, consistent with safety, and as all the shoring had to be done by divers, both from the point of view of economy and speed, this was most important.

The points that require careful watching in designing a dam are:

1.—Strength of skin (which can be taken as a beam supported at several points, and to an extent this is advantageous, as benefit is derived from contraflexure);
2.—Strength of walings or longitudinal beams;
3.—Strength of shores or transverse columns; and,
4.—Factor of safety on the dam.

Great benefit may be derived from working in water, as it is possible to calculate exactly the loads which the various members of the structure have to carry; and, needless to say, the object is to place the walings and shores so that they and also the skin will have an ample factor of safety.

For many reasons, it was decided to use jarrah for the walings and shores, and, as the writer had no previous knowledge of this timber, it was with no small interest that he watched its behavior. As jarrah is a product of Western Australia, a supply could be obtained at the reasonable price of 2 shillings per cu. ft. delivered in railway trucks on the job. It is nearly always heavier than water, and consequently will sink, which is an advantage for divers' work; its strength lies in its outer fibers, therefore it is safer to use hewn than sawn jarrah, as hewers will always hew with the grain.

As heart timber was being accepted in this case, the heart was in the neutral axis or center of the log; further, as jarrah is short in grain, it is certainly advisable not to accept sawn logs, as there is danger of the grain running out unless great care is exercised. In addition to this, as the dam was being built in sections, the divers keeping ahead of the pumped-out sections, the *Teredo navalis* had to be guarded against, and jarrah is the best local timber for resisting this pest.

In designing the dam, a maximum tide of 6 ft. 6 in. above low-water mark was considered (this is seldom if ever reached), and the dredged bottom was taken at 49 ft. 0 in. below low-water mark, thus giving a total calculated head of 55 ft. 6 in., which in actual work could be taken at 51 ft. Further, clay puddle was tipped to a minimum height of 9 ft. at the skin of the dam, in order to make a seal of the porous rock, and, at the same time, reduce considerably the head on the dam. Assuming that the shores are placed at 10-ft. centers horizontally, the pressure on a strip of dam, 10 ft. wide, is:

$$\frac{55 \text{ ft. } 6 \text{ in.} \times 10 \times 55 \text{ ft. } 6 \text{ in.} \times 64}{2 \times 2\,240} = 440 \text{ tons.}$$

The strength of a jarrah beam, loaded uniformly and supported at each end, is given by the following formula, in which K is a constant which has been ascertained to be 13; B is the breadth, and is

assumed to be 14 in.; D is the depth, and is assumed to be 14 in.; and L is the length, which is 9 ft., or 108 in.:

$$\text{Breaking weight, in hundredweights} = \frac{8KBD^2}{L}$$
$$= \frac{8 \times 13 \times 14 \times 14 \times 14}{108}$$
$$= 2{,}642 \text{ cwt.}$$
$$= 132 \text{ tons.}$$

Thus, using a factor of safety of 3, the safe load $= \frac{132}{3} = 44$ tons.

Thus the number of walings or beams required is $\frac{440}{44} = 10$.

It is worthy of note that, in calculating the strength of walings, no allowance was made for the fact that the beams were continuous over several supports, thus giving a greater margin of safety than is shown. The shores or columns were 12 in. square and 22 ft. 8 in. long, and were worked out by Gordon's formula in a similar manner, one end being considered rounded and the other fixed, the factor of safety being slightly less than 3.

When the driving of the piles was completed, it was found that it was impracticable to keep them absolutely vertical or in line, due to the hard nature of the ground; and, although the divers packed between all piles and the back of the walings, a certain amount of unquestionable bridging or arching took place. This was so marked that, without any further delay, additional shores were placed alongside those already in, the factor of safety of the walings thus being increased to $3\frac{3}{4}$ and the shores to almost $4\frac{1}{2}$.

The skin of the dam is important, and the largest span was settled empirically from observations taken while pumping out the small trial shaft, and was a clear span of 8 ft. 8 in., subjected to an actual head of 17 ft. 7 in. of water. In the dam in question, the span was 8 ft. 7 in. between the second and third shores. Between the first and second shores the clear span is 9 ft. 11 in., and, although allowance was made for a high tide of 6 ft. 6 in., it is seldom if ever reached. From the writer's experience, a clear span of 8 ft. 8 in., subjected to a mean head of 16 ft. 8 in., is quite satisfactory, the total load on a pile being 4.88 tons, and the maximum stress about 10 tons per sq. in. From the foregoing it may be noted that uniformity has been reached in the temporary dam, and certainly not at the expense of safety.

The embayment for the pumping station offered difficulties outside the ordinary section of the dam, and the writer proposes to touch on it briefly at this stage.

The maximum length of the shores (shown on Fig. 3) is 57 ft. They were built up of 14 by 14-in. jarrah logs, with fish-plates at top and bottom consisting of 20-ft. half timbers of jarrah (14 by 7 in.), without heart, held together with fourteen 1-in. bolts. Care was taken to alter the lengths of the timbers in each line of shores so as to alter the position of the joint; this is important.

In turn, these shores were subdivided, by vertical and horizontal "toms", into small shores 18 ft. in length. Each tier of shores was carefully anchored to the line below by long bolts, and, during excavating, they were invariably kept packed down to the ground by relieving "toms". Further, a deflection of 1½ in. in the center was allowed so as to overcome any tendency of the shore to bend upward or break, and, in addition, there was always considerable weight on the top setting, due to the staging carrying the crane and railway tracks. No trouble was experienced in any way from these shores, the factor of safety on them being 5.27.

Practical Points on Construction.—Important points were observed during the construction, and perhaps the writer may be pardoned for stating them in some detail.

First, it is of the utmost importance that the female end of the pile should always be driven over the male, and not the male in the female. If the latter is done, a column of spoil will be compressed under the male in the jaws of the female which will finally end in the bursting of the structure. To enable rapid progress two piles were split down the center and a double male pile manufactured, riveting a 6 by 3 by ½-in. T-iron on the back for stiffness. By this means two piling machines were utilized; one was built on an outrigger, with one end supported on staging and the other end on a log on the ground, the piling frame, winch, boiler, etc., being self-contained and easily moved. The other machine was on a barge, and was also self-contained.

In passing, it may be mentioned that the piling winches were made by the Lidgerwood Manufacturing Company (No. 72½), and were capable of working a 2-ton "tup" or hammer. A 30-cwt. tup was found to be best in practice, and a good man can get 20 blows per

Fig. 3.

min., a 5-ft. drop being quite sufficient. From the plan it will be noticed that provisions were made for subdividing the dam every 100 ft. by using T-piles, a male and female T-pile being left opposite each other; this was done in accordance with the catalogue of the makers of the piling. When the time came to drive, however, difficulties arose, and as they could be overcome very easily by the manufacturers of the piles, the writer mentions them, hoping that he may thus assist others.

First.—By having a female T-pile, it would mean, in the ordinary course, driving a male pile in it; as previously mentioned, if this is done, it will end in disaster, unless the spoil in which it is driven is a fluid mud. To overcome this, a double female pile was made, and on one side a strip of iron, 1 in. wide and ½ in. thick, was tapped on the outside on one jaw in order to make a lock. The jaws were then interlocked, and the pile was driven, there being clearance for any displacement of spoil between the jaws.

Second.—Great care must be exercised in keeping the two T-piles parallel, otherwise obvious difficulties will arise in closing. The manufacturers could overcome this by making an expanding pile with slotted holes, so as to enable the closing pile to vary its width from the top to the bottom.

Third.—Even with parallel piles, it is extremely hard to marry in with the closing pile, and it is desirable to have a few piles of different width.

Fourth.—If a male T-pile is used at each side of the dam, as should be done, a double female pile is required with which to end, and such should be supplied by the manufacturers.

Fifth.—If a male T-pile is urgently required, it can easily be made, and at small cost, by riveting an ordinary 45-lb. rail to an ordinary pile.

Sixth.—In driving the piles, the moment one seems to be hardening up and has not reached the required depth, another should be driven ahead of it, and, if necessary, this should be repeated until there are signs of having reached soft ground again. It is then possible to exert more force, but even then abuse must not be resorted to, as there is grave danger of parting the piles, but if this does happen by having driven ahead, that danger is limited in extent and is only local.

From the cross-section it will be noted that the piles toward the shore were driven on the side of a cliff, which had been left in a very irregular condition by the dredging, and added considerably to the difficulties of the piling gang; it also rather retarded the progress, as some piles had to be drawn. A fair month's work for the two machines, there being two 8-hour shifts on each machine, averaged 370 piles, representing 9 361 lin. ft. of driving.

The first steel pile was driven on July 14th, 1911, and pumping was started in Dam Section No. 1 on November 16th, the entire dam being framed by the end of that year.

It is interesting to note that 1 872 steel piles were used, representing 47 385 lin. ft., or 9 miles of actual driving. In the first dam section there were 401 piles, which gives 24 060 lin. ft. of joint, representing very nearly 5 miles of joint.

Constructional Work.—At the top of the piles it will be noted that a substantial back-strap is provided, consisting of a 12 by 12-in. jarrah log. This strap was bolted through every fourth steel pile and the inside waling by a 1-in. bolt. Although no trouble was experienced, the writer would recommend 1¼-in. bolts for this purpose.

The walings were hung by two 1-in. bolts from the top timber, breaking joint, and between each there were placed distance pieces or "toms", cut to the required lengths; in this way the necessary accuracy of placing the walings by the divers was assured, and the progress was rapid.

Owing to the fact that the piles were over at the heads and out of plumb, there was a tendency to lift the walings, so that the "toms" and through bolts play an active part, and require most careful watching, as in the event of any small movement, a disaster of great magnitude to life might result, and almost without any warning. No movement was observed, but careful examinations were made and soundings were taken every 10 ft. daily on the clay outside the dam.

When necessary, packings were placed between the walings and the steel piles by the divers, and, when the dam was pumped dry, their work was found to have been done both creditably and satisfactorily.

Across the embayment to the pumping station some interesting work was done. As there was only a sloped bank to which to shore, it was obvious that some other method would have to be adopted. Accordingly, half timbers were bolted on the long shores, top and

bottom, and packed against the top and bottom of the fish-plates which served to build up the long shores and for which purpose fourteen 1-in. bolts were used. This is shown clearly by the section at *B B*, Fig. 3.

King piles, composed of two 14 by 14-in. jarrah logs, bolted side by side, were driven into the ground, and shores were then placed by the diver from the waling to the king pile, and again shored to the bolted half timbers, as previously mentioned, when the dam was pumped down.

As soon as the water was below each setting, the long shores were put in, and all "tomming" and "lacing" done at once.

Pumping Plant.—Three 15-in., centrifugal pumps were used, each capable of working as follows:

Total head, in feet.	Revolutions per minute.	Capacity, in gallons per minute.
40	500	4 900.
50	500	4 400.
60	500	3 800.

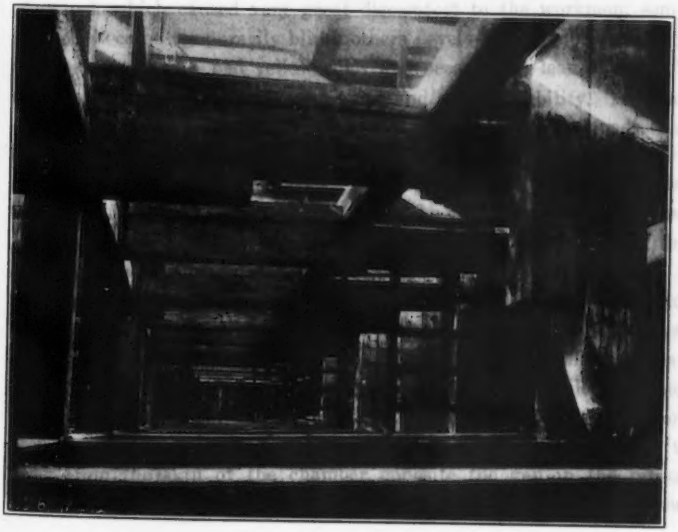
The weight of the pumps and engine combined was about 4 tons, so that they were within convenient compass of the 5-ton cranes in use.

Allen "Conqueror" centrifugal pumps were used, and were direct-coupled to "Allen" enclosed two-cylinder compound engines. Each engine developed 110 h.p. at 450 rev. per min. and a steam pressure of 110 lb. per sq. in., the diameter of the cylinders being 10 and 14 in., and the length of the stroke 6½ in.

The boilers were made by Ruston, Proctor and Company, Limited, of Lincoln, England, and at first consisted of two semi-portable, multi-tubular boilers, each having a grate area of 26 sq. ft., capable of evaporating 4 000 lb. of steam per hour, with a pressure of 150 lb. per sq. in., the heating surface being 814 sq. ft. Their length over all was 20 ft. 1 in., their diameter, 4 ft. 6½ in., and each contained 105 2½-in. tubes. The weight of each boiler without fittings was 9 tons 2 cwt., and with fittings, 11½ tons.

Pumping was started on November 16th, 1911, and continued without intermission until July 23d, 1912. It was found necessary to add another boiler, due partly to the low calorific value of the coal used, but mainly on account of the necessity for cleaning and washing out the boilers, such operations being prejudicial to the continuous running

FIG. 4.—EXCAVATION FOR PUMPING STATION, FREMANTLE GRAVING DOCK.



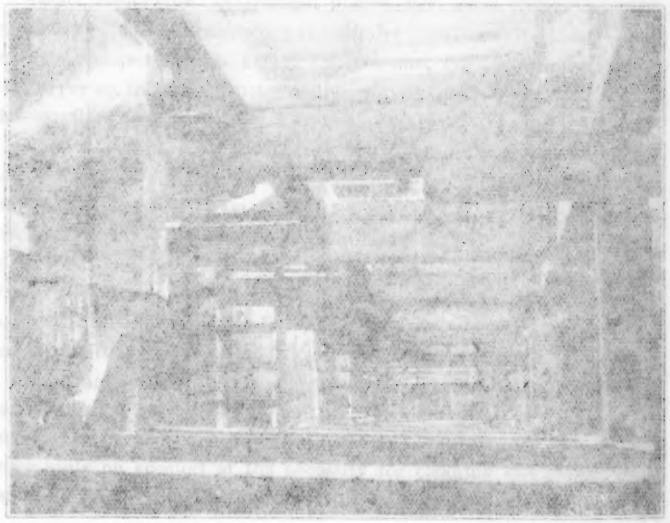


FIG. 5.—METHOD OF SHORING DAM FOR FREMANTLE GRAVING DOCK.

of three pumps. In addition, one 7-in. steam pulsometer pump was used for well sinking, etc.

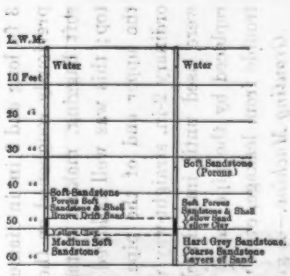
The Imperial Electric and Engineering Company, of Perth, Western Australia, was the local agent for the above firms, and it is satisfactory to note that from start to finish there were no breakdowns, a result which is most satisfactory when the entire work is at the mercy of the pumps.

Work Done Under Cover of the Temporary Dams.—The pumps were first placed in the bays by the bulkhead, one pump taking up one bay of the dam. They were supported on a staging well braced, checked, and bolted to timber piles driven inside the dam. At first all three pumps were engaged, but gradually a reduction in the pumping took place. The area to be unwatered was 10 453 sq. ft.

After excavating some 20 ft., it was found that, due to the hardness of the rock in that locality, some of the piles had not driven. On reaching a level of 20 ft. below low-water mark, it was decided to excavate a 10 by 7½-ft. well for the temporary pumps, down to 43 ft. below low-water mark, within steel piles, and in the center of the main pumping station, as shown on Fig. 6. This was done, using a 7-in. pulsometer for sinking purposes. Sulphureted hydrogen gas was encountered, which caused very great discomfort to the workmen, some of whom became temporarily blind, others developed eczema, and every one concerned had a bad yellow color and became "as lean as crows", suffering from severe attacks of cramps and general debility. A silver coin placed in the water became of a bronze color in a few seconds. In front of the well, the piles were of steel cut into 5-ft. lengths, and a grating was provided which worked in a groove, so that, when excavating in the body of the dam, a 5-ft. length would be removed, and the pumps were protected by the grating. This answered admirably, and no inconvenience was caused by the silting up of the rose on the pumps.

Unfortunately, after everything had been completed in the shaft, a blow occurred in the bottom of the well, and, although not serious, it was necessary to discover its source. The first thought was that the flow might be coming under the ground where the piles had not driven satisfactorily, or, in other words, the hydraulic gradient had not been cut off. To ascertain this, holes, 30 ft. deep, were drilled 5 ft. away from the skin of the chamber opposite the gap in the piling and 5 centers apart; on drilling to a depth of 28 ft., or 48 ft. below

low-water mark, the drill dropped 2 ft. and water spurted up through the hole. It was thought that the source of the trouble had been found.



To try and trace the flow of water, a strong solution of potassium permanganate ($KMn\,O_4$) was forced under pressure down the drilled holes, but no results were observed. On mentioning the matter to Mr. E. A. Mann, the Government Analyst, he pointed out that the sulphureted hydrogen would change the purple color of the permanganate rapidly to brown, and then to a colorless solution, this being due to the sulphureted hydrogen ($H_2\,S$) changing the permanganate to an oxide of manganese with a deposition of pure sulphur. Some sulphate due to the formation of sulphuric acid ($H_2\,S\,O_4$) is also probably formed.

Mr. Mann kindly gave this question of the presence of sulphureted gas his attention, as it was very noticeable that there was considerable corrosion on the steel piling, in addition to the other features mentioned previously. The writer will refer to this matter later.

For tracing the flow of water, Mr. Mann recommended fluorescein or resorcinolphthalein ($C_2\,H_{12}\,O_5$), a few grains of which gave an extremely bright green fluorescence, which did not lose its color even in a considerable volume of water.

Almost immediately a flow of water was traced in the main dam, a few seconds only elapsing after putting in a few grains of fluorescein before its presence was apparent. Accordingly, systematic drilling and grouting under pressure was adopted, and, as it was novel to the writer, he may be pardoned for referring to the subject in some detail.

Drilling.—It was found advisable, from experience, first to procure a 4-in. iron pipe, from 18 to 24 in. long, and concrete it flush with the ground with a 12-in. cube of concrete, as shown on Fig. 6. This was used for drilling purposes, and prevented the ground from being fretted by the drill; it also stopped any leakage during grouting under pressure. Machine drills and compressed air were available for drilling, but the strata were such as to render them useless, and it was found to be cheaper to jump the holes down by hand. A chisel drill, 3 in. across the bit, was used, and, in the pumping-station area, 30 ft. was the minimum depth of hole drilled. On reaching a level of 48 ft. below low-water mark, as previously mentioned, a cave 2 ft.

TYPICAL BORES

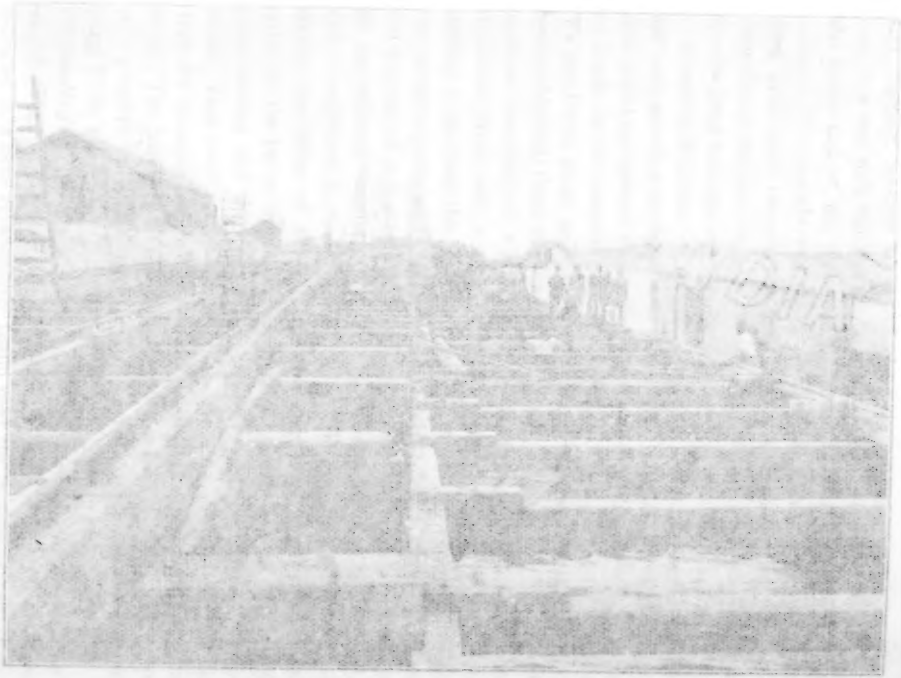
GROUTING PIPE

POSITION OF PUMPS, AND PLAN OF GROUTING BORES

FIG. 6.

deep was entered, and a strong flow of water under pressure was set free. The hole having been drilled to the requisite level, an iron pipe, 3 ft. long and 2 in. in diameter, was hammered in. This pipe had been previously roughened on the outside and tightly wound with strips of soft bagging, making a tapered shape very much like an ordinary top; this was well tallowed and tightly bound with strong twine; on the upper end of the pipe was a thread on which was screwed an ordinary 2-in. straight-way valve. In some cases tapered wooden plugs were used until immediately previous to grouting, when they were replaced by the pipe valve. It may be mentioned that there was no trouble from leakage, even under a pressure of 75 lb. per sq. in.



Grouting Machine.—A grouting machine, Fig. 9, similar to the Canniff tank grouting machine* was made. Small modifications, which possibly might be regarded as improvements were introduced, such as having no bends in the pressure pipes, such bends being obviated by having T's fitted with plugs and used for cleaning purposes. When the pipes became blocked, these plugs were found to be invaluable. The Canniff machine consisted of a steel tank, 2 ft. 7½ in. high and 18 in. in diameter, fitted with a movable hopper on top of a hinged door, a grating 9 in. from the bottom, to prevent lumps from going through the pressure pipes, and an air diffuser again below, which also served the purpose of a grating. The pressure was admitted to a T again by an ordinary coupling, and had a screw-down valve on each side and, in addition, a straight-way valve on the grout exit pipe. By a simple regulation of these valves, air pressures could be admitted either at the top or bottom, by which means the grout was prevented from settling and the clogging of the pipes was reduced to a minimum. Legs were provided on the bottom, and on the top flange rings for slinging, so that the machine could be moved readily by a crane. The tank was built in the Government workshops, and tested at a pressure of 100 lb. per sq. in., the maximum working pressure being 75 lb. per sq. in.

Grouting Under Pressure.—A systematic plan of grouting was arranged (Fig. 6). By using fluorescein, a flow of water had been indicated in a cave subsequently found near the locality of the temporary pumps (first position); in addition to this, a flow of water was

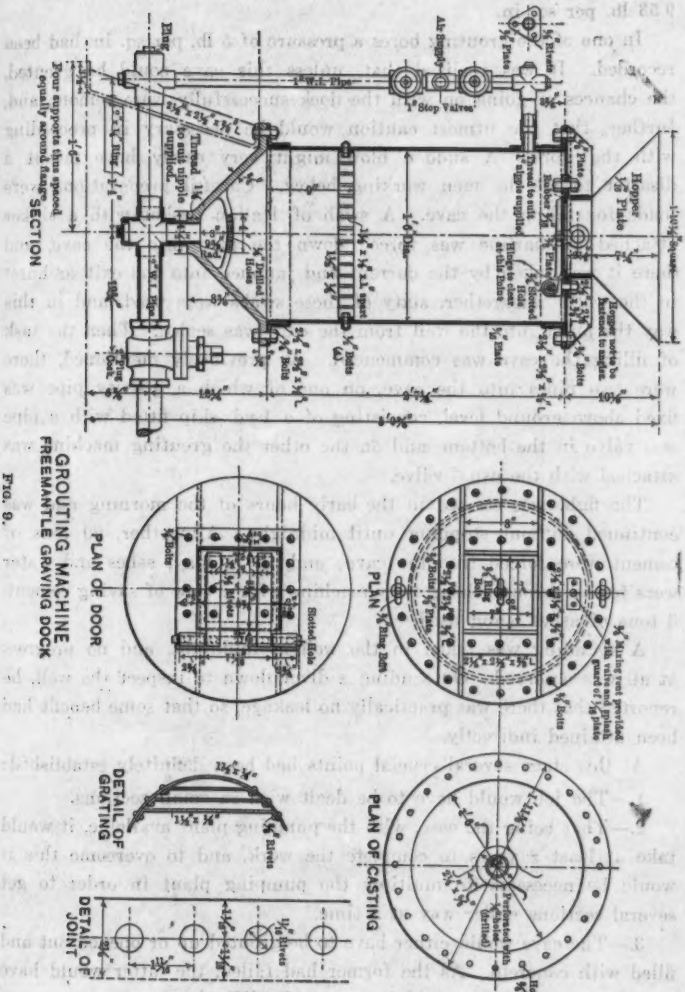
also found opposite the temporary pump-well in grouting the bore marked *C* on Fig. 6.

On grouting the west bores next to the sheeting, it was found that the flow of water had been entirely stopped. This was proved conclusively by the fact that when grouting holes were drilled 2 ft. 6 in. behind them, no water spouted up, and, further, the drilling was done through layers of hard cement; this was most encouraging.



As regards grouting the east side: A strong flow of water was observed, particularly in those grouting holes near the northeast corner, and the entire line was grouted up solid by the machine working from one hole in the center, showing that considerable penetration could be had for the cement.

As a precaution, all valves on the grouting pipes in the vicinity of the pipe being grouted were left open unless they were running freely. In the latter case one valve nearest the pipe being grouted was left partly open. The reason for this was that with a grouting pressure of 75 lb. per sq. in., there would have been grave danger of blowing up the ground which was being grouted, and a valve in the vicinity left open would act as a safety valve. In actual practice it was observed that the surface ground started to crack, due to being in tension, and, but for turning off the pressure promptly, trouble would have been experienced, everything indicating the formation of a miniature volcano.

On an average, each hole took 43 cu. ft. of grout (equal parts of cement and water), and, when the machine ran very freely, saw-dust was added. From subsequent excavations it was shown that the results were most satisfactory, and the penetration of the cement most marked.

An appreciable decrease in pumping was now observable, but the flow in the well was still considerable. It was decided to put down some trial holes in the neighborhood of the burst, and Holes *A* and *B*, were drilled, as shown on Fig. 6. While drilling Hole *A*, the drill dropped 20 ft. 6 in. without any warning, indicating that a fissure or cave had been entered, the invert being 67 ft. 5 in. below low-water mark. Hole *B*, which was 4 ft. 9 in. from Hole *A*, indicated by a sudden drop of the drill that the cave entered was at that place 10 ft. deep, the invert being 57 ft. 5 in. below low-water mark.

A larger hole was then drilled into the cave and a 4-in. pipe was inserted. The water rose in this pipe to within a few feet of the

GROUTING MACHINE
FREEMANTLE GRAVING DOCK

FIG. 9.

level of the water in the river, and the pressure was found to be 9.53 lb. per sq. in.

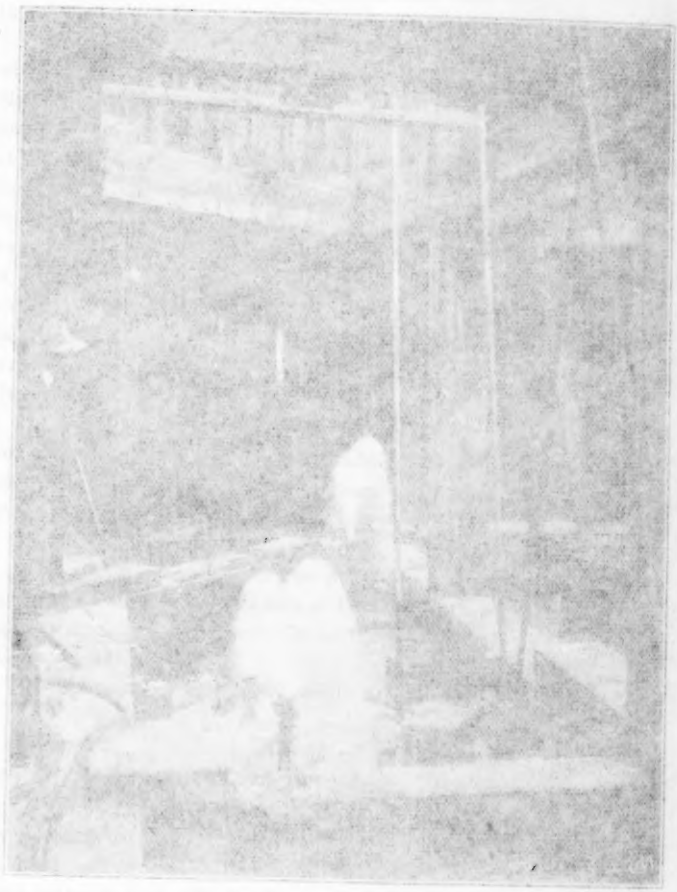
In one of the grouting bores a pressure of 5 lb. per sq. in. had been recorded. It was realized that, unless this cave could be grouted, the chances of going on with the dock successfully were remote, and, further, that the utmost caution would be necessary in proceeding with the work. A sudden blow might very easily have meant a disaster to all the men working below. Careful preparations were made for filling the cave. A swab of Italian gasket with a sinker attached to marline was forced down the pipe into the cave, and there it was taken by the current and jammed into the exit or burst in the well. Altogether, sixty of these swabs were used, and in this way the burst into the well from the cave was sealed. Then the task of filling the cave was commenced. As previously mentioned, there were two pipes into the cave, on one of which a gravity pipe was fixed above ground level, consisting of a 1-yd. skip fitted with a pipe and valve in the bottom, and on the other the grouting machine was attached with the usual valve.

The fight was started in the early hours of the morning and was continued without stopping until midnight. Altogether, 29 tons of cement were forced into the cave; and, at midday, ashes and water were forced through the gravity machine with a view of saving cement, 6 tons of ashes being used.

A sounding was taken in the well at midnight, and no progress at all was observed. On sending a diver down to inspect the well, he reported that there was practically no leakage, so that some benefit had been attained indirectly.

At this stage several crucial points had been definitely established:

1.—The job would have to be dealt with in small sections.



2.—That being the case, with the pumping plant available, it would take at least 8 years to complete the work, and to overcome this it would be necessary to multiply the pumping plant in order to get several sections under way at a time.

3.—The cave would either have to be grouted up or opened out and filled with concrete. As the former had failed, the latter would have to be attempted, and would be extremely difficult.

4.—The ground was of such a doubtful character as to render it necessary to grout all over the site, which having been done, the safe

FIG. 10.—DRILLED HOLES SUBSEQUENTLY GROUTED SUCCESSFULLY.

permissible load that it would carry would be low, and the writer was doubtful whether 3 tons per sq. ft. could be exceeded.

5.—Corrosion due to sulphureted hydrogen gas was going on so rapidly as to render the re-using of the front steel piles more than doubtful.

6.—Steps would have to be taken to decrease the pressure of the sulphureted hydrogen gas. This gas caused the writer considerable anxiety, and it is necessary to remember that the stability of the floor depended on the concrete being fortified by steel, and such fortified concrete had to be designed to withstand a hydrostatic pressure from below and a statical load due to a vessel on the keel blocks.

This latter was necessary owing to the ascertained uncertainty of the ground and the presence of caves. Therefore, if this steel in the ferro-concrete was attacked by corrosion accelerated by sulphureted hydrogen gas, the consequences would be serious.

A supplementary estimate was given to the Government, which brought the estimated cost of the dock from its inception up to £725 000, and the writer advised the Engineer-in-Chief to recommend the Government to abandon the site and look elsewhere.

From a harbor point of view, the site was a bad one, and if, as the writer firmly believes will happen, liners in the Australian trade materially increase in size, it is more than probable that either the dock or the Port of Fremantle would have to be moved.

Bearing in mind that a great deal of the work done on the site, such as dredging, would be reproductive, the Government decided:

1.—To look elsewhere for a dock site;

2.—To build a quay on the north side of the dock site capable of berthing any mammoth liner afloat, and as such berth was at the mouth of the river, it would entail the minimum amount of dredging for an entrance to the deep-water berth; and

3.—To dredge away everything to the south and west and so very materially improve the harbor.

It is never satisfactory to abandon any engineering work; nevertheless, it is the duty of the engineer to keep a careful watch, and forecast the ultimate expenditure of the work.

Taking all items into consideration, everything indicated that the ultimate cost of the dock would be exceptionally heavy, and, at the

same time, the probable return on the money expended through steamers utilizing the dock would be small; consequently, the Government was fortunate in being able to take advantage of the alternative scheme and utilize the work already done.

The latent resources of Western Australia, such as timber, mining, agriculture, dairying, wool, and fruit, are being rapidly developed by a progressive Government, and a further extension of the Harbor of Fremantle has been authorized.

Table 1 is a schedule of the rates of pay for the various classes of workmen engaged on the work, and may be of interest. The hours worked totaled 48 per week, and, in addition, there were 10½ paid holidays per annum.

DISCUSSION

Mr. Archer.

A. R. ARCHER, ASSOC. M. AM. SOC. C. E. (by letter).—The work described by Mr. Ramsbotham is noteworthy by reason of the unusual conditions surrounding the driving of the steel sheet-piling, the varied character of the ground through which it was driven, and the extreme penetration obtained on the shore side, that is, at the back of the embayment for the pumping station.

In designing the bracing the author evidently desired to use a uniform size of timber throughout, with as little framing as possible, and, had it been necessary to brace the dam for the full depth of the diagram shown in Fig. 6, the spacing of the wales near the bottom would have been too close, as far as the strength of the steel skin was concerned. Within the limits to which excavation actually progressed, the spacing approximated very closely to that which the manufacturers of the piling recommended, but at greater depths this, necessarily, depends more on the character of the ground than on any theoretical considerations. The details of the bracing are in accordance with modern American practice, but the hardness of the jarrah wood used evidently permitted the omission of short foot-blocks at each end of the shores, in the lower tiers of bracing, such as are commonly used in the United States to reduce the span of the wales and prevent the end of the shore from cutting into the face of the waling, something which the writer has observed several times in relatively deep coffer-dams in which these foot-blocks were omitted. The bracing as a whole was designed for water pressure, but, from the conditions shown in the diagrams, that portion of the coffer-dam forming the shore side of the embayment for the pumping station was subjected to earth pressure, and it would be interesting to learn whether there was any indication of this exceeding the calculated water pressure. That something of the sort was anticipated is shown by the use of the concrete anchors with wire cable ties shown on Figs. 3 and 8.

The author has made several suggestions to the manufacturers of the steel sheet-piling, and in justice to the latter it should be stated that the pamphlet* published by them in 1912, covers most of the points to which attention has been drawn. A copy of this pamphlet is in the Library of the Society, and therefore available for reference by members.

In view of the large area to be unwatered—10 453 sq. ft.—and the severe leakage from the bottom, one might assume that leakage through the joints of the steel sheet-piling was not a serious factor; some information on this point would be of value. It is also to be assumed that the rapid corrosion of the steel by the discharge of sulphureted hydrogen would rapidly check any leaks which might exist.

* "Steel Sheet Piling: Tables and Data on the Properties and Uses of Sections."

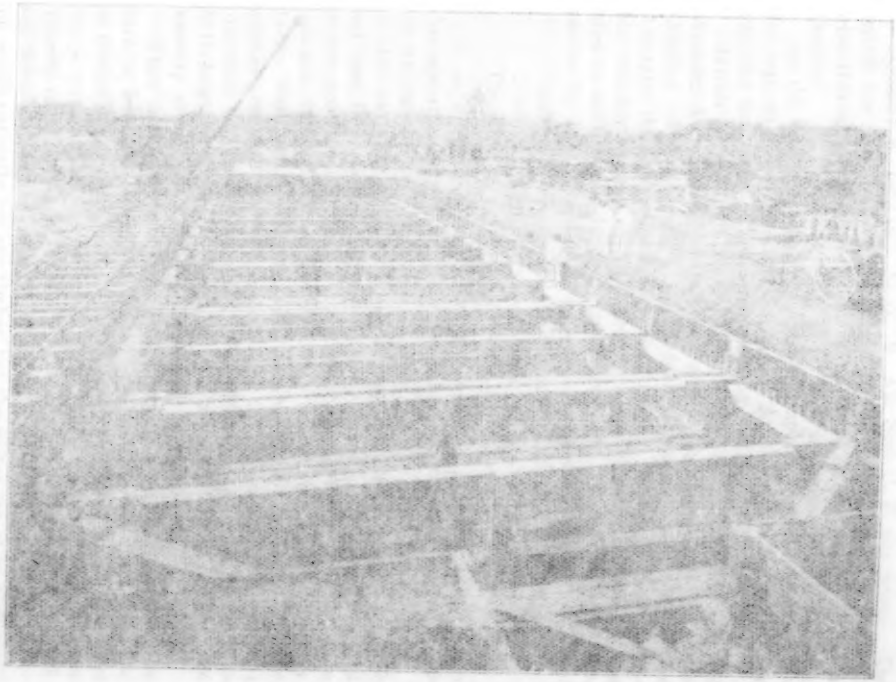
Mr. Archer. The author should have the thanks of the entire Profession for his very careful description of grouting the bottom, as this is a subject on which but scant information can be gleaned from published engineering works.

Mr. Bellamy. HERBERT E. BELLAMY, ASSOC. M. AM. SOC. C. E. (by letter).—The writer has read Mr. Ramsbotham's paper with much interest, and is glad that a matter of such importance has been presented before the Society.

As the writer has had considerable experience with jarrah timber for walings and shores, as referred to by the author, the following remarks may not be considered out of place.

Jarrah (*Eucalyptus marginata*) is one of the most valuable of Western Australian timbers, and one of the best in the Australian Colonies. It is, perhaps, more widely known to engineers outside Australia than any other timber grown there. It is exceedingly durable, whether exposed so as to be alternately wet and dry, or used as piles in sea-water or damp ground. Its weight varies from 56 to 68 lb. per cu. ft. Recent tests of this timber afford the following information:

Transverse strength per square inch.....	1 800 lb.
Tension: direct cohesion on 1 sq. in.....	2 940 "
Crushing strain on 2-in. cubes.....	3.198 tons.



It is a singular fact, however, that the majority of engineers throughout Australia do not view with favor the use of hard woods for walings.

One particular instance, in which absolutely nothing but jarrah was used for timbering, was in the excavation for the main pumping station executed under the writer's supervision in connection with the Colombo (Ceylon) Main Drainage Works, for which works, Messrs. James Mansergh and Sons were the Consulting Engineers. All the walings and struts were 12 by 12-in. and fixed at 4-ft. centers. Fig. 11 illustrates the system adopted. All sets were independent and in 20-ft. lengths, so as to facilitate the easy striking of the timbers as the masonry arose from the bottom.

When the excavation was down to formation level and all timbers were in, heavy monsoonal rains set in, and the trench was allowed to be flooded for several weeks. After the rains had ceased, pulsometer pumps were fixed, and the water was pumped out so that the bottom concrete could be put in. On several subsequent occasions, the trench was flooded and pumped out again. This alternate wetting and drying would naturally tax any timber, but the writer can state with every confidence that every waling and strut removed from this excavation after being in use for about 12 months, was in practically the same good condition as when first put in. Indeed, the majority of the

FIG. 11.—WIDE TRENCH, AT COLOMBO, CEYLON, SUPPORTED BY 12 BY 12-IN. WALING AND STRUTS OF JARRAH TIMBER.

timbers taken out were sawn into 12 by 6-in. and 12 by 3-in. scantlings and used in other parts of the work. Mr. Bellamy.

The writer has also used jarrah extensively for side-trees, head-trees, and sills in tunnels, which have been flooded on several occasions, and not in a single instance was there failure or disappointment.

Steel sheet-piling has been used so extensively and successfully, and in so many different classes of work, that the author's elaborate description calls for no further comment.

JOSHUA FIELDEN RAMSBOTHAM, ASSOC. M. AM. SOC. C. E. (by letter).—Mr. Archer has referred to the penetration of the piles obtained on the shore side of the pumping station, and as it may be of interest the writer submits Fig. 12, showing a pile which failed; altogether, there were eight piles which went astray. It is only fair to state that the rock in the locality was as hard as bell-metal, and the behavior of the piles in no wise contributed to the abandonment of the work. The writer would again emphasize the advisability of not forcing the piles until soft ground has been found ahead of piles which have encountered a hard patch. Mr. Ramsbotham.

Mr. Archer is quite correct in his surmise that the hard wood (jarrah) permitted the omission of short foot-blocks.

For the information of the members the writer has forwarded, for the Library of the Society, two books* which give all details about the various timbers of Western Australia, and he ventures to suggest that that country has been singularly blessed by Providence in this respect.

No doubt Mr. Archer has observed that a larger factor of safety was allowed on the pumping station shores; this was because of the additional weight due to earth pressure and any surcharge from cranes, etc., and also on account of their length.

As regards the suggestions to the manufacturers, the writer begs to state that he gave freely any benefits of his experience at the time to Mr. U. V. Burke, Agent for the United States Steel Products Company, and also Consul for the United States of America, and Mr. Burke reciprocated with all particulars from the manufacturers; by this means the Engineering Profession is best served.

Mr. Archer is quite correct in assuming that there were no leaks in the joints; the skin was quite tight, and this tightness was obtained by the following method: Steel rods, 20 ft. long and ¼ in. in diameter, were procured, their lower ends were made an inverted **V** shape, and their upper ends a wedge shape with a small hole drilled through. A loop was made in one end of a strand of Italian gasket, the diameter not being increased. The inverted **V** end of a rod was in-

* "Western Australian Timber Tests, 1906: The Physical Characteristics of the Hardwoods of Western Australia," by G. A. Julius. Second Edition, 1908; and "Notes *re* Timbers of Western Australia Suitable for Railways, Engineering Works, and Constructional Purposes Generally," Second Edition, 1908.

Mr. Ramsbotham.

serted in this loop and the rod lowered in the space between the male and female piles by a fine string put through the eye. This was repeated by lowering another rod on a separate string with an additional length of gasket, until the entire length of joint was traversed. The gasket made a complete seal and, of course, the rods were removed.

In the first instance Oregon pine fillets were inserted when driving the pile, but there is no exaggeration in stating that they were completely eaten up by the teredo in one month.

Any small trickles can be cured instantly by throwing in a mixture of saw-dust, ashes, and horse manure.

The writer is glad to hear that Mr. Bellamy has used jarrah with success, and this opportunity is taken to supplement his remarks on this head.

Jarrah (*Eucalyptus marginata*) trees average 90 or 100 ft. in height and from 2 to 3 ft. in diameter at the base. The wood is very hard and dense, weighing when seasoned 60 lb. per cu. ft. It is used economically for railway sleepers, jetties, bridges, marine and engineering works of all kinds, building construction, flooring, wood blocking, boat building, fencing, furniture, etc.

Its strength is as follows: Shearing, 2 010 lb. per sq. in.; end compression, 9 050 lb. per sq. in.; cross-bending, 15 000 lb. per sq. in.; tension, 15 500 lb. per sq. in. Additional information regarding this wood may be found in the books previously quoted.

Paper No. 1278

TIDAL PHENOMENA IN THE HARBOR OF NEW YORK.*

By H. de B. Parsons, M. Am. Soc. C. E.

With Discussion by Messrs. Allen Hazen, T. Kennard Thomson, James Owen, Kenneth Allen, and H. de B. Parsons.

The Harbor.

For the purpose of this paper, the harbor of New York is taken to include the Lower Bay, the Upper Bay, the Hudson River to Mount St. Vincent, the East River to Throgs Neck, the Harlem River, Newark Bay, the Kill van Kull, the Arthur Kill, and Jamaica Bay. Each of these divisions can be considered a distinct branch, although the tidal phenomena, taken as a connected whole, are affected by the characteristics of each.

A map of the harbor, Fig. 1, shows the positions of these different parts and their relations to each other.

It is difficult to describe the tidal actions clearly and concisely because the movements of the water in all parts of the harbor are not synchronous. This is due to the following causes:

1.—The harbor is so extended that there is a considerable difference in time between the periods of high water at various points;

2.—The variation in the range of tides;

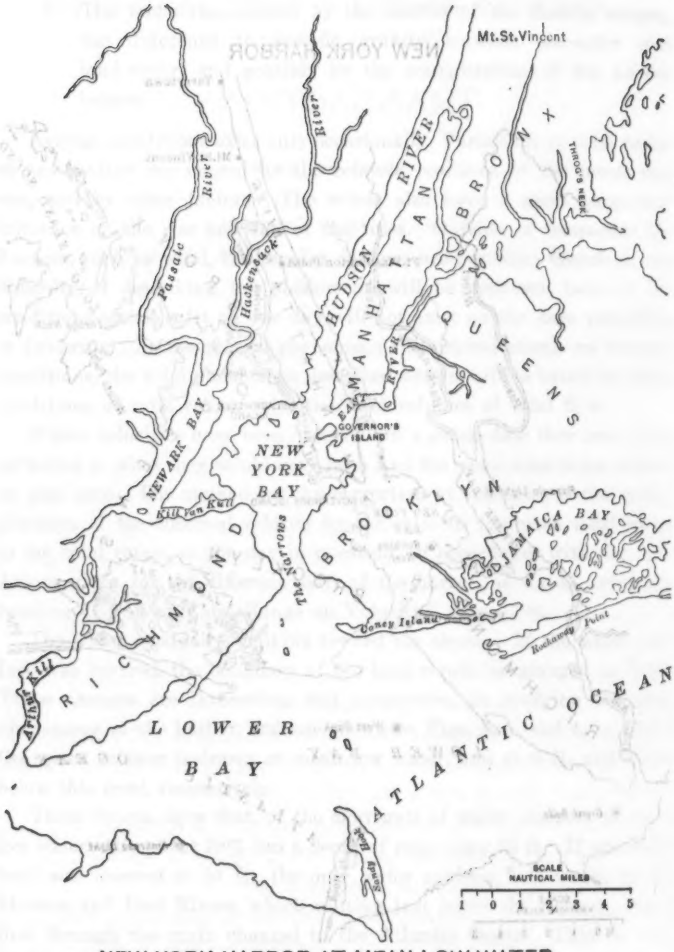
3.—Some of the currents being produced by progressive tidal wave motion, some by hydraulic conditions (that is, difference in water levels), and some by the interference of two distinct tidal waves;

* Presented at the meeting of May 7th, 1913.

4.—The variable flow of fresh-water into the harbor from the rivers (that is, seasonal variation);

5.—The under-run, caused by the inertia of the flowing stream, the difference in specific gravity between sea-water and land-water, and possibly by the configuration of the harbor bottom.

Average conditions exist only occasionally. Variations in tidal range at any station are caused by the relative positions of the moon and sun, and by other factors. The winds also have a great temporary influence on the rise and fall of the tides. Outside of temporary influences, such as wind, the regular changes are periodic; therefore, the difficulty of describing the phenomena will be apparent, because the conditions which exist on one day will not exist on the days preceding or following. As the general phenomena will depend closely on average conditions, the tidal phenomena described herein will be based on mean conditions of tidal range, velocities, and volumes of tidal flow.



Where velocities have been observed on a given date they have been corrected to what they would have been had the mean conditions existed on that date. The method for the correction of velocities is the multiplication of the observed velocity by the ratio of the mean tidal range to the tidal range on the day in question, in accordance with the conditions given for the different parts of the harbor, as stated under the heading "Effect of Tidal Range on Velocity," page 1996.

The water gradually shallows toward the shores. If the water surface was lowered, the boundary of the land would be changed in form. These changes are interesting and instructive, in studying the tidal phenomena of the harbor, and are shown in Figs. 2, 3, and 4, in which the water surface is drawn at mean low water, and at 6 ft. and 12 ft. below this level, respectively.

These figures show that, of the aggregate of water surfaces at mean low water, only about 58% has a depth of more than 12 ft. If the water level was lowered to 24 ft., the only water surfaces left would be the Hudson and East Rivers, which uniting just below the Battery, would flow through the main channel to the Atlantic Ocean. That is, only the important channels would remain. Taking the harbor divisions as defined in Appendix A, the water surfaces at different planes would be approximately as given in Table 1.

	211.03	157.57	123.79
	100%	74.6%	58.6%

The phenomena of "under-run" and "inertia" are well confined within areas having a depth of water greater than 12 ft. below mean low-water level.

Profiles of the harbor bottom are shown in Figs. 5 and 6. The former is a profile through the Lower Bay, Upper Bay, East River, and Hudson River, along the line of the channel; the latter is a profile of average depths of sections across the stream along the same line. Between the Atlantic and the Sound entrances of the harbor, the depths of the sections in general tend to vary inversely as their widths.

TIDAL CURRENTS.

The normal currents in the harbor are produced by progressive or periodic waves, by hydraulic conditions, or by a combination of these two causes.

The progressive wave is the natural motion, due mainly to the attractions of the moon and sun. When the wave is unobstructed, the maximum flood and ebb velocities occur at about the times of high and low water, respectively. The profile of a true tidal wave is a sinusoid The velocities, as well as the heights (stages) of the water, are proportional to the ordinates of a sinusoid the abscissas of which have time values.

When hydraulic conditions obtain, a current flows, on account of the difference in head which exists temporarily between the bodies of water connected. In this case the maximum velocities occur at some time between local high and low waters, depending on the time of greatest hydraulic slope and the characteristics of the channel.

Fig. 6.

When a combination of progressive wave and hydraulic conditions obtains, the greatest flood and ebb velocities occur irregularly, depending on which condition predominates. When the wave is restricted by interference or other causes, the curves (having ordinates which represent velocities or heights of water surface at different periods of time) depart from true sine curves, in amounts depending on the restriction.

The time of a complete tidal period, comprising a flood and an ebb, is 12 lunar hours. Under normal conditions, the flood and ebb flow during 6 lunar hours each, except for the small time lost at slack waters.

A lunar hour is equivalent to 1.03505 solar hours, or 6 lunar hours are equivalent to about 6 hours, 12.6 min., solar time.

In a channel where the current follows closely a true tidal wave action, which is harmonic in character, a floating object will be carried, during a complete flood or ebb period, a distance of

$$\frac{2}{\pi} \times A \times \frac{12.4206}{2} \text{ knots,}$$

or nearly $4A$ knots, in which A denotes the maximum velocity of the current, in knots per solar hour.

Similarly, the velocity at which a floating particle will be carried by the current at any time can be estimated from the formula,

$$A \cos. 30t,$$

where t denotes the number of lunar hours after the time of strength; or

$$A \cos. 28.98t,$$

where t denotes the number of solar hours after the time of strength.

By computing and plotting a number of these velocities at different stations in a selected locality, it is possible to make an estimate of how a floating object will be drifted by the currents.

There is some difference, however, due to the following causes:

1.—The under-run at the times of tidal changes;

2.—The inertia of the flowing stream when it changes from ebb to flood;

3.—The shore currents not being the same as the channel currents;

4.—Variations due to wind;

5.—Variations due to land-water flow coming down the rivers from drainage areas above;

6.—Variations in tidal ranges.

Owing to variations in channel sections and directions, which cause side currents, it is not safe to predict the course which a floating particle will take. It is safer to rely on observations with floats, many of which have been made by the Metropolitan Sewerage Commission,* and will be referred to later.

It must be remembered that the surface velocities do not readily indicate the mean velocities of tidal streams. Although the surface particles may have a known velocity in one direction, the velocity and direction of the particles beneath the surface often differ materially.

To determine accurately the mean velocity of a tidal current, it would be necessary to take synchronous observations at many points across a stream and at many points in depth below the surface. Such observations should extend over a considerable period of time in order to obtain fair averages.

Interference Tides.

When separate tidal waves enter a strait from opposite ends, there results in the strait an "interference" tide. This is not necessarily the algebraic sum of the two separate tides. In other words, when the two waves meet and overlap, the result of the overlap is not necessarily a superposition of one wave upon the other.

The actual tidal rise or fall above or below mean sea level, other things being equal and not acting as disturbing factors, at any hour of the tidal interval, is equal to a coefficient multiplied by the algebraic sum of the rises or falls of the two tides.† The difference in times between high and low water at each end of the strait is an important factor.

Interference tides occur in the harbor because separate tidal waves enter, one from the sea past Sandy Hook and the other from Long Island Sound past Willets Point. These separate tidal waves are not synchronous, that is, their periods of high or low water do not occur at the same time.

The Sound tide‡ (through Hell Gate) is distinctly traced to Governors Island, where, although much reduced in range, it is frequently found to affect the observed tide, mostly in the way of reducing the

* Report, April 30th, 1910.

† Henry Mitchell, Chief Physical Hydrographer, used 0.65 for the coefficient in computing the composite tide in the East River. Thus, the predicted tide was estimated by taking 0.65 times the algebraic sum of the difference in heights of the tides measured from mean sea level. U. S. Coast and Geodetic Survey, 1867. Appendix No. 13.

‡ U. S. Coast and Geodetic Survey, 1866. Appendix No. 6.

rise and fall. The southern tide from The Narrows meets a small propagation of the Sound tide, the lunar interval of which differs nearly 6 hours; the result is a reduction in range. This is the principal reason why the tidal range at Governors Island is less than that at Sandy Hook. The tidal range is also reduced by the expansion of The Narrows' tidal wave in Upper New York Bay.*

The East River is a strait, at one end of which the tidal range is 4.4 ft., and at the other 7.2 ft. Where the high range occurs (Willets Point) the tidal wave enters 3 hours, 5 min. later than the tidal wave at the other end (Governors Island). The two tides meet and cross or overlap each other at Hell Gate; and as they differ in times and heights, they cause contrasts of water elevations which call into existence violent currents.

The volume of water flowing through the strait in one direction is not necessarily equal to that flowing in the opposite direction, but depends on the relative times when each wave enters its respective end of the strait, as well as on the total range at each end.

If one wave enters later than the other, and has a greater range, the mean height of the water when the current is flowing one way will be higher than the mean height when the current is flowing contrariwise. Consequently, the sectional area of the stream in one case will be greater than in the other, and a larger volume of water is likely to pass during a tidal variation.

Suppose curves for the waves entering at each end of a strait be drawn, and then that the two curves be superimposed so that the distance between the peaks will represent the difference in time between high waters at each end, as shown in Fig. 7. The upper curves are true sinusoids, representing the mean ranges of tide at each end of the East River, namely Governors Island and Willets Point. The lower curves show the East River conditions for one set of observations, as recorded in the Report of the U. S. Coast and Geodetic Survey for 1888, Appendix No. 9.

Lunes† will be formed at *A* and *B*. When the curves are true sinusoids, their areas are equal; but, under actual tidal conditions, their areas are only approximately equal. These lunes are unbalanced, for the center of one is higher than that of the other, as shown by the crosses on Fig. 7.

EAST RIVER CONDITIONS

FIG. 7.

During the time of the formation of Lune *A*, the water surface at Willets Point is higher than that at Governors Island, thus tending to produce a current from the former toward the latter. Conversely, during the time of the formation of Lune *B* the tendency is to produce a current in the opposite direction.

The centers of these lunes are at the mean levels of the water during the times the water has the hydraulic conditions represented by Lunes *A* and *B*, respectively. Therefore, the mean cross-sectional area of one stream is greater than that of the other. If the mean velocities of the currents are the same in each direction, then, as the hydraulic slopes are equal, a greater volume will flow in one direction than in the other, on account of the larger area of the stream section.

In the case of the East River, the greater section and the tendency toward a greater volume of flow is for the current running from Willets Point to Governors Island.

The Harlem River conditions are the result of interference tides, with waves entering from the Hudson River and the East River at different times. The Harlem River is really a strait, and what has been said about the East River would also apply in a modified way to it.

Tidal Prisms.

A tidal prism is the volume of water contained between low-water and high-water levels. The tidal prisms were calculated by multiplying the area of the water surface by the mean range of the tide. The areas of the water surfaces, the tidal ranges, and the volumes of the tidal prisms are given in Table 2.

For equal ranges of tide, the percentage which the tidal prism is of the volume below mean low water will increase inversely as the average depth below mean low water; therefore, the shallower the water the greater will be the ratio of change of volume during each tide. The least ratio of change is in the Hudson River, and the greatest in Newark Bay, as shown in the last column of Table 2.

Quantity of Water in Harbor.

The water surface of the harbor was calculated from the Government charts.* This surface is 65.12 sq. miles, exclusive of the Lower Bay and Jamaica Bay. The areas of the several divisions are given

*The boundaries of the harbor divisions are given in Appendix A.

in Table 2. The area of the Lower Bay is 124.3 sq. miles, and of Jamaica Bay 21.61 sq. miles.

TABLE 2.—AREAS, DEPTHS, TIDAL RANGES, VOLUMES, AND TIDAL PRISMS.

Arthur Kill	4.63	13.1	5.4	1 690	697	41.2
Totals	65.12	....	...	41 011	8 789.0	....

* Ratio of tidal prism to volumes below M. L. W. expressed as a percentage.

An estimate of the volumes of water below mean low water was made in the following manner: For the Upper Bay, Newark Bay, and the East River between East 88th Street, Manhattan, and Throgs Neck, the chart areas were divided into squares, and the depths as given on the chart were averaged for each square or fraction thereof. The shore lines were taken as marked on the charts for mean low water. The volumes under each square were found and added. For the Hudson River, East River south of 88th Street, Harlem River, Arthur Kill, and Kill van Kull, cross-sections were drawn at regular intervals, from information on Government charts of large scale, and cross-sectional areas were obtained. From these areas and their distances apart the volumes were calculated. The results are given in Table 2.

At any hour, there is more water in the harbor than is given by the sum of these figures, because mean low water does not occur at the same hour in all its parts.

The volume of water is variable from hour to hour, and the approximate mean value is nearly the sum of the quantity of water below mean low water and one-half of the mean tidal prism. The tidal prisms are given in Table 2. The average quantity of water, therefore, is not far from the sum of 41 011 000 000 and 4 394 500 000, or 45 405 500 000 cu. ft., exclusive of the Lower Bay and Jamaica Bay.

Tidal Ranges.

The tidal ranges, or the rise and fall of the tides, are not the same at all points in the harbor; also, the hours at which high and low water occur at different points vary considerably. These statistics are given in Table 3.

TABLE 3.—Mean Range of Tides, and Times of High and Low Water.*

† Solar time, in hours and minutes, after transit of moon.
‡ From that at Governors Island, in hours and minutes.

Current Velocities.

The current velocities are variable throughout the harbor, and are dependent on the conditions existing at the time of observation. Under normal conditions, the coefficient which expresses the relation between the swiftest surface thread of a current and the mean cross-sectional velocity is probably fairly constant for any one section, although it is affected by inertia and the reversal of the currents due to change of direction, which reversal does not take place simultaneously throughout a section.

Under normal conditions, the swiftest surface velocities (or the velocities just under the surface) of the tidal currents, when flowing at strength, are given in Table 4, in knots per solar hour, as well as the normal duration of surface currents, in lunar hours. These velocities and durations were obtained from records of the Coast and Geodetic Survey and from float observations made by the Metropolitan Sewerage Commission.

The mean surface velocity of the swiftest thread is approximately $\frac{2}{\pi}$ times the velocity at strength, as the wave formation is harmonic in character.

*The durations of slack-water are not the same in all parts of the harbor, nor does the current change at the same time in all parts of a section. The slack-water periods are included in the duration of the currents, which add to 12 lunar hours.

Some observations of the velocities of the currents at different depths have been made in a few sections in the harbor.* They were made at one or at only a few stations in a section, and the records are not sufficiently full to be of material value in determining the mean cross-sectional velocity, or the value of the coefficient expressing the relation between the velocity of the swiftest surface thread and the mean velocity of the section. They show, however, that the currents do not reverse simultaneously in a section, and also that the period of time occupied by a complete change of current is not the same for ebb to flood as for flood to ebb. Generally speaking, the period is longer in the former case and shorter in the latter.

The surface of some parts of the bottom of the harbor is much freer from fine silt and light deposits than others. It also appears that when the velocities exceed 1½ ft. per sec., the finer and lighter materials are washed away and deposited in the deeper or quieter parts.

*Reports of U. S. Coast and Geodetic Survey.

Effect of Tidal Range on Velocity.

In the East River the tidal currents are nearly hydraulic, that is, they flow from the body having temporarily the higher water-surface level to the one having temporarily the lower. In other words, the flow is caused by the difference in height which temporarily exists between the bodies connected. In consequence, the velocities in the East River vary closely as the square root of the range of tide.

In the Hudson River the tidal currents are due chiefly to the progressive wave motion, as is shown by the fact that the greatest flood and ebb velocities occur at nearly the times of local high and low waters. In the Hudson, therefore, the velocities vary directly as the range of tide.

In the Kill van Kull and in the Arthur Kill the tidal currents are nearly hydraulic, and in them, as in the East River, the velocities vary closely as the square root of the range of tide.

In The Narrows the tidal currents are partly hydraulic and partly due to the progressive wave motion. In consequence, the velocities there vary approximately midway between the square root of and directly as the range of tide.

In the Harlem River the tidal currents are nearly hydraulic, and are due to a temporary difference in water level in the East River and in the Hudson. Therefore, the velocities vary approximately as the square root of the range of tide.

In Rockaway Inlet, joining Jamaica Bay and the Atlantic Ocean, the currents are hydraulic. The velocities, therefore, vary as the square root of the range of tide, the greatest velocities occurring about 3 hours before high or low water.

Currents at Each Lunar Hour.

The currents which exist in the harbor at each lunar hour of a tidal cycle are given below. The directions of the currents were obtained chiefly from the float experiments of the Metropolitan Sewerage Commission, and were checked from the curves shown on Fig. 8. Other observations were also made, for purposes of verification. The construction of the curves in Fig. 8 is explained on page 2056.

I Lunar Hour.—The water is flowing out of the Upper Bay, through The Narrows, toward the sea; into the Upper Bay, through the Kill

van Kull, the East River, and the Hudson River; and the water level in the Upper Bay is falling.

II Lunar Hour.—The water is flowing out of the Upper Bay, through The Narrows, toward the sea; into the Upper Bay through the East River and the Hudson River; the Kill van Kull is nearly slack; and the water in the Upper Bay is at about mean low water.

III Lunar Hour.—The water is flowing out of the Upper Bay, through The Narrows, toward the sea; out of the Upper Bay, through the Kill van Kull; into the Upper Bay, through the East River and the Hudson River; and the water in the Upper Bay is rising.

IV Lunar Hour.—The water is flowing into the Upper Bay, through The Narrows, from the sea; into the Upper Bay, from the Hudson River; out of the Upper Bay and Hudson River, into the East River; out of the Upper Bay, into the Kill van Kull; and the water in the Bay is rising.

V Lunar Hour.—The water is flowing into the Upper Bay, through The Narrows, from the sea; the Hudson River is nearly slack; the water is flowing out of the Upper Bay, through the East River and the Kill van Kull; and the water in the Bay is rising.

VI Lunar Hour.—The water is flowing into the Upper Bay, through The Narrows, from the sea; out of the Upper Bay, through the Hudson River, East River, and Kill van Kull; and the water in the Bay is rising.

VII Lunar Hour.—The water is flowing into the Upper Bay, through The Narrows, from the sea; out of the Upper Bay, through the Hudson River, East River, and Kill van Kull; and the water in the Bay is rising.

VIII Lunar Hour.—The water is flowing into the Upper Bay, through The Narrows, from the sea; out of the Upper Bay, through the East River and the Hudson River; the Kill van Kull is nearly slack; and the water in the Bay is at about mean high water.

IX Lunar Hour.—The water is flowing into the Upper Bay, through The Narrows, from the sea; into the Upper Bay, through the Kill van Kull; out of the Upper Bay, through the Hudson River and the East River; and the water in the Bay is falling.

X Lunar Hour.—The water is flowing out of the Upper Bay, through The Narrows, toward the sea; out of the Upper Bay, through

the Hudson River; into the Upper Bay and Hudson River, through the East River; into the Upper Bay, through the Kill van Kull; and the water in the Bay is falling.

XI Lunar Hour.—The water is flowing out of the Upper Bay, through The Narrows, toward the sea; the Hudson River is nearly slack; the water is flowing into the Upper Bay, through the East River and the Kill van Kull; and the water in the Bay is falling.

XII Lunar Hour.—The water is flowing out of the Upper Bay, through The Narrows, toward the sea; into the Upper Bay, through the Hudson River, East River, and Kill van Kull; and the water in the Bay is falling.

Water Levels at Each Lunar Hour.

The water surfaces are changing continually throughout the tidal cycle, and the differences in elevation create slopes which are influential in causing the water to flow first in one, and then in a reverse, direction.

Figs. 9 to 20, inclusive, show the water surfaces at each lunar hour during the cycle. By comparing one figure with those for the preceding and subsequent hours, the rapid changes in levels are apparent. The figures show the cause of the violent currents through Hell Gate, and the steep slopes which exist at this interesting place. These figures were drawn from information contained in Appendix 15, Report of 1887, and Appendix 9, Report of 1888, of the U. S. Coast and Geodetic Survey, with the elevations for some additional points calculated by the writer from Tide Table information.

Land-Water Discharges.

The land-water discharged into the harbor comes from the rivers and their contributing basins. The U. S. Coast and Geodetic Survey made an estimate* of this land-water, based on the records of the gauging stations maintained by the U. S. Geological Survey and the New York State Engineer and Surveyor at Mechanicsville on the Hudson (1890 to 1905), and at a point about 4 miles below Rexford Flats on the Mohawk River (1901-1905). The quantity of land-water running off areas below these stations has been assumed to be related to these

areas as the measured discharges are to the areas above the gauging stations. The results thus obtained were then multiplied by factors representing the ratios of the annual rainfalls over the regions under consideration to the annual rainfall over the regions above the gauging stations. These rainfall ratios were obtained from Professor A. J. Henry's "Climatology of the United States." The final results or estimates of the land-water discharges are given in Table 5.

Current Phenomena.

The turn of the tide takes place first along the shore, so that the shore currents often flow contrariwise to the channel currents. In The Narrows, the first change of current appears on the east side of the channel.

When the tidal currents turn from flood to ebb or from ebb to flood, the inertia of the moving stream plays a very important part. As the specific gravity of the sea outside of New York bar is about 1.024, the sea-water is approximately 2½% heavier than the fresh-water discharged from the rivers. As the tide begins to flood, there is a tendency for this lighter fresh-water to flow out over the top of the incoming heavier salt-water, and for the formation of top and bottom currents flowing in opposite directions. Consequently, an "under-run" is formed. The "under-run" of salt-water up the Hudson River extends above Poughkeepsie, where the water is often found brackish during seasons when the river discharge of land-water is small.

The Metropolitan Sewerage Commission made more than ninety float experiments during 1907, 1908, and 1909. The floats were made deep, in order that they might not be influenced by the wind, and were of two kinds: a submerged can supported by a wire to a can float, and a wooden post carrying vanes at the lower end supported by a wooden float at the upper end. The can float was made in the following way: The submerged can was 6¼ in. in diameter and 14 in. high, and had a ring at the top to which was fastened a copper wire connecting it to the float proper. The length of this wire could be varied, but was usually about 4 ft. The float was a can, 5⅜ in. in diameter and 5 in. high, hermetically sealed, and had a socket on the cover in which could be placed a staff for a small flag. The submerged can had an opening in the cover through which sand could be introduced so as to weight the apparatus until the float became almost submerged.

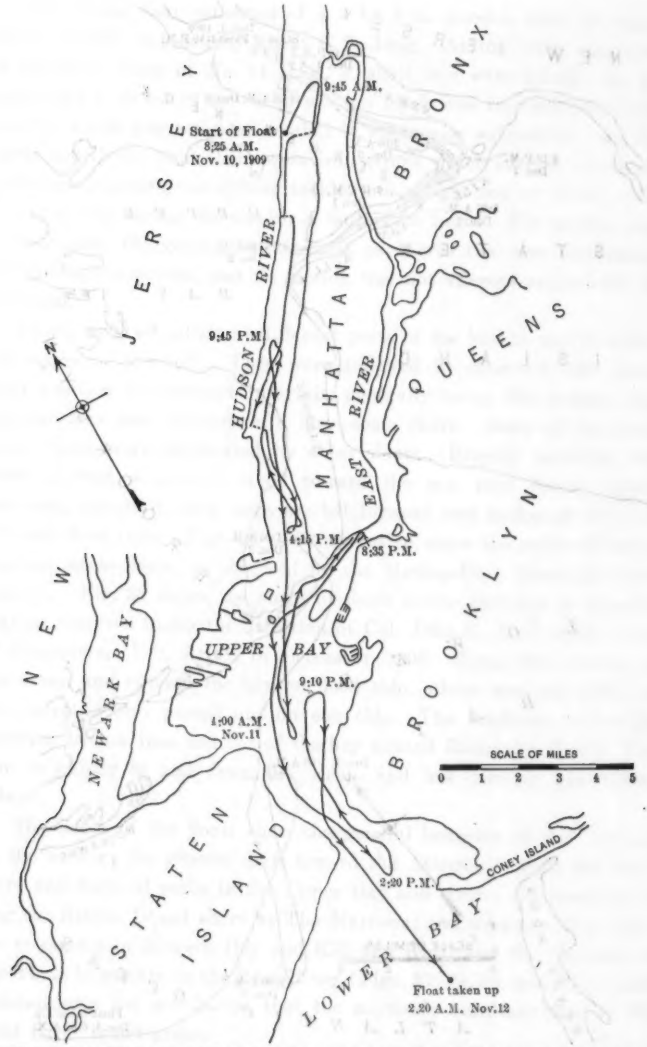
*Total from Arthur Kill, Newark Bay, and Raritan River, but not Shrewsbury River or similar drainage areas.

The second float consisted of a 4 by 4-in. wooden standard, varying in length, but usually about 6 ft. long. At the lower end, four 18 by 18-in. vanes of No. 14 B. w. g. sheet-iron were bolted. At the upper end a 12 by 12 by 24-in. wooden block was fastened vertically, and the whole was weighted so that it was nearly submerged. On the upper end of the float there were iron straps which carried two heavy hooks for fastening the lifting tackle, and a light rod on which could be put a flag during the day or a lantern at night. The second type of float gave the greater satisfaction, as it was the more substantial for this heavy service, and its motion was not affected appreciably by the wind.

Floats were set adrift in different parts of the harbor and at different stages of the tide. They were followed by observers who noted their position at frequent intervals, generally using the sextant, and the positions were plotted on a large-scale chart. Many of the paths thus traced were duplicated by other floats. Broadly speaking, the floats showed a general trend toward the sea, past Sandy Hook; although, naturally, they were carried forward and backward with the ebb and flood tides. Figs. 21 to 32, inclusive, show the paths of twelve representative floats, as observed by the Metropolitan Sewerage Commission. Fig. 33 shows the paths of floats at the entrance to Jamaica Bay as observed under the direction of Col. John G. D. Knight, Corps of Engineers, U. S. Army, in December, 1908. Some were started in the ocean and entered the bay on flood tide, others were set adrift in the entrance and passed out on ebb tide. The tendency is for the currents to flow into and out of the bay around Rockaway Point. The flow is chiefly to and from the ocean, and less directly past Coney Island.



The paths of the floats show the general behavior of the currents in the harbor; the general drift toward the Atlantic Ocean; the backward and forward paths in the Upper Bay and rivers; the tendency to hug the Staten Island shore at The Narrows; the tendency of a particle to remain in Newark Bay and Kill van Kull; and the tendency of a particle to remain in the East River (Figs. 27, 28, 29, and 30); which substantiates the conclusion that the southerly resultant flow of the East River is not great.

When velocity data are worked out from float experiments, a correction should be made for the range of tide existing on the day of

observation, in order to change the observed velocity to that which would have existed for a normal range, as discussed under the heading, "Effect of Tidal Range on Velocity," page 1996.

Calculations were made of the theoretical paths which particles would take during successive tides, as explained on page 1988. Such paths are shown in Fig. 34 for a particle starting in the Hudson River, off Grant's Tomb, on a flood tide; and in Fig. 35, starting off College Point, in the East River, one on flood and one on ebb tide. The paths were worked out by calculating the distance traveled by a particle during a complete flood or ebb period by substituting in the formula, $\frac{2}{\pi} A\ t$, in which A denotes the velocity, in knots at strength, and t the duration of the current, in solar hours, both as given in the Tide Tables. The distances traveled on both ebb and flood currents were thus determined for each mile, and the results arranged in proper order. The plottings of the paths in Figs. 34 and 35 were then made by using the average of the results of the calculated distances for the miles which the particle would pass during the current being considered. The path calculated for the Hudson River and Upper Bay, Fig. 34, agrees closely with that actually traversed by a float, as shown in Fig. 22. The paths calculated for the East River were longer than the distances traversed by the floats on each current, which was to be expected, as the calculation is based on the particle remaining in the swiftest thread. However, Fig. 35 indicates that a particle set adrift in the East River near College Point is likely to remain in the river, as was the result with a float, Fig. 28, which was followed for nearly 3½ days and never passed farther south than the Brooklyn Bridge, nor farther east than Whitestone Point.

Volumes of Water Flowing on Flood and Ebb Currents.

The volume flowing on each tidal current can be estimated in accordance with the principles deduced for calculating the flow of rivers. The estimates will be approximately correct, and, considering the daily variations, will be sufficiently accurate for all practical purposes. These estimates are based on the area of a selected section below the mean level of the water surface, the mean velocity of the current, and the time during which the current flows.

It is neither a simple nor an easy matter to make gaugings of the volumes flowing on the tidal currents, because the volumes are so large,

and the measurements would have to extend over long periods, in order to average out the daily variations; and they would have to be made at stations located so closely together as to interfere with navigation. For exact results, current velocity measurements would have to be taken at many different depths at each station. Such measurements should be made nearly coincident at each station, and repeated at short intervals of time, because the velocities of the threads at different depths may vary, and are subject to changes in direction which are not synchronous, due to the reversals of the tidal currents. The work of making actual gauge measurements of such large volumes as flow in the East River, the Hudson River, and through The Narrows would be very costly.

The volumes of the currents passing any selected section during a tidal interval are not constant, because of lunar and seasonal variations. The average or mean volumes, however, can be estimated with sufficient accuracy for all practical purposes.

With the exception of the East River and the Harlem River, where the currents are purely hydraulic, that is, produced by a difference in level of the water surfaces at each end, the main currents are complicated by the discharges of the land-waters from the water-sheds above. In consequence, the ebb currents exceed the flood currents in volume by just the discharges of land-water. This is true under mean conditions, that is, when the ranges of consecutive tides are the same.

Therefore, each tidal flow is composed of a periodic portion due to the true tidal wave, and a non-periodic portion due to the land-water discharge. These two portions are mixed into one volume, but, for purposes of estimate, must be kept distinct. It will be clear, then, that the resultant discharge from the harbor to the sea will be the land-water discharges of the rivers, and no more, except the southerly net flow of the East River, which, as will be shown later, is not great.

The rise and fall of the tides and the current velocities may be assumed to vary according to the ordinates of a sinusoid. Any deviation is due to local conditions or to temporary irregularities. The true tidal actions are periodic, and each tide extends over a period of 6 lunar hours or (nearly) 6.21 solar hours.

The U. S. Coast and Geodetic Survey has made estimates of the volumes of the tides flowing past selected sections, for each month, by

SURFACE CURRENT MOVEMENTS DURING SUCCESSIVE TIDES THROUGH THE HUDSON RIVER, UPPER AND LOWER NEW YORK BAYS.

CALCULATED FROM VELOCITIES GIVEN IN TIDE TABLES FOR 1908.

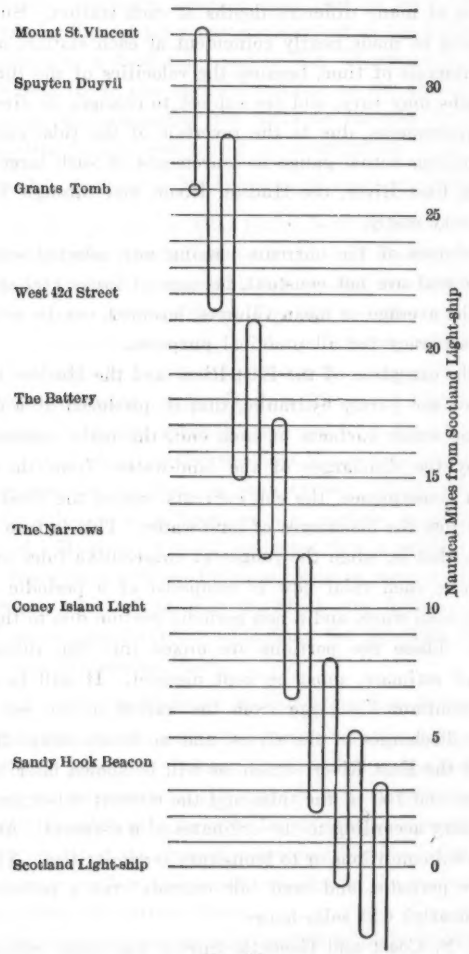

FIG. 34.

SURFACE CURRENT MOVEMENTS DURING SUCCESSIVE TIDES THROUGH THE EAST RIVER, UPPER AND LOWER NEW YORK BAYS.

CALCULATED FROM VELOCITIES GIVEN IN TIDE TABLES FOR 1908.

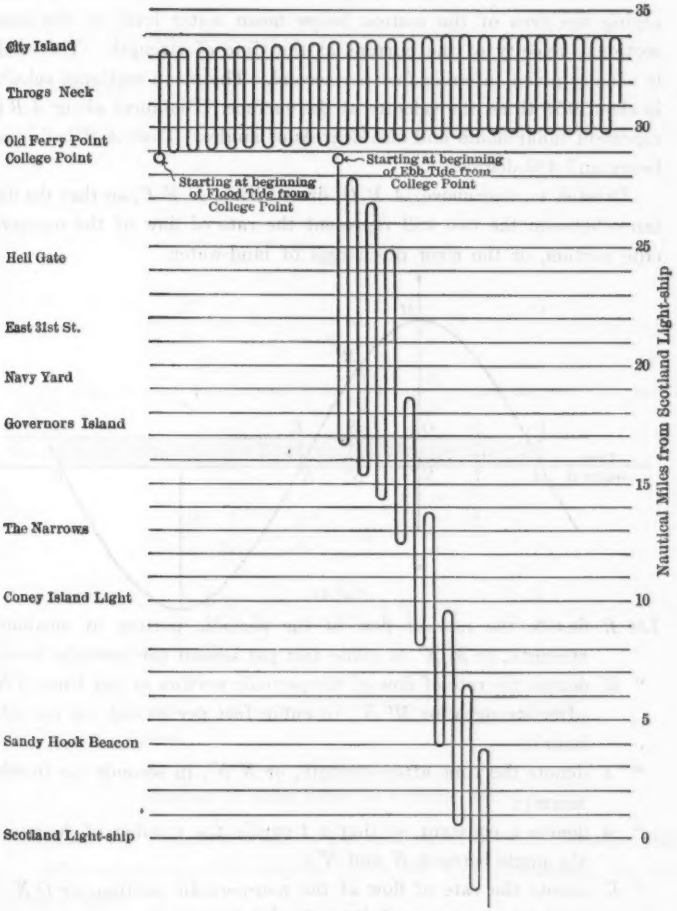

FIG. 35.

using the monthly mean discharge of land-water, and then averaging these monthly results for the yearly mean.

Draw a line, *A B C*, Fig. 36, and divide it into lunar hours. Draw a curve of sines, *A M B C*, such that *M N* represents the maximum rate of flow due to the periodic portion. Its value is found by multiplying the area of the section below mean water level by the mean sectional velocity of the current at the time of strength. The result is usually given in cubic feet per second. The mean sectional velocity is about 0.75 times the velocity at the surface. Distances along *A B C* represent lunar hours and also degrees of angles. Thus *A B* is 6 lunar hours and 180 degrees.

Parallel to, and above, *A B C*, draw a line, *D E F*, so that the distance between the two will represent the rate of flow of the non-periodic portion, or the river discharges of land-water.

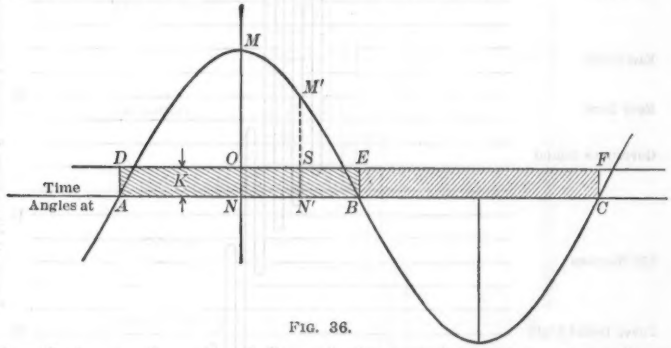

FIG. 36.

Let *R* denote the rate of flow of the periodic portion at maximum strength, or *M N*, in cubic feet per second (or per solar hour);

" *R'* denote the rate of flow of the periodic portion at any time, *N N'*, after strength, or *M' N'*, in cubic feet per second (or per solar hour);

" *t* denote the time after strength, or *N N'*, in seconds (or in solar hours);

" *a* denote a constant, so that *a t* equals the number of degrees in the angle between *N* and *N'*;

" *K* denote the rate of flow of the non-periodic portion, or *O N*, in cubic feet per second (or per solar hour);

" θ denote the number of degrees in the angle between *O* and *E*, or where *R'* equals *K*.

Then:

$M'\ N' = R' = R \cos.\ a\ t$

$M'\ S = y = R \cos.\ a\ t - K.$

As θ is the angle at which $R \cos.\ a\ t = K$, $\cos.\ \theta = \frac{K}{R}$.

$O\ E =$ half duration of flood $= \frac{\theta}{a}$.

Therefore,

the area, $O\ M\ M'\ E = \int_0^\theta y\ dt = \int_0^\theta (R \cos.\ a\ t - K)\ dt,$

or, the volume of half flood $= \int_0^\theta R \cos.\ a\ t\ dt - K\ dt$

$$= \left[{}_0^\theta \frac{R}{a} \sin.\ a\ t - Kt \right]$$

$$= \frac{R}{a} \sin.\ \theta - K\frac{\theta}{a} - \frac{R}{a} \sin.\ O + K\frac{O}{a} \ldots\ldots\ldots (1)$$

As $\sin.\ \theta = \sqrt{1 - \cos.^2 \theta}$, or $\sqrt{1 - \frac{K^2}{R^2}}$, and as θ is the angle the cosine of which is $\frac{K}{R}$, Equation (1) becomes

$$= \frac{R}{a}\sqrt{1 - \frac{K^2}{R^2}} - K\frac{\cos.^{-)}\frac{K}{R}}{a}$$

$$= \frac{1}{a}\left[R\sqrt{1 - \frac{K^2}{R^2}} - K \cos.^{-)}\frac{K}{R} \right] \ldots\ldots\ldots\ldots (2)$$

For time in seconds,

$$a = \frac{\pi}{\text{number of seconds in 6 lunar hours}} = \frac{\pi}{22\,357},$$

or, for solar hours,

$$a = \frac{\pi}{\text{number of solar hours in 6 lunar hours}} = \frac{\pi}{6.21};$$

therefore, the volume flowing on the total flood is twice Equation (2).

After substituting the value of a, for the time in seconds, the total flood volume

$$= 14\,233 \left[R\sqrt{1 - \frac{K^2}{R^2}} - K \cos.^{-)}\frac{K}{R} \right] \ldots\ldots\ldots\ldots (3)$$

The volume flowing on the total ebb is the flood volume plus the run-off for 12 lunar hours. This latter quantity is represented by the area, $A\ B\ C\ F\ E\ D$, or by $\frac{2\ \pi\ K}{a}$, as $A\ C = \frac{2\ \pi}{a}$.

The volume flowing on the ebb, therefore, is

$$= \frac{2\ K\ \pi}{a} + 14\,233\left[R\sqrt{1 - \frac{K^2}{R^2}} - K \cos.^{-)} \frac{K}{R}\right]$$

$$= 44\,714\ K + 14\,233\left[R\sqrt{1 - \frac{K^2}{R^2}} - K \cos.^{-)} \frac{K}{R}\right] \ldots\ldots\ (4)$$

Taking a section between Sandy Hook and Coney Island, the value of R is 1 685 812 cu. ft. per sec.,* being the product of the mean cross-sectional area and 0.75 of the average surface velocity. The value of K, or the rate of run-off, is variable for each month, but the monthly means are given in Table 5. Substituting these values in Equations (3) and (4), and working out the volumes of flood and ebb for each month, the mean flood and ebb volumes can be estimated by averaging the monthly results.

The mean total ebb volume is 24 658 499 000 cu. ft.
The mean total flood volume is 23 322 888 000 " "

A section was taken across The Narrows, and Equations (3) and (4) were solved for each monthly result; the details are given in Table 6. In this way the flood and ebb volumes for each month can be ascertained. The mean result for the year has been calculated, and the averages for the 12 months are also given.

The velocities of current at strength have been taken from Table 4. The values of K have been found by adding the resultant flow of the East River, which is about 40 000 000 cu. ft. per 6 lunar hours (page 2041), to the total of the land-water entering the Upper Bay above The Narrows, as given in Table 5, and dividing the sum by 22 357, or the number of seconds in 6 lunar hours.

The mean volumes of the normal tidal flows past any section can be estimated closely by a shorter process: Find the mean height of the curve, *AMB*, Fig. 36, for both flood and ebb currents; then multiply this average rate of flow by the area of the section and by the duration of the current in time, and the result will be the mean of the volumes

*From information received from the U. S. Coast and Geodetic Survey, January 22d, 1910.

TABLE 6.—SECTION AT THE NARROWS.

flowing through the section on both ebb and flood currents. The flood volume will be the mean, thus found, less one-half of the land-water discharged during 12 lunar hours; and the ebb volume will be the mean volume plus one-half of the land-water.

The writer thus estimated the volumes flowing on the tidal currents past various sections of the harbor, chiefly based on investigations made by the Metropolitan Sewerage Commission. These results agree fairly well with the estimates made by the United States Coast and Geodetic Survey.

For comparison, the tidal volumes at The Narrows are given in cubic feet:

	Ebb.	Flood.
By short method.....	12 041 200 000	10 778 800 000
" Equations (3) and (4).	12 024 200 000	10 762 000 000
" U. S. C. and G. Survey.	12 211 187 000	11 028 853 000

The U. S. Coast and Geodetic Survey results were calculated by Equations (3) and (4), but were based on a mean velocity at strength of 2 knots, with no allowance for any resultant discharge from the East River.

Volumes of Tidal Discharges.

The Narrows.

The section between Fort Wadsworth and Fort Hamilton is 5 280 ft. wide, and its average depth below mean water level is 61 ft., so that its area is 322 000 sq. ft.

The average velocity of the swiftest surface thread during the tidal period on ebb is 1.34 knots, and on flood 1.17 knots. These velocities were obtained by plotting the results of the float observations of the Metropolitan Sewerage Commission and drawing a smooth curve through the points. The areas below these approximate sinusoids were then divided by their lengths, giving the average velocities. The mean of the ebb and flood average velocities of the swiftest surface thread is 1.255 knots, or 7 631 ft. per solar hour.

The coefficient to reduce the surface velocities to cross-sectional velocities was taken at 0.75. The mean cross-sectional velocity, therefore, is 5 723 ft. per solar hour. Multiplying the area of the section by the mean cross-sectional velocity gives 1 837 000 000 cu. ft. per solar hour as the mean rate of flow through the section.

The length of time that each current flows was taken at 6 lunar hours, or 6.21 solar hours. The mean volume flowing on ebb and flood currents is 11 410 000 000 cu. ft., obtained by multiplying the mean rate of flow through the section by the length of time.

The mean yearly discharge of land-water run-off past The Narrows for 6 lunar hours is 591 200 000 cu. ft., or 1 182 400 000 cu. ft. per tidal cycle of 12 lunar hours. These figures are from the records of the U. S. Coast and Geodetic Survey and the New York State Engineer and Surveyor. See Table 5.

In addition to this run-off, there is a net discharge through the East River from the Sound into the Upper Bay which passes out through The Narrows. This net discharge is about 80 000 000 cu. ft. per tidal cycle, as explained on page 2041.

The total net discharge, therefore, is 1 262 400 000 cu. ft.; and, from what has been stated on page 2034, the average ebb volume will be approximately the mean given above plus one-half of this net discharge, and the average flood volume will be the mean less one-half of this net discharge, or:

Average volume of ebb current, 12 041 200 000 cu. ft.
Average volume of flood current, 10 778 800 000 " "

Hudson River.

The section of the river opposite West 39th Street, Manhattan, is 3 900 ft. wide, and its average depth below mean water level is 37.44 ft., so that its area is 146 000 sq. ft.

The average velocity of the swiftest surface thread during the tidal period on ebb is 1.86 knots, and on flood 1.26 knots. These velocities were obtained by plotting curves from information obtained from the U. S. Coast and Geodetic Survey and from the U. S. Coast Pilot, in the same manner as those for The Narrows. The mean of the ebb and flood average velocities of the swiftest surface thread is 1.56 knots, or 9 485 ft. per solar hour.

The coefficient to reduce the surface velocities to cross-sectional velocities was taken at 0.75. The mean cross-sectional velocity, therefore, is 7 113 ft. per solar hour. Multiplying the area of the section by the mean cross-sectional velocity gives 1 038 000 000 cu. ft. per solar hour as the mean rate of flow through the section.

The mean volume flowing on ebb and flood currents is 6 447 000 000 cu. ft., obtained by multiplying the rate of flow through the section by the length of time, or 6.21 solar hours.

The mean yearly discharge of land-water run-off past Battery Place for 6 lunar hours is 543 600 000 cu. ft., or 1 087 200 cu. ft. per tidal cycle of 12 lunar hours. These figures are from the records of the U. S. Coast and Geodetic Survey and the New York State Engineer and Surveyor. See Table 5.

From what has been stated on page 2034, the average ebb flow will be the mean given above plus one-half of this net discharge, and the average flood volume will be the mean less one-half of this net discharge, or:

Average volume of ebb current, 6 990 600 000 cu. ft.
Average volume of flood current, 5 903 400 000 " "

East River.

The run-off from the areas which naturally drain into the East River is small compared with the volumes of the tidal discharges. As the East River is a strait, the flow is subject to the actions of the separate tidal waves entering at each end, Throgs Neck and Governors Island.

The difference in water level creates a hydraulic flow through the strait or river. As the "westerly and southerly" and the "northerly and easterly" hydraulic slopes are equal, there would be no reason to expect a greater flow in one direction than in the other.

A sufficient number of actual measurements of velocity, and extending over sufficiently long periods of time, have not been made to determine positively the mean volumes flowing on the two tidal currents; therefore, the difference between the volumes can only be estimated by theoretical reasoning.

If a base line is drawn and divided into equal spaces, each of which represents a lunar hour, and if a sinusoid be drawn on this base line to represent the rise and fall of the water above and below mean water level off Willets Point, then each ordinate would represent the surface level of the water above or below mean water level at each lunar hour.

If a second sinusoid be drawn in a similar manner for the rise and fall of the tide at Governors Island, then, by placing it so as to be spaced at the proper interval of time relative to the Willets Point

sinusoid, a comparison can be made of the elevations of the water surface at both ends of the strait for every lunar hour. These curves are represented in Fig. 7, and from a study of them it will be noted that, from the lunar hours of IX to III after the transit of the moon, the surface of the water at Willets Point is above that at Governors Island, and a reverse condition is maintained from the lunar hours of III to IX. These two sinusoids form lunes, the ordinates of which represent the difference of the water levels between the ends of the straits at each lunar hour. If the centers of these lunes are determined, it will be noted that, during the time when the current is flowing from Willets Point to Governors Island, the water level is 0.74 ft. above mean water level. For the reverse current, from Governors Island to Willets Point, the average water level is the same distance below mean water level. In other words, the cross-sectional area of the stream during the "westerly and southerly" flow would be greater than during the "northerly and easterly" flow; or, a greater flow would occur from the Sound to the Upper Bay than in the reverse direction, if the velocities were the same in each direction.

Assuming that the average depth of the river below mean water level is 38 ft., then the average depth during the southerly flow would be

$$38 + 0.74 = 38.74 \text{ ft.},$$

and in a similar way the average depth during the northerly flow would be

$$38 - 0.74 = 37.26 \text{ ft.}$$

If the velocities are the same in each direction, and the lengths of time during which the currents flow are equal, then the mean volumes flowing on a southerly current would be

$$\frac{38.74}{37.26} = 1.04$$

times the volume flowing on a northerly flow. In other words, the southerly discharge of the river would be, from this reasoning, about 4% greater than the northerly discharge.

If, at different sections of the river between Willets Point and the Battery, sinusoids are drawn to represent the surface of the water above and below mean water level, and on these diagrams the northerly and southerly currents are marked, and the average water levels are determined for each current, it will be found that the cross-sectional

area of the river is greater on the southerly current for those sections between Willets Point and some place at about 60th Street; but for the sections between the Battery and about 60th Street, the reverse condition obtains. From this it would seem as if the southerly flow did not exceed the northerly flow by the quantity which would be expected from the difference in water level at each end of the strait.

Observations made by the U. S. Coast and Geodetic Survey indicate that, generally speaking, the current having the larger section has the smaller velocity, and *vice versa,* thus leaving the question of the quantity of net discharge uncertain.

Henry Mitchell* gives, as the result of some of his observations, the volumes passing through a section opposite Wall Street, 4 341 100 000 cu. ft. on flood and 4 383 500 000 cu. ft. on ebb, or a difference of only 1% in favor of the southerly flow.

The Coast Survey's observations for sections between Wallabout Bay and the southern extremity of Blackwells Island indicate† that the flood volume is quite as great as that of the ebb. These observations covered work done at 18 stations. The Survey's observations between Blackwells Island Light and Throgs Neck, taken at 21 stations, indicate† that the easterly current is decidedly stronger than the westerly, but that the average cross-sectional area of the currents is greater on the westerly flow. Thus the westerly net discharge cannot be great, for these figures would indicate a small net discharge easterly into the Sound.

The Survey's observations around Blackwells Island, taken alone, indicate‡ a small net southerly discharge, the west-and-south-going volume being about 3% greater than the north-and-east-going volume. As Blackwells Island is about midway between the ends of the strait, and as the stream is well defined at this point, these observations seem to be important in deciding the question of whether there is or is not a net westerly and southerly discharge.

Although Henry Mitchell lays great stress on the difference in cross-sectional areas, which at Hell Gate amounts to nearly 8%, and thus reasons that the westerly discharge is about that much greater than the easterly discharge, the theoretical state of the conditions indicates

*Report of the U. S. Coast and Geodetic Survey, 1871, p. 131.
†U. S. Coast and Geodetic Survey, Letter of February 6th, 1909.
‡U. S. Coast and Geodetic Survey, February 6th, 1909.

that the volume flowing on the currents will not vary directly as the cross-sections of the two streams at Hell Gate. This is true, because, the smaller the section at the Gate, the greater must be the velocity at that point, as the length through the Gate is a small fraction of the lengths of the other reaches of the river. This result can be shown by Bernoulli's theorem applied to a strait, which becomes, when friction is taken into account,*

$$v^2 = \frac{2\,g\,(\zeta_{,} - \zeta_{,,})}{1 + \zeta' \frac{P_1}{\Omega_1} L_1 + \zeta' \frac{P_2}{\Omega_2} L_2 \left(\frac{\Omega_1}{\Omega_2}\right)^2 + \zeta' \frac{P_3}{\Omega_3} L_3 \left(\frac{\Omega_1}{\Omega_3}\right)^2 + \ldots.}$$

in which $\zeta_{,}$ and $\zeta_{,,}$ denote the heights of the surface of the water, at the Gate and beyond, above half-tide level; ζ' a friction factor; P the wetted perimeter; Ω the area of the section, and L the length of the channel. The subscript, 1, refers to the Gate, and subscripts, 2, 3, etc., refer to other portions of the channel. The resistance, as expressed in the denominator, increases if the cross-section at the Gate, Ω_1, increases, the other sections, Ω_2, Ω_3, etc., remaining the same. The velocity then would vary inversely as Ω_1. Because the other sections, Ω_2, Ω_3, do not remain the same for both streams, the real velocity will vary less than changes in Ω_1.

Taking into account the information thus briefly outlined, for the whole length of the river, it "seems probable that the volume transmitted westerly can be not more than one or two per cent. greater than the volume transmitted easterly."†

As the volume flowing on each tidal current is about 4 000 000 000 cu. ft., the net or resultant flow from the Sound to the Upper Bay would be, at 2%, 80 000 000 cu. ft. per tidal cycle.

East River at Brooklyn Bridge.—The section of the river at Brooklyn Bridge is 1 500 ft. wide, and its average depth below mean water level is 44.20 ft., so that its area is 66 300 sq. ft.

The average velocity of the swiftest surface thread during the tidal period on ebb is 2.42 knots, and on flood 2.22 knots. These velocities were obtained by plotting the results of the float observations of the Metropolitan Sewerage Commission, in the same manner as those for The Narrows. The mean of the ebb and flood average velocities of the swiftest surface thread is 2.32 knots, or 14 105 ft. per solar hour.

* See Appendix C.

† Letter, U. S. Coast and Geodetic Survey, August 14th, 1908.

The coefficient to reduce the surface velocities to cross-sectional velocities was taken at 0.75, the same as for The Narrows and Hudson River. The mean cross-sectional velocity, therefore, is 10 504 ft. per solar hour. Multiplying the area of the section by the mean cross-sectional velocity gives 696 500 000 cu. ft. as the mean rate of flow through the section.

The mean volume flowing on ebb and flood currents is 4 330 000 000 cu. ft., obtained by multiplying the rate of flow through the section by the length of time, or 6.21 solar hours.

On page 2041 it is shown that there is a net discharge through the East River from the Sound into the Upper Bay, and that it is about 80 000 000 cu. ft. per tidal cycle. This figure includes the mean yearly discharge of land-water run-off, which amounts to about 3 400 000 cu. ft. per tidal cycle of 12 lunar hours. From what has been stated on page 2034, the average ebb flow will be the mean given above plus one-half of this net discharge, and the average flood volume will be the mean less one-half of this net discharge, or:

Average volume of ebb current, 4 370 000 000 cu. ft.
Average volume of flood current, 4 290 000 000 " "

East River off 11th Street.—The section of the river off East 11th Street, Manhattan, is 2 235 ft. wide and its average depth below mean water level is 36.13 ft., so that its area is 80 750 sq. ft.

The average velocity of the swiftest surface thread during the tidal period on ebb is 1.91 knots, and on flood 1.85 knots. These velocities were obtained by plotting the results of the float observations of the Metropolitan Sewerage Commission, in the same manner as those for The Narrows. The mean of the ebb and flood average velocities of the swiftest surface thread is 1.88 knots, or 11 430 ft. per solar hour.

The coefficient to reduce the surface velocities to cross-sectional velocities was taken at 0.75, the same as for The Narrows and Hudson River. The mean cross-sectional velocity, therefore, is 8 572 ft. per solar hour. Multiplying the area of the section by the mean cross-sectional velocity gives 692 200 000 cu. ft. per solar hour, as the mean rate of flow through the section.

The mean volume flowing on ebb and flood currents is 4 299 000 000 cu. ft., obtained by multiplying the rate of flow through the section by the length of time, or 6.21 solar hours.

As shown on page 2041, the net discharge toward the Upper Bay is about 80 000 000 cu. ft. per tidal cycle. The average volumes of ebb and flood currents were obtained in the same manner as those for the East River at Brooklyn Bridge.

Average volume of ebb current, 4 339 000 000 cu. ft.
Average volume of flood current, 4 259 000 000 " "

East River off 31st Street.—The section of the river off East 31st Street, Manhattan, is 3 180 ft. wide, and its average depth below mean water level is 39.07 ft., so that its area is 124 250 sq. ft.

The average velocity of the swiftest surface thread during the tidal period on ebb is 1.13 knots, and on flood 1.29 knots. These velocities were obtained by averaging a number of observations, made near this section by the U. S. Coast and Geodetic Survey, of the surface velocities at strength. It was assumed that the velocities vary as ordinates of a sinusoid, and the average velocities were obtained by multiplying the velocities at strength by $\frac{2}{\pi}$.

The mean of the ebb and flood average velocities of the swiftest surface thread is 1.21 knots, or 7 357 ft. per solar hour.

The coefficient to reduce the surface velocities to cross-sectional velocities was taken at 0.75, the same as for The Narrows, Hudson River, and the other sections on the East River. The mean cross-sectional velocity, therefore, is 5 518 ft. per solar hour. Multiplying the area of the section by the mean cross-sectional velocity gives 685 600 000 cu. ft. as the mean rate of flow through the section.

The mean volume flowing on ebb and flood currents is 4 258 000 000 cu. ft., obtained by multiplying the rate of flow through the section by the length of time, or 6.21 solar hours.

As shown on page 2041, the net discharge toward the Upper Bay is about 80 000 000 cu. ft. per tidal cycle. The average volumes of ebb and flood currents were obtained in the same manner as those for the East River at Brooklyn Bridge.

Average volume of ebb current, 4 298 000 000 cu. ft.
Average volume of flood current, 4 218 000 000 " "

*East River off 81st Street.**—The west channel is 800 ft. wide, and its average depth below mean water level is 39 ft., so that its area

* The data for this estimate are from a letter of the U. S. Coast and Geodetic Survey dated August 14th, 1908.

is 31 200 sq. ft. Similar figures for the east channel, a little southward from Graham Avenue are 600, 26.5 and 15 900, respectively. In the former section the maximum surface velocity is 4.9 knots and in the latter 4.0 knots, according to observations made in 1857 and 1874. Multiplying these velocities by 0.75 to reduce them to cross-sectional velocities at time of strength, and by $\frac{2}{\pi}$ to reduce them to mean cross-sectional velocities during each tide, and by the area of the section, the following volumes were obtained:

2 756 295 600 cu. ft. passing western section.
1 146 685 915 " " " eastern "

The sum of these two volumes is 3 902 981 515 cu. ft., which is the mean volume flowing on ebb and flood currents. Dividing this figure into the average volume flowing on ebb and on flood, in the same manner as for the East River off Brooklyn Bridge, the following figures were obtained:

Average volume of ebb current, 3 943 000 000 cu. ft.
Average volume of flood current, 3 863 000 000 " "

East River off Old Ferry Point.—The section of the river off Old Ferry Point is 3 000 ft. wide, and its average depth below mean water level is 43.88 ft., so that its area is 131 650 sq. ft.

The average velocity of the swiftest surface thread during the tidal period on ebb is 0.88 knot, and on flood 1.09 knots. These velocities were obtained by averaging a number of observations of the surface velocities at strength at this point, made by the U. S. Coast and Geodetic Survey. Assuming that the velocities vary as the ordinates of a sinusoid, the average surface velocity at strength was multiplied by $\frac{2}{\pi}$ to obtain the average velocity of the swiftest surface thread. The mean of the ebb and flood average velocities of the swiftest surface thread is 0.985 knot or 5 989 ft. per solar hour.

The coefficient to reduce the surface velocity to cross-sectional velocity was taken at 0.75, the same as for The Narrows, Hudson River, and the other sections on the East River. The mean cross-sectional velocity, therefore, is 4 491 ft. per solar hour. Multiplying the area of the section by the mean cross-sectional velocity gives 591 300 000 cu. ft. as the mean rate of flow through the section.

The mean volume flowing on ebb and flood currents is 3 672 000 000 cu. ft., obtained by multiplying the rate of flow through the section by the length of time, or 6.21 solar hours.

As shown on page 2041, the net discharge toward the Upper Bay is about 80 000 000 cu. ft. per tidal cycle. The average volumes of ebb and flood currents were obtained in the same manner as those for the East River at Brooklyn Bridge.

Average volume of ebb current (westerly), 3 712 000 000 cu. ft.
Average volume of flood current (easterly), 3 632 000 000 " "

Reason for the Volumes of Flow Diminishing from the Southerly End to the Easterly End of the East River.

The average volumes of flow for the ebb and flood currents at different sections of the East River, in cubic feet, are as follows:

	Ebb.	Flood.
Off Brooklyn Bridge.....	4 370 000 000	4 290 000 000
Off East 11th Street.....	4 339 000 000	4 259 000 000
Off East 31st Street.....	4 298 000 000	4 218 000 000
Off East 81st Street.....	3 943 000 000	3 863 000 000
Off Old Ferry Point.....	3 712 000 000	3 632 000 000

It will be seen from this statement that the volumes of flow decrease from the southerly end to the easterly end of the river. A reason for this decrease was sought, with the following result:

On Fig. 37 curves are drawn for each lunar hour, with distances as abscissas and velocities as ordinates, flood velocities being plotted above, and ebb velocities below, the datum lines. Another curve is plotted to the right showing the average elevation of the water in the East River for each lunar hour. This latter curve is cross-hatched for the times when the water is rising, and is left blank when falling.

It will be noted that, during the 6 lunar hours when the average level of the water is rising, practically for the entire length of the river, the current is flowing flood (north and east). In order that the level of the water may rise, it is necessary for more water to flow in at the Battery than flows out at Throgs Neck, in order to make up this rise. In the same way, for the 6 lunar hours when the average elevation of the water is falling, the current is ebb (flowing west and south) for practically the entire length of the stream.

In order that the elevation of the water may fall, it is necessary that a greater quantity should flow out of the river at the Battery than flows in at Throgs Neck.

In discussing this subject, it must be kept clearly in mind that the velocities of the currents are due to the heads produced by the varying hydraulic slopes, and that the rise and fall of the water are due to the progress of the tidal waves entering the East River from each end.

The advance of the tidal waves is retarded by the shallowness of the waters and by the natural obstructions. The tidal wave entering the East River at Governors Island is about 3 hours, 5 min. ahead of the wave entering at Throgs Neck. As these waves progress through the river in opposite directions, there is a superposition and a consequent interference. This interference and the natural obstructions of the river have the effect of making the wave vary from a true sinusoid.

As the Governors Island wave enters the river before the Throgs Neck wave, greater quantities of water have to flow past points on the lower reaches of the river than points farther up (northerly and easterly) so as to provide for the tidal prism, for, if not, there would be some point in the river (near its mid-length) where the water would not rise or fall.

Kill van Kull.

Kill van Kull off Port Richmond.—The section of the river off Port Richmond is 1 380 ft. wide, and its average depth below mean water level is 28.30 ft., so that its area is 39 060 sq. ft.

The average velocity of the swiftest surface thread during the tidal period on ebb is 1.48 knots, and on flood 1.24 knots. These velocities were obtained by plotting the results from the float observations of the Metropolitan Sewerage Commission, in the same manner as those for The Narrows. The mean of the ebb and flood average velocities of the swiftest surface thread is 1.36 knots, or 8 269 ft. per solar hour.

The coefficient to reduce the surface velocity to cross-sectional velocity was taken at 0.75, the same as for The Narrows, Hudson River, and East River. The mean cross-sectional velocity, therefore, is, 6 202 ft. per solar hour. Multiplying the area of the section by the mean cross-sectional velocity gives 242 200 000 cu. ft., as the mean rate of flow through the section.

FIG. 37.

The mean volume flowing on ebb and flood currents is 1 502 000 000 cu. ft., obtained by multiplying the rate of flow through the section by the length of time, or 6.21 solar hours.

The mean yearly discharge of land-water run-off through Kill van Kull for 6 lunar hours is 44 100 000 cu. ft., or 88 200 000 cu. ft. per tidal cycle of 12 lunar hours. These figures are from the records of the U. S. Coast and Geodetic Survey and the New York State Engineer and Surveyor. See Table 4.

From what has been stated on page 2034, the average ebb volume will be the mean given above plus one-half of this net discharge, and the average flood volume will be the mean less one-half of this net discharge, or:

Average volume of ebb current, 1 546 100 000 cu. ft.
Average volume of flood current, 1 457 900 000 " "

*Kill van Kull Between Constable Point and New Brighton.**—The section is 1 425 ft. wide, and its average depth below mean water level is 26 ft., so that its area is 38 475 sq. ft. The maximum surface velocity for this section is 2.3 knots at time of strength, according to observations made in 1856 and in 1885. Multiplying these velocities by 0.75 to reduce them to cross-sectional velocities at time of strength, and by $\frac{2}{\pi}$ to reduce them to mean cross-sectional velocities during each tide, and by the area of the section, the mean volume flowing through the section was obtained, namely, 1 595 475 341 cu. ft.

As a check on this figure, the U. S. Coast and Geodetic Survey* made the following calculation: The area of the waters above this section, including most of Kill van Kull, Newark Bay, the Passaic River as far as the Falls, and the Hackensack River and branches, is 15.3 sq. statute miles, or 426 539 520 sq. ft. The level of Newark Bay and near-by branches rises and falls about 4.5 ft. The tidal volume, therefore, is $426\,539\,520 \times 4.5 = 1\,919\,427\,840$ cu. ft.

A few observations in the Arthur Kill off Elizabethport, just above the mouth of the Elizabeth River, in 1856 and 1885, indicate a maximum surface velocity of 1.8 knots, or $\frac{18}{23}$ of the value observed in the

* These calculations are from a letter of the U. S. Coast and Geodetic Survey, dated August 14th, 1908.

Kill van Kull. The section of the Arthur Kill is about $600 \times 16 =$ 9 600 sq. ft., which would be equivalent to $\frac{18}{23}$ of 9 600, or 7 513 sq. ft., if the velocity were 2.3 knots, instead of 1.8 knots. Hence, the proportion of the volume flowing through the mouth of the Kill van Kull would be

$$\frac{38\ 475}{38\ 475 \quad + \quad 7\ 513} = 0.8366313.*$$

This proportion, 0.8366313, multiplied by 1 919 427 840, gives 1 605 853 409 cu. ft. for the mean volume entering and leaving Kill van Kull. This agrees well with the results from the determination first given.

Averaging the two figures given by the U. S. Coast and Geodetic Survey for the flow of water through Kill van Kull between Constable Point and New Brighton, 1 600 000 000 cu. ft. is obtained as the mean volume flowing on ebb and flood currents. This figure was divided into volumes flowing on ebb current and flood current in the same manner as for Kill van Kull off Port Richmond, using 88 200 000 cu. ft. per tidal cycle for the mean yearly discharge of land-water run-off.

Average volume of ebb current, 1 644 100 000 cu. ft.
Average volume of flood current, 1 555 900 000 " "

The tidal prism (or the area multiplied by the mean range of tide) between the section off Port Richmond and the section from Constable Point to New Brighton is about 100 000 000 cu. ft.

The mean volume flowing through the section off Port Richmond would be less than the quantity flowing past the section at Constable Point by the tidal prism between these two places, as that much water would be used in increasing the level of the water. Subtracting the tidal prism from the flow through the section, 1 600 000 000 — 100 000 000 = 1 500 000 000 cu. ft. This figure agrees well with the mean volume flowing on ebb and flood currents, 1 502 000 000, as calculated for Kill van Kull, off Port Richmond, as stated on page 2048.

Harlem River.

Harlem River off 144th Street.—The section of the river off West 144th Street, Manhattan, is 460 ft. wide and its average depth below mean water level is 15.67 ft., so that its area is 7 210 sq. ft.

* The proportion flowing through the Arthur Kill would be 0.1633687.

The average velocity of the swiftest surface thread during the tidal period on ebb is 0.71 knot, and on flood 0.69 knot. These velocities were obtained by plotting the results of the float observations of the Metropolitan Sewerage Commission, in the same manner as those for The Narrows. The mean of the ebb and flood average velocities of the swiftest surface thread is 0.70 knot, or 4 256 ft. per solar hour.

The coefficient to reduce the surface velocities to cross-sectional velocities was taken at 0.75, the same as for The Narrows, Hudson River, East River, and Kill van Kull. The mean cross-sectional velocity, therefore, is 3 192 ft. per solar hour. Multiplying the area of the section by the mean cross-sectional velocity gives 23 010 000 cu. ft. as the mean rate of flow through the section.

The mean volume flowing on ebb and flood currents is 142 900 000 cu. ft., obtained by multiplying the rate of flow through the section by the length of time, or 6.21 solar hours.

At 144th Street the average water level during ebb (northerly) current is 0.98 ft. above mean water level, and during flood (southerly) current is 0.98 ft. below mean water level. The average area of cross-section during ebb current, therefore, is the mean area of the section plus the width multiplied by 0.98, or 7 660 sq. ft.; and the average area of cross-section during flood current is the mean area of the section minus the width multiplied by 0.98, or 6 760 sq. ft. The mean volume flowing on ebb and flood was divided in proportion to the average area of cross-sections on the ebb current and on the flood current.

Average volume of ebb current, 151 800 000 cu. ft.
Average volume of flood current, 134 000 000 " "

Harlem River 600 Feet North of High Bridge.—The section of the river 600 ft. north of High Bridge is 410 ft. wide, and its average depth below mean water level is 11.71 ft., so that its area is 4 800 sq. ft.

The average velocity of the swiftest surface thread during the tidal period on ebb is 1.30 knots, and on flood 1.22 knots. These velocities were obtained by plotting the results of the float observations of the Metropolitan Sewerage Commission, in the same manner as those for The Narrows. The mean of the ebb and flood average velocities of the swiftest surface thread is 1.26 knots, or 7 661 ft. per solar hour.

The coefficient to reduce the surface velocities to cross-sectional velocities was taken at 0.75, the same as for The Narrows, Hudson

River, East River, and Kill van Kull. The mean cross-sectional velocity, therefore, is 5 746 ft. per solar hour. Multiplying the area of the section by the mean cross-sectional velocity gives 27 580 000 cu. ft. as the mean rate of flow through the section.

The mean volume flowing on ebb and flood currents is 171 200 000 cu. ft., obtained by multiplying the rate of flow through the section by the length of time, or 6.21 solar hours.

At this section the average water level during ebb (northerly) current is 0.58 ft. above mean water level, and during flood (southerly) current is 0.58 ft. below mean water level. The average area of cross-section during ebb current, therefore, is the mean area of the section plus the width multiplied by 0.58, or 5 040 sq. ft.; and the average area of cross-section during flood current is the mean area of the section minus the width multiplied by 0.58, or 4 560 sq. ft. The mean volume flowing on flood and ebb was divided in proportion to the average area of cross-sections on the ebb current and on the flood current.

Average volume of ebb current, 179 800 000 cu. ft.
Average volume of flood current, 162 600 000 " "

Reason for the Volumes of Flow Diminishing from the Northerly End to the Southerly End of the Harlem River.

Although it was not possible to calculate accurately the flow of water in the Harlem River at places other than 144th Street and 600 ft. north of High Bridge, because enough float observations were not made at other points, it is apparent that the quantity of water flowing past any section decreases from the northerly to the southerly end.

The float observations by the Metropolitan Sewerage Commission near Wards Island, in the Harlem River, show small velocities and a tendency of the floats to eddy and drift toward the shore.

The few float observations in the Harlem River near Spuyten Duyvil show velocities considerably greater than those at the southerly end.

Fig. 38 was made to show why the volumes of flow diminish from the northerly to the southerly end. This diagram is similar in construction to Fig. 37 for the East River. The distance from Spuyten Duyvil to Wards Island is laid off for the lunar hours as abscissas and the velocities as ordinates. The flood velocities, or those flowing south,

are laid off to scale below the datum lines, and the ebb velocities, or those flowing north, are laid off to scale above the datum lines.

A curve is drawn at the left to show the average elevation of the water in the Harlem River at each lunar hour. This curve is cross-hatched for the times when the water is rising, and is left blank when falling.

It will be noted that, during the 6 lunar hours when the average level of the water is rising, the current is flowing flood for the entire length of the river. In order that the level of the water may rise, it is necessary that a greater quantity should flow in through Spuyten Duyvil than flows out at Wards Island, to make up this increase of elevation.

In the same way, for the 6 lunar hours during which the average level of the water is falling, the current is flowing ebb for the entire length of the river. In order that the level of the water may fall, it is necessary that more water flow out through Spuyten Duyvil than flows in at Wards Island. If the same quantities should pass Wards Island and Spuyten Duyvil during these 6 lunar hours, the average elevation of the water in the river would not fall, but would remain practically constant. The converse is also true. This is the reason that the volumes of flow diminish from the northerly to the southerly end of the Harlem River.

Resultant Flows.

The volumes flowing on ebb currents exceed those flowing on flood currents, so that there is a resultant flow during each tidal period through the harbor toward the sea.

In the rivers discharging into the harbor, the mean resultant flow equals the mean fresh-water run-off from the water-sheds above. When the ranges (rise and fall) of two successive tides are equal, a quantity equal to the fresh-water run-off must flow out and not return, so as to keep the elevation of the water the same on the next tide. As the ranges change from tide to tide, this will not be true in each individual instance, but will be true under mean conditions.

The following resultant flows are true only for mean conditions; this is, when the range of tide is normal and the mean quantity of land-water run-off is flowing. They are the difference between the flood and ebb discharges, as shown in the preceding paragraphs.

FIG. 38.

The Narrows.—The resultant flow through The Narrows is made up of the resultant flows of the Hudson River, the East River, and the Kill van Kull. It amounts to 1 262 400 000 cu. ft. per tidal cycle.

Hudson River.—The resultant flow in the Hudson River is the fresh-water run-off from the water-sheds above, namely, 1 087 200 000 cu. ft. per tidal cycle.

East River.—The resultant flow in the East River is small, and is caused probably by the average cross-sectional area being slightly greater when the water is flowing ebb (south) than when it is flowing flood (north). As shown on page 2041, the resultant flow (south) amounts to about 80 000 000 cu. ft. per tidal cycle.

The Kill van Kull.—The resultant flow in the Kill van Kull is made up of its proportionate share of the fresh-water run-off of the rivers tributary to Newark Bay. By proportionate share is meant 83.66313% of the total. The other 16.33687% flows out through the

Arthur Kill (page 2048). The resultant flow through the Kill van Kull amounts to 88 200 000 cu. ft. per tidal cycle.

Harlem River.—The resultant flow in the Harlem River is probably due to the greater average cross-sectional area which obtains on the ebb (northerly flow) than when the flow is in the reverse direction. Calculations gave 17 800 000 cu. ft. off 144th Street, and 17 200 000 cu. ft. at a section 600 ft. north of High Bridge. The mean resultant flow throughout the length of the river is about 17 400 000 cu. ft. per tidal cycle.

Under conditions of maximum net outflow toward the sea, the resultant flow is a little more than twice that under normal conditions. Under conditions of minimum net outflow, the resultant flow is about one-half of that under normal conditions.

In Table 7 are given the various steps by which the ebb and flood discharges, and the resultant flows, were calculated. This table is a

summary of the matter contained under the heading, "Volumes of Tidal Discharges," pages 2036 to 2049.

It is self-evident that, under the conditions which obtain for the East and Harlem Rivers, especially the former, there may be great variations from day to day in the resultant flow as given in the preceding paragraphs. It is possible that in the East River the resultant flow on some days may be many times greater than that stated for the normal, and on other days it is possible that it is in the opposite direction, or northerly and easterly. These variations are brought about by various causes, the principal one being the wind inducing abnormal tides in the Upper Bay and in Long Island Sound.

Volumes of Tidal Flow Into and Out of the Upper Bay.

Taking the Upper Bay as a central basin, the entrances and exits are the East River, Hudson River, Kill van Kull, and The Narrows. Into the Upper Bay there is a discharge of water from the Hudson and a proportion of the discharge of the Hackensack and Passaic Rivers, as well as the resultant flow from the Sound through the East River. This resultant flow through the East River toward the Upper Bay may or may not be great, but, under normal conditions, there is a small resultant discharge into the Bay. In consequence, there is a net flow of water seaward through The Narrows, and the effect of this seaward flow is felt possibly some 60 miles off Sandy Hook.*

While the water is flowing into and out of the Upper Bay during a full tidal cycle, the volume of water in the Upper Bay is changing, as is shown by the rise and fall of its water surface. In order to create this rise, more water must flow into the Upper Bay during approximately 6 lunar hours than runs out during the same hours. The converse also is true. As the water surface of the Upper Bay is nearly 21 sq. miles, and the mean range of tide is 4.4 ft., the tidal prism and also the volume of tidal change between any two periods of time can be estimated.

The rates or volumes of flow, in millions of cubic feet per lunar hour, are shown graphically by Fig. 8. To determine the volumes of flow through any one of the entrances to the Upper Bay at any given lunar hour, measure the ordinate to the proper curve in accordance

* U. S. Coast and Geodetic Survey, Vol. VII, 1859-60, Appendix 26.

with the scale marked at the side of the figure. These rates of flow are those under mean conditions, and are sufficiently accurate for all practical purposes.

Fig. 8 was constructed by estimating that the rates of flow vary as the ordinates of a curve of sines. Therefore, for each tidal flow, a sine curve was drawn to scale, so that its length would represent the number of lunar hours that the current would flow on either ebb or flood; and its area, between the curve and the base line, would represent the volumes of flow transmitted, as estimated under the heading, "Volumes of Tidal Discharges," page 2036. Dividing any volume of tidal discharge by six will give the average flow for one lunar hour. Multiplying this result by $\pi \div 2$, which is the ratio that the maximum ordinate of a sine curve bears to its average ordinate, will give the maximum flow for the current selected. This point was plotted to scale, and a sine curve was drawn through it. This work was repeated for each branch of the harbor.

In drawing the curves on Fig. 8 the lunar times were advanced by the number of minutes that the tidal waves required to progress from the Upper Bay to the sections selected for estimating the volumes of flow.

The rates of flow, in millions of cubic feet per lunar hour, were calculated, and the results are given in Table 9 for each branch of the harbor. The results for each lunar hour were obtained by multiplying the maximum flow for the current selected, as determined previously, by the cosine of the angle, which represents in degrees the difference between the lunar time of maximum strength and the lunar time for which the calculation was made.

By way of illustration, the calculation for the first lunar hour is given in Table 8.

The figures in Table 9 are the calculated rates of flow at each lunar hour. The rates of flow are not the volumes flowing throughout a full lunar hour, although they approximate to the latter. In consequence, the columns add up only approximately to the ebb and flood discharges, as given in the preceding paragraphs.

The quantity of water flowing in at any lunar hour should equal that flowing out, when allowance is made for the tidal prism in the Upper Bay. The accuracy of the work is shown by taking the algebraic sum of the ordinates in Fig. 8, which should be zero,

or by adding the horizontal lines at each lunar hour in Table 9, which should give equal quantities of water flowing into and out of the Upper Bay. The error is small, considering the assumptions made, in view of the lack of actual current observations extending over long periods of time.

Division of Sea- and Land-Water.

The salinity of the water in different parts of the harbor was observed by the Metropolitan Sewerage Commission from September, 1908, until December, 1909, inclusive. Eleven observation stations were established, as shown in Fig. 1. At each station observers were trained during the last months of 1908, and a complete record was made for every day of the year, 1909. Samples of water were taken each day at three different times, usually at 8.00 A. M., 12.00 Noon, and 4.00 P. M.

The term "land-water," as used in this investigation, represents any water between fresh-water and water containing approximately 300 parts of chlorine per 1 000 000 parts. Between these limits the observers would record the water as being 100% of land-water. The standard for "sea-water" was a water containing a salinity of 18 000 parts of chlorine per 1 000 000 parts, assuming that the chlorides represent 88.6% of the total specific gravity of sea-water. Under this condition, the salinometer reading would be 1.025 when corrected to a standard temperature of 60° Fahr.

The instruments were all calibrated, and, as a further check, their readings were compared with results obtained by chemical analyses. The indicated chlorine and the actual chlorine, as found by analysis, agreed very closely.*

The quantity of land-water discharged into the harbor varies according to the season, being greatest during April and least during August. When the discharge of land-water is at a maximum, the salt-water of the sea is driven down the Hudson, so that the river at Tarrytown is practically fresh. When the discharge of land-water is at a minimum, the salt-water works its way up the Hudson as far as Poughkeepsie.

If no land-water entered the harbor, the water therein would be as salty as that of the sea. As the record shows that the harbor water is salty, but less salty than sea-water, it is evident that the former is a mixture of sea-water and land-water. It was considered that these salinometer records could be used in finding the proportions of sea- and land-water in the harbor waters, and a study was made of them for this purpose.

About 13 000 observations for salinity were made in the harbor during 1909. Additional observations were made at different depths

* Report, Metropolitan Sewerage Commission, April 30th, 1910, p. 519.

below the surface. These indicated that, usually, the water was slightly more salty as the depth from the surface increased, that the difference was small, and that the difference in salinity at the surface and at various depths depended on the currents at the place of observation. If the currents were irregular in character, the difference in salinity was very small.

These observations were tabulated. The monthly averages of land-water are given in Table 10 for the different stations. In this table, the figures in the columns headed "All" are the averages of all the observations taken during a month. The figures in the column headed "Out" and "In" are the averages of all the observations taken during inflowing or outflowing currents. Some observations were taken when the direction of the current was doubtful, as at slack water, and these are not included under either "In" or "Out," but under "All."

A study was made of the records of the Weather Bureau, U. S. Department of Agriculture, so as to compare the rainfall of 1909 with the normal. The monthly and yearly precipitation at Albany, Carmel, Wappinger Falls, West Point, and New York, were averaged. The results of these averages are given in the last line of Table 10, and show the percentage of precipitation above or below the normal for each month of 1909.

The volumes of water flowing on ebb and flood currents, for different parts of the harbor, are stated under the heading, "Volumes of Tidal Discharges." From these data the volumes flowing at intermediate places were estimated (see Appendix B). These volumes are given in Table 11.

Additional information regarding specific gravities and temperatures of the water is given in Appendix D, as recorded by the salinity observations made by the Metropolitan Sewerage Commission.

The Upper Bay and Hudson River.—A longitudinal section was taken from The Narrows, through the Upper Bay and Hudson River as far as Tarrytown, the distance between the places being laid off as abscissas in Fig. 39. At the places named, the mean tidal flows of ebb tide, in cubic feet, were laid off as ordinates, and a smooth curve was drawn through these points.

This mean quantity of water flowing on ebb tide was then divided into land- and sea-water, using the salinometer percentages given in

TABLE 10.—Summary of Salinometer Records for 1909.

" " " Old Ferry Point	3 712	3 632
Newark Bay	1 972	1 866

The land-water was then divided into "land-water which will return" and "land-water which will not return." This was done by plotting to scale at the different places the mean discharge of land-water for 12 lunar hours above the middle line. The remainder of the land-water is "land-water which will return." The discharge of land-water is the same as that given in Table 5. The land-water is held back by flood tide, so that the discharge for 12 hours has to pass out during ebb tide. The principle on which this division was made is, that if the density of the water in two successive ebb tides is to remain constant, the same quantity of land-water must flow out and not return on each ebb tide.

The sea-water was divided into "sea-water which will return" and "sea-water which will not return" by making the "sea-water which will not return" the same proportion of the total sea-water, as the "land-water which will not return" is of the total land-water. This is so because the land- and sea-waters are mixed, and the quantity of "land-water which will not return" will take with it its proportionate quantity of sea-water.

The division of sea- and land-water in a flood tide, when the yearly mean quantity of land-water is flowing, is shown in Fig. 40. This diagram was constructed by laying off the tidal flow of the mean flood,

UPPER BAY AND HUDSON RIVER.
DIVISION OF SEA- AND LAND-WATER.

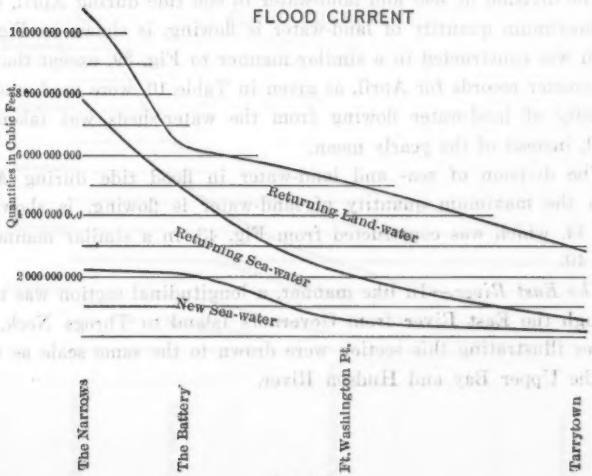

FIG. 40.

in cubic feet, as ordinates, and drawing a smooth curve through the points. This result is the same as subtracting from the top curve of Fig. 39, the quantity of "land-water which will not return." The "returning land-water" was obtained by laying off, from this top curve, the "land-water which will return," as given in Fig. 39. Below the second curve, the "sea-water which will return" was laid off, as given in Fig. 39, and marked "returning sea-water." The remaining part of the figure, the "new sea-water," is the same in quantity as the "sea-water which will not return," as given in Fig. 39.

In order to show the variation from mean conditions, Figs. 41, 42, 43, and 44 were constructed to show the division of sea- and land-water in ebb and flood tides during August and April, when the minimum and maximum quantities of land-water are flowing.

The division of sea- and land-water in ebb tide during August, when the minimum quantity of land-water is flowing, is shown in Fig. 41, which was constructed in a similar manner to Fig. 39, except that the salinometer records for August, as given in Table 10, were used, and the quantity of land-water flowing from the water-sheds was taken for August, instead of the yearly mean.

The division of sea- and land-water in flood tide during August, when the minimum quantity of land-water is flowing, is shown in Fig. 42, which was constructed from Fig. 41, in a similar manner to Fig. 40.

The division of sea- and land-water in ebb tide during April, when the maximum quantity of land-water is flowing, is shown in Fig. 43, which was constructed in a similar manner to Fig. 39, except that the salinometer records for April, as given in Table 10, were used, and the quantity of land-water flowing from the water-sheds was taken for April, instead of the yearly mean.

The division of sea- and land-water in flood tide during April, when the maximum quantity of land-water is flowing, is shown in Fig. 44, which was constructed from Fig. 43, in a similar manner to Fig. 40.

The East River.—In like manner, a longitudinal section was taken through the East River from Governors Island to Throgs Neck, and figures illustrating this section were drawn to the same scale as those for the Upper Bay and Hudson River.

‡This figure is 80 000 000 cu. ft. less than the "sea water which will return," as given in Table 16, because this is the mean resultant flow through the East River.

The Narrows.—The division of sea- and land-water in ebb tides by months is shown in Fig. 51. This diagram was constructed by laying off monthly divisions as abscissas, and the mean quantity of water flowing in ebb tide as ordinates. The curves dividing the "land-water which will return" and the "land-water which will not return" and the "sea-water which will return" and the "sea-water which will not return," were drawn in a similar manner to the curves shown on Fig. 39; except that the salinometer records were taken for each month from Table 10, instead of the mean for the year, and also the quantities of land-water flowing were taken for the different months, instead of the yearly mean.

The division of sea- and land-water in flood tides by months is shown in Fig. 52. This diagram was constructed by deducting from Fig. 51 the quantity of "land-water which will not return." This gives the upper curve of the diagram. The returning land-water was plotted by laying off, from this upper curve, the quantity of "land-water which will return," as given in Fig. 51. In a similar manner, the "returning

*Shown graphically on Fig. 52.

†Average of daily readings.

‡These figures are 80 000 000 cu. ft. less than the "sea-water which will return," as given in Table 18, because this is the mean resultant flow through the East River.

HUDSON RIVER, OFF THE BATTERY.
DIVISION OF SEA- AND LAND-WATER BY MONTHS.
FROM SALINOMETER RECORDS MADE BY THE METROPOLITAN SEWERAGE COMMISSION.

EBB CURRENT.

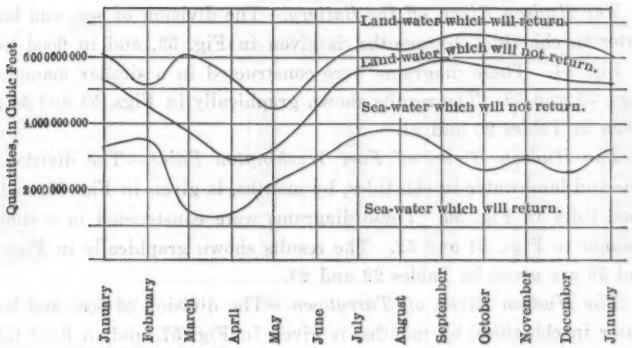

FIG. 53.

FLOOD CURRENT.

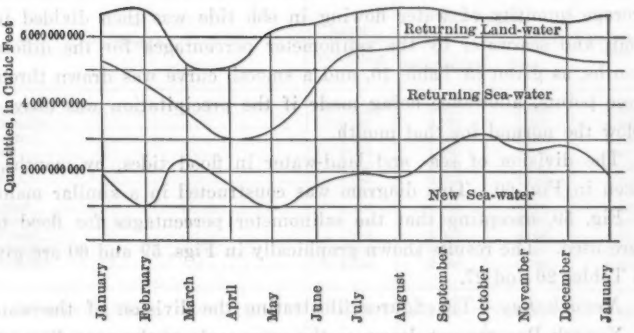

FIG. 54.

sea-water" was laid off, and the difference (the quantity to complete the diagram) is, therefore, "new sea-water," which is the same in quantity as the "sea-water which will not return," as given in Fig. 51. The results shown graphically in Figs. 51 and 52 are given in Tables 18 and 19.

The Hudson River, off the Battery.—The division of sea- and land-water in ebb tides, by months, is given in Fig. 53, and in flood tides in Fig. 54. These diagrams were constructed in a similar manner to Figs. 51 and 52. The results shown graphically in Figs. 53 and 54 are given in Tables 20 and 21.

The Hudson River, off Fort Washington Point.—The division of sea- and land-water in ebb tides, by months, is given in Fig. 55, and in flood tides in Fig. 56. These diagrams were constructed in a similar manner to Figs. 51 and 52. The results shown graphically in Figs. 55 and 56 are given in Tables 22 and 23.

The Hudson River, off Tarrytown.—The division of sea- and land-water in ebb tides, by months, is given in Fig. 57, and in flood tides, in Fig. 58. These figures were constructed in a similar manner to Figs. 51 and 52. The results shown graphically in Figs. 57 and 58 are given in Tables 24 and 25.

The East River, off Blackwells Island.—The division of sea- and land-water in ebb tides, by months, is given in Fig. 59. This diagram was constructed by laying off monthly divisions as abscissas, and the average quantity of water flowing in ebb tide as ordinates. The average quantity of water flowing in ebb tide was then divided into land- and sea-water by the salinometer percentages for the different months, as given in Table 10, and a smooth curve was drawn through these points, allowance being made if the precipitation was above or below the normal for that month.

The division of sea- and land-water in flood tides, by months, is given in Fig. 60. This diagram was constructed in a similar manner to Fig. 59, excepting that the salinometer percentages for flood tide were used. The results shown graphically in Figs. 59 and 60 are given in Tables 26 and 27.

Newark Bay.—The figures illustrating the division of the waters in Newark Bay are not drawn to the same scale as the preceding ones. The scale was increased in order to show more clearly the division of the waters.

Interpretation of Diagrams.

The sudden rise in the curve at the Battery, in Figs. 39, 40, 41, 42, 43, and 44, is caused by the discharge from and into the East River at the Battery, and also by the discharge from and into the Kill van Kull at Staten Island near The Narrows.

The salinometer readings at the station on Governors Island were used for the Battery, as it was the nearest observation station to this place. The salinometer readings at this station were affected more by the discharge from the East River than by that from the Hudson. In consequence, it is possible that more land-water should be shown at the Battery than in Figs. 39, 40, 41, 42, 43, and 44.

The diagrams showing the conditions existing in the East River, namely, Figs. 45, 46, 47, 48, 49, and 50, are not divided up like the others to show the "water which will return" and the "water which will not return." It was not possible to divide them in this manner, first, because the East River is a strait, open at both ends to bodies of salt-water, and second, because the water-sheds draining into it were so small that if a division had been attempted, as was done with the Hudson River, the "land-water which will not return" would have been so small that it would appear to be scarcely thicker than a line on the diagrams.

Conclusions.

A study of these diagrams shows that the flushing action of the waters of the harbor is not as great as the large volumes flowing on the tides would seem to warrant. All the diagrams show that the quantity of "sea- and land-water which will not return" is not a large proportion of the quantity flowing on an ebb tide. There is always a large quantity of "water which will return" on the succeeding flood tide.

The quantity of "new sea-water" is never a large proportion of the total quantity flowing on a flood tide. This "new sea-water" is only new off places situated near the ocean, and is not new at such places as the Upper Bay, Fort Washington Point, Tarrytown, East River, or Newark Bay. At these places the "new sea-water" is really water which has not been at the place on the previous tide, but comes from some other part of the harbor. For instance, at Fort Washington Point, the "new sea-water" would be from the lower reaches of the

Hudson, or Upper Bay, or perhaps some from the East River entering the Hudson at the Battery.

The water which has a seaward trend and will not return is the quantity of land-water from the water-sheds. For places near the ocean, this seaward trend is increased by some "sea-water which will not return"; but, for places well within the harbor, such "sea-water which will not return" is replaced by sea-water (as explained previously) which comes from some other part of the harbor, and is not clean ocean-water.

The diagrams indicating the division of sea- and land-water by months show that the "sea-water which will return" is always greatest during the summer and least during the spring.

The "sea- and land-water which will not return" is least during February and the summer, and greatest during the spring.

The flushing out of the harbor, or the seaward trend, is greatest during the spring and least in February, under normal conditions.

ACKNOWLEDGMENTS.

The writer acknowledges his thanks to David C. Johnson, Jun. Am. Soc. C. E., his office assistant, for aid in making the diagrams and calculations, and for numerous valued suggestions; also to O. H. Tittmann, M. Am. Soc. C. E., and Mr. F. W. Perkins, both of the U. S. Coast and Geodetic Survey, for their courtesies in permitting an inspection of the Survey records, and for their advice and criticisms.

APPENDIX A.

HARBOR DIVISIONS.

The boundaries for the several divisions of the harbor were selected as follows: At the entrance to the Lower Bay, by a line from Hook Beacon, on Sandy Hook, tangent to the westerly end of Rockaway Beach, to Barren Island. At the mouth of the Raritan River, by a line from Ferry Point to the extreme easterly point of South Amboy. At the entrance to the Shrewsbury River, by a line from the Post Light at Spermaceti Cove southwesterly to Highlands. At The Narrows, by a line drawn from the point at the south of Fort Hamilton Reservation to the dock about ½ mile south of Fort Wadsworth Light. At the south end of the East River, by a line drawn from the Battery to the foot of State Street, Brooklyn. At the south end of the Hudson River, from Castle Garden to the south end of the docks at Communipaw. At the east end of Kill van Kull, from Constable Point to the northerly point at New Brighton, Staten Island. At the west end of Kill van Kull, from the extreme end of Bergen Point southerly to Port Richmond. At the northerly end of Arthur Kill, by a line drawn from the railroad dock just east of Port Avenue, Elizabethport, southerly to Staten Island. At the south end of Arthur Kill, by a line drawn from Ferry Point to the extreme southwest end of Staten Island. At the upper end of Newark Bay, by lines drawn from the extreme southerly end of the Meadows, between the mouths of the Passaic and Hackensack Rivers, westerly across the Passaic and southeasterly across the Hackensack to the point of the Meadows. At the east end of the East River, by a line from the light on Throgs Neck to the northerly end of Willets Point. At the southerly end of the Harlem River, by a line from the foot of East 126th Street to the northerly corner of the Bronx Kills. At the northerly end of the Harlem River, by the New York Central and Hudson River Railroad bridge. The Bronx Kills, Little Hell Gate, the west branch between Manhattan and Randalls and Wards Islands, Newtown Creek, and Wallabout Bay are included in the East River. The areas of all islands have been subtracted.

APPENDIX B.

Calculation of Volumes Flowing on Tides.

Figures in Cubic Feet per Tidal Flow.

Hudson River, off the Battery:

The ebb flow equals the ebb off 39th Street plus the tidal prism between the Battery and 39th Street, Manhattan.

Ebb: 6 990 000 000 + 3.7 sq. miles × (5 280)² × 4.3 ft., mean rise of tide	7 430 000 000
Mean discharge of fresh water in 12 lunar hours	1 087 000 000
Flood: Taken as the difference	6 343 000 000

Hudson River, off Fort Washington Point:

The ebb flow equals the ebb off 39th Street, minus the tidal prism between Fort Washington Point and 39th Street, Manhattan.

Ebb: 6 990 000 000 — 6.6 sq. miles × (5 280)² × 4.15 ft., mean rise of tide	6 230 000 000
Mean discharge of fresh water in 12 lunar hours	1 087 000 000
Flood: Taken as the difference	5 143 000 000

Hudson River, off Tarrytown:

The ebb flow equals the ebb off Fort Washington Point, minus the tidal prism between Tarrytown and Fort Washington Point.

Ebb: 6 230 000 000 — 21.0 sq. miles × (5 280)² × 3.85 ft., mean rise of tide	3 980 000 000
Mean discharge of fresh water in 12 lunar hours	1 087 000 000
Flood: Taken as the difference	2 893 000 000

Newark Bay:

The figures were taken from those of the Coast and Geodetic Survey, August 14th, 1908, as they contained an estimate of the flow through Arthur Kill.

The average of flood and ebb:	
Through Kill van Kull	1 600 000 000
Through Arthur Kill	319 000 000
(1) Total, average for Newark Bay	1 919 000 000
(2) Mean fresh water discharged into Newark Bay during 6 lunar hours	52 757 000
Mean ebb flow, (1) + (2)	1 972 000 000
Mean flood flow, (1) — (2)	1 866 000 000

APPENDIX C.

BERNOULLI'S THEOREM.

Bernoulli's theorem, applied to a strait connecting two large bodies of water, becomes, where friction is taken into account,

$$\frac{V_1^2}{2} = g\,(\zeta_{'} - \zeta_{''}) - \zeta' \frac{P_1}{\Omega_1} \frac{V_1^2}{2} L_1 - \zeta' \frac{P_2}{\Omega_2} \frac{V_2^2}{2} L_2 - \ldots\ldots$$

Where V_1 = the velocity at the smallest section;
V_2, etc. = the velocities at other sections;
$\zeta_{'}$ and $\zeta_{''}$ = the heights of the water each side of the smallest section;
ζ' = a friction factor;
P = the wetted perimeter;
Ω_1 = the area of the smallest cross-section;
Ω_2, etc. = areas of other cross-sections;
L_1 = the length of the channel for the smallest section;
L_2, etc. = lengths of other parts of the channel.

The conditions of continuity require, with the same volume flowing, the velocity to vary inversely as the cross-sections,

$$\frac{V_2}{V_1} = \frac{\Omega_1}{\Omega_2}; \frac{V_3}{V_1} = \frac{\Omega_1}{\Omega_3}; \text{ etc.}$$

$$V_2 = V_1 \left(\frac{\Omega_1}{\Omega_2}\right); V_3 = V_1 \left(\frac{\Omega_1}{\Omega_3}\right).$$

Substituting in the first equation,

$$\frac{V_1^2}{2} = g\,(\zeta_{'} - \zeta_{''}) - \zeta' \frac{P_1}{\Omega_1} \frac{V_1^2}{2} L_1 - \zeta' \frac{P_2}{\Omega_2} \frac{V_1^2}{2} L_2 \left(\frac{\Omega_1}{\Omega_2}\right)^2 - \ldots.$$

Solving for V_1,

$$V_1^2 = \frac{2\,g\,(\zeta_{'} - \zeta_{''})}{1 + \zeta' \frac{P_1}{\Omega_1} L_1 + \zeta' \frac{P_2}{\Omega_2} L_2 \left(\frac{\Omega_1}{\Omega_2}\right)^2 + \ldots\ldots\ldots}$$

NOTE.—The value of ζ' is about 0.007, according to report of U. S. Coast and Geodetic Survey, 1907, Appendix 6, page 425.

DISCUSSION

Mr. Hazen.

ALLEN HAZEN, M. AM. SOC. C. E.—It is extremely fortunate that the observations recorded in this paper have been made, and that they have been compiled and put in convenient and readily understood shape. The author's method of analysis follows closely that used by the speaker in discussing the same problem* seven years ago. At that time the data for salinity, tidal flow, and fresh-water flow, were meager, and there was no information as to the extent of underrun. The figures then obtained, with limited data, in comparison with those of the author, are given in Table 31. The author's figures afford a striking confirmation of the substantial accuracy of those used by the speaker in discussing the sewage disposal problem in the harbor at that time, and in a professional report made soon afterward.

TABLE 31.

	Annual Average Figures:	
	Hazen, 1906.	Parsons, 1913.
Ebb Tide:		
Percentage of river-water on its last trip out	7	9.8
Percentage of river-water which will come back	28	25.0
Percentage of sea-water on its last trip out	14	18.4
Percentage of sea-water which will come back	51	46.8
Flood Tide:		
Percentage of new sea-water which has never been in the harbor before	23	20.5

The figures in Tables 18 and 19, containing corresponding data by months, are most interesting. The quantity of new water passing The Narrows at each tide by months, from these tables, and the corresponding flow of a stream necessary to furnish an equal quantity of new water in the course of the 24 hours, are as shown in Table 32.

The figures in Table 32 show that 65% of the new water in the harbor throughout the year is sea-water, and that 35% is land-water. For every cubic foot of water that goes through The Narrows from all the rivers draining 14 395 sq. miles, 2 cu. ft. of water come in from the ocean, circulate up and down the harbor, and go out to sea again. The exchange of water in the harbor is as great as that which would result from the fresh water from an area of 41 000 sq. miles. Practically, it is equivalent to much more, because, in a river, the flow is variable, and there is a period in summer when it is much less than the average. In New York Harbor there is, practically speaking, no dry-weather period. When the flow of fresh water is less, the flow of sea-water is greater, and the total flow is maintained so that the

* *Journal*, Assoc. of Eng. Societies, Vol. XXXVI, p. 293.

minimum is a larger percentage of the average than would be the case in any natural river. Mr. Hazen.

The author's figures indicate a minimum flow for February of 30 000 cu. ft. per sec., between much larger values for January and March. The low figure for February is due to a very low figure for sea-water exchanged during that month. The reasons for fluctuations in the volume of land-water are obvious, but there is no apparent reason why the quantity of sea-water should fluctuate to as great an extent as is indicated by Table 32. The tide must have risen and fallen during that month as in other months, and the opportunities for exchange of sea-water were the same as at other times. When the rivers are in flood, the quantity of fresh water entering the harbor is greatly increased, and tends to take the place of, and keep out, an equal volume of salt water. For the February in question no such condition existed. On the other hand, the land-water was nearly down to the low figure for the year. The speaker thinks that the explanation of this apparently low February flow is to be found in some matters, not sufficiently taken into account in the calculation, which, perhaps, cannot be taken into account at the present time.

TABLE 32.—NEW WATER IN THE HARBOR WITH EACH TIDE, IN MILLIONS OF CUBIC FEET, DURING EBB TIDE.

Month.	Land-water.	Sea-water.	Total.	Totals, in cubic feet per second.
January	880	2 240	3 120	70 000
February	690	670	1 360	30 000
March	2 500	2 510	5 010	112 000
April	2 590	1 740	4 330	97 000
May	1 340	1 050	2 390	54 000
June	1 090	1 780	2 870	64 000
July	700	2 180	2 880	65 000
August	620	1 520	2 140	48 000
September	710	2 150	2 860	64 000
October	990	3 610	4 600	103 000
November	910	3 190	4 100	92 000
December	1 070	3 470	4 540	102 000
Averages	1 180	2 210	3 390	76 000

The assumption is made, if the speaker understands correctly, that the quantity of water passing through The Narrows during each month is the same as that of the fresh water flowing in all the tributary rivers. This assumption must be more or less in error, because, obviously, there is retardation of the flow of fresh water through the large and variable reservoir of brackish water between The Narrows and the farthest points to which salt water extends. This retardation must have the effect of modifying, probably to a substantial extent, the quantity of fresh water flowing through The Narrows during any

Mr. Hazen.

calendar month. If these differences could be adequately taken into account and allowed for, the speaker suggests that the monthly variation of the combined flow might be found to be more nearly constant than is indicated by the author's tables. Taking this matter into account probably would not greatly change the annual average figure. It would have a steadying effect on the monthly flows, and reduce the fluctuations.

If it is assumed that the lowest months in the author's tables may be accounted for in this way, it appears that the exchange of water in the harbor is equivalent to a steady flow of between 50 000 and 100 000 cu. ft. per sec., averaging 76 000 cu. ft. per sec. In comparison with this, the speaker, in 1906, on the basis of the few data then available, estimated the corresponding flow at 68 000 cu. ft. per sec. No river in the United States has a minimum flow as great as this. Probably no other great city in the world is as favorably situated as New York on rivers having currents of such volume and strength.

It has been sometimes assumed that a flow of 3 cu. ft. per sec. would suffice to dilute the sewage from 1 000 people enough to make it inoffensive. This ratio is not everywhere accepted, but, taking it as a basis, if the flow through The Narrows could be fully utilized for dilution, it would serve to carry off the sewage of from 17 000 000 to 34 000 000 people. Even if a larger relative dilution is assumed to be necessary, as, for instance, 4, or even 5 cu. ft. per sec., per 1 000 of population, it is still adequate to serve a population which will not be attained for many years.

One of the practical difficulties, in the utilization of this great water quantity for dilution, is to arrange matters so that the sewage will be mixed evenly with it. At present more than a proportionate quantity of sewage is discharged into some branches of the harbor, as, for instance, into the East River and the Harlem River, and these branches have a higher relative pollution and are nearer to a permissible limit than is the harbor as a whole.

The figures for tidal flow, put in convenient and accessible form in this paper, will be of the greatest service in future discussions of this most important question.

Mr. Thomson.

T. KENNARD THOMSON, M. AM. SOC. C. E.—The Society owes a hearty vote of thanks to Mr. Parsons for this very valuable and interesting paper. It is especially interesting to the speaker on account of his plan for relieving the congestion in New York Harbor.

This plan has already been brought to the attention of the Society,* and this opportunity is taken to show the same plan with an addition, Fig. 63, which has been seriously suggested by a very able man.

* "The Problem of the Lower West Side Manhattan Water-Front of the Port of New York," by B. F. Cresson, Jr., M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXV, p. 268.

Mr. Thomson.

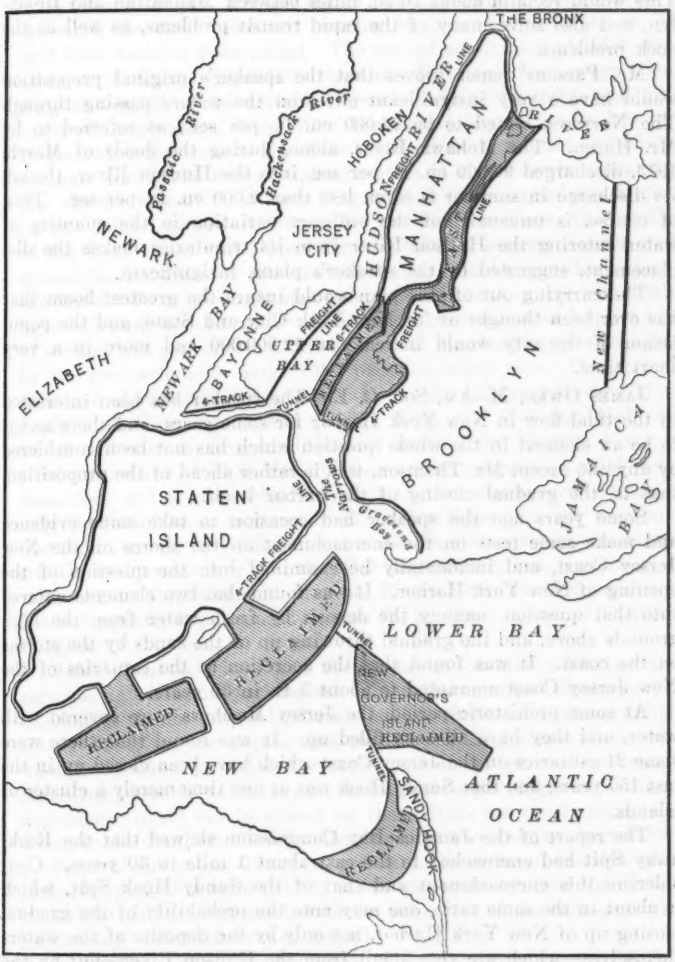

FIG. 63.

Mr. Thomson.

The plan consists of the reclamation of the East River, and the building of a serviceable channel between Flushing and Jamaica Bays. This would reclaim about 10 sq. miles between Manhattan and Brooklyn, and also solve many of the rapid transit problems, as well as the dock problems.

Mr. Parsons' paper proves that the speaker's original proposition would have a very insignificant effect on the waters passing through The Narrows, stated to be 75 000 cu. ft. per sec., as referred to by Mr. Hazen. The Mohawk River, alone, during the floods of March, 1913, discharged 96 000 cu. ft. per sec. into the Hudson River, though its discharge in summer is often less than 2 000 cu. ft. per sec. This, of course, is unusual, but the ordinary variation in the quantity of water entering the Hudson River from its tributaries makes the displacement, suggested by the speaker's plans, insignificant.

The carrying out of this plan would insure the greatest boom that has ever been thought of for New York City and State, and the population of the city would increase to 12 000 000 and more in a very short time.

Mr. Owen.

JAMES OWEN, M. AM. SOC. C. E.—The speaker has been interested in the tidal flow in New York Harbor for some years, and there seems to be an element in the whole question which has not been considered by any one except Mr. Thomson, who is rather ahead of the proposition, that is, the gradual closing of the harbor itself.

Some years ago the speaker had occasion to take some evidence and make some tests on the encroachment on the shores on the New Jersey Coast, and incidentally he examined into the question of the opening of New York Harbor. It was found that two elements entered into that question, namely the deposit by fresh water from the high grounds above, and the gradual throwing up of the sands by the storms on the coast. It was found that the accretion at the estuaries of the New Jersey Coast amounted to about 3 ft. in 30 years.

At some prehistoric period, the Jersey Meadows were covered with water, and they have all been filled up. It was found that there were some 21 estuaries on the Jersey Coast which have been closed up in the last 150 years, and that Sandy Hook was at one time merely a cluster of islands.

The report of the Jamaica Bay Commission showed that the Rockaway Spit had encroached to the east about 1 mile in 30 years. Considering this encroachment and that of the Sandy Hook Spit, which is about in the same ratio, one may note the probability of the gradual closing up of New York Harbor, not only by the deposits of the waters themselves—which are very small from the Hudson River—but by the encroachment of the sea.

Whatever experiments are made will have to be carried along year by year, counting on the encroachments of the ocean. It is a very

important question, this gradual closing up of New York Harbor by the encroachment of the sea. Mr. Owen.

KENNETH ALLEN, M. AM. SOC. C. E. (by letter).—The author has described the tidal condition existing in New York Harbor so fully that little remains to be added. The special application of tidal studies to those of sewage disposal is obvious. Dilution of a sewage effluent may be secured by the variable currents induced by winds and differences of temperature, as in cities discharging sewage into a lake; but, in general, dependence is placed on the much more reliable and effective currents due to the flow of upland waters in rivers or the tides of the sea. In the case of New York City, though large dependence is placed on the upland waters discharged by the Hudson River, the condition of the East River and Upper Bay depends in a great degree on the refreshing influence of the new sea water brought in twice a day by the tides. To a much greater extent is this true of the two shallow bays—Newark and Jamaica—the waters of which receive large volumes of sewage, but yet contain a fair amount of dissolved oxygen brought in by the proportionately large tidal prism at every tide. Owing to the existence of such connecting waterways as the East and Harlem Rivers, Little Hell Gate, Bronx and Arthur Kills, and Kill van Kull, combined with the varying conditions of flow in the Hudson River, the tidal phenomena of New York Harbor are as complex as could well be imagined, and a reasonable approach to true average conditions can only be found by a long series of observations. In the case under discussion, much information was available from past observations of the U. S. Coast Survey and the War Department, but, especially with reference to the East and Harlem Rivers, this was incomplete and has but recently been secured by Col. W. M. Black, Corps of Engineers, U. S. A. Mr. Allen.

Aside from velocities and discharges at certain points or cross-sections, information was desired by the Metropolitan Sewerage Commission as to the probable dispersion and drift of floating solids if set adrift at specific points, and though the float observations which were undertaken provided a certain amount of general information regarding probable velocities, on which discharges might be estimated, dependence could not be placed on these alone for the latter purpose, owing to the manifest discrepancies due to local or temporary conditions.

Float observations, however, are valuable as an indication of the probable trend of sewage (which in salt water rises to near the surface), its oscillation back and forth with the tides, and of the shores on which its floating constituents may strand.

In 1897 the writer made a series of float observations for the Baltimore Sewerage Commission* in Chesapeake Bay off North Point, to

* Report, Baltimore Sewerage Commission, 1897, Mendes Cohen, Past-President, Am. Soc. C. E., Chairman.

Mr. Allen.

determine the most favorable location for the discharge of sewage. At six selected points, about ½ mile apart and from ⅝ to 2½ miles from shore, poles were set in the bottom, which was nowhere more than about 20 ft. from the surface at low water, the tidal range being about 1 ft.

A 30-ton schooner was chartered and anchored in the vicinity of the work as headquarters for the party, which consisted of an observer, a recorder, the captain, mate, and cook. A small steam launch, with captain and engineer, was secured with which to follow the floats. For communication with the party a tug was engaged.

The floats consisted of 2 by 2-in. by 7-ft. yellow pine sticks weighted on the lower end by cast-iron washers strung on a wire until only 5 or 6 in. of the other end were left above water. A ¼-in. iron rod was inserted in this upper end on which a 12 by 12-in. red or black flag was attached bearing a serial number in white. These were set adrift at the several points in succession, beginning at about 6 A. M. and continuing at stated intervals, by a man in a rowboat. They were observed by sextant as often as practicable from the launch, passing from one float to another until dark. No attempt was made to recover the floats, which finally went down the bay or grounded on shoals.

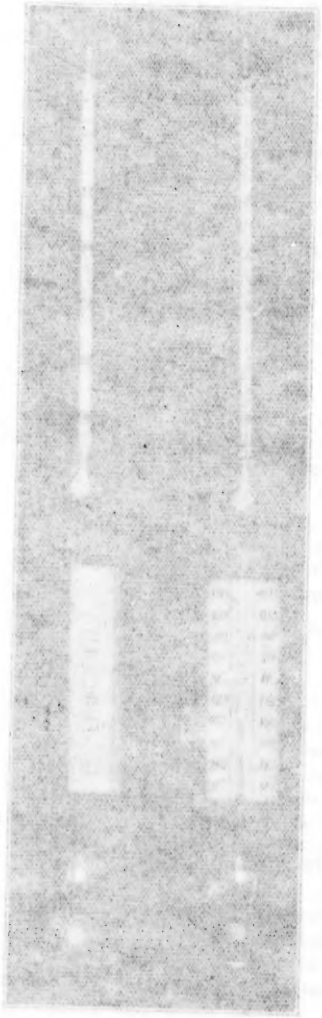
In this way 150 floats were set adrift during an entire month, May 27th to June 26th, so as to include all phases of the moon and tide.

A tide gauge was set up at a neighboring light-house and a record of the tides and wind was kept during the work.

The cost of these observations was:

Schooner, crew, and launch	$296.98
Salaries	378.50
Provisions	53.91
Coal for launch	32.00
Floats	70.05
Supplies, fares, and miscellaneous	53.44
Plotting traces of floats on charts	54.50
Total	$939.38

On account of the unseaworthiness of the launch in bad weather 10½ days were lost.



By this method, a large number of observations were made during the day of floats set out at different points, at different times, and at different stages of the tide. The records of individual floats were not very complete, nor were they often continued beyond the day they were set adrift, but, taken together, they indicated very graphically the points likely to be reached by floating matter starting from any one of the six assumed points of outfall.

FIG. 64.—SPAR FLOAT.

FIG. 65.—SALINOMETER.

Mr. Allen.

They also indicated: (1) a general trend off shore toward the main ship channels and away from the oyster beds which were farther down the bay and near the shores, or in the estuaries; (2) that under rare conditions would floating material set out at the point finally recommended (2 miles from shore) be carried up the Patapsco River as far as Sparrows Point; and (3) that after a continuous discharge for 33 consecutive hours sewage would be dispersed in all probability over an area of some 16 sq. miles, and hence become thoroughly diluted.

The type of float selected was inexpensive and, on the whole, satisfactory, being convenient to handle and but little affected by the wind. Tests were made with black, white, and red flags, and, contrary to expectations, the black was generally discovered most easily and white the least so, although this depended on the weather. Red or black flags, appearing the same in the distance, were usually first seen with low-power field glasses at distances ranging from ½ to 1 mile.

The New York experiments, taken up by the writer in 1908, were conducted under quite different conditions.* Considerable populations occupy the shores for many miles along the several watercourses, and the currents are so swift as to render useless any attempt to follow any number of floats with one boat. It was decided, therefore, to set out only one float at a time and observe its position at frequent intervals throughout the day. To avoid the loss of the float by the absorption of water, the double-can type, described by the author, was devised. This was found convenient, inexpensive, and in general satisfactory, except that it was easily destroyed by being run down by tugs in the crowded waterways. Also, the small flag which it was intended should be carried by the upper can made it top-heavy, and, as the observer was never far from the float, the flag was finally omitted as unnecessary.

During the following year the longer "spar" float, Fig. 64, was adopted and found well suited to the conditions to be met. It was open to the objection found with the Baltimore float of absorbing water, but, having large submerged vanes, the influence of the wind was relatively small, and there was no objection in allowing the top to project above the water sufficiently to prevent loss from this cause. The size of this float, moreover, permitted two lanterns to be carried on a ⅜-in. steel rod supported by a light frame at a height of some 3 ft. or more above the water surface, and so it was possible to follow the float by night as well as by day. This was found essential in order to secure the information desired.

Locations in the open water of the bay were generally made with a sextant, as on the Chesapeake Bay work; but, in the strong currents of the rivers, and when near the shore, where locations could be identi-

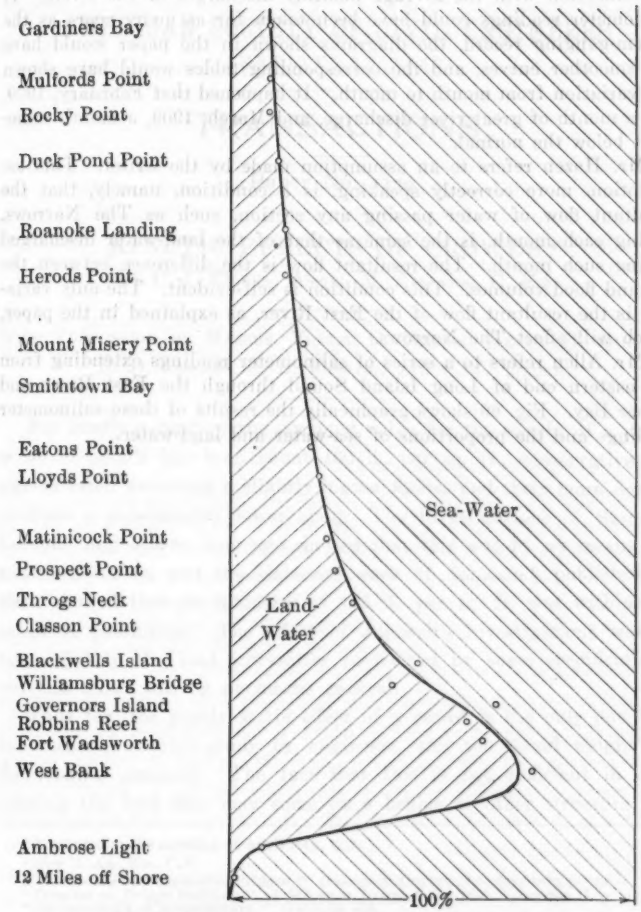
* Report, Metropolitan Sewerage Commission of New York, 1910, George A. Soper, M. Am. Soc. C. E., President.

Mr. Allen. fied, an estimate of the position noted briefly in the recorder's book was found more reliable. The azimuth compass was used to a limited extent in taking bearings up or down stream to objects not too distant, such as bridge piers, but was found unreliable where the plotted position depended on the accuracy of the bearing from a distant point, and considerable care was required to see that the dial swung free.

Although these experiments were intended primarily to indicate the possible drift of floating matter, the results have been utilized in confirming or modifying existing values for the velocity at strength of tide, and for the tidal flow at different points in the harbor.

Where current velocities at specific locations were desired, these were obtained by anchoring at such locations and noting the time taken by a double-can float to drift 100 ft. The distance was measured by a fine cord attached to the float, and the time by a stop-watch.

In order to obtain continuous night-and-day observations, three motor boats were chartered, each with an observer who was to follow the float for an 8-hour shift, but the long distances traveled during a tide, the inaccessible location of much of the work, and the prevailing fogs caused so great a loss of time, and, in addition, it was found so difficult to maintain operations with small boats during stormy winter weather in the crowded thoroughfares, that a seaworthy tug was finally secured and provisioned for a week's continuous work. In this way floats were followed well out into the Lower Bay, and there was little loss of time.



In studying the circulation of water in New York Harbor the salinometer* (Fig. 65) proved to be an important adjunct, indicating at the same time the specific gravity of the water and its temperature, by which the proportion of "normal" sea water could be determined at once by reference to a diagram. By a series extending from the eastern end of Long Island Sound through the East River to the Upper Bay, for instance, it was shown by the high salinity east of Hell Gate that the waters of the Sound were not those which had come from the Upper Bay, where the Hudson River causes the proportion of sea water to drop to 60 or 70%, but were essentially those of the Atlantic entering from the east, and hence that there exists a definite net discharge to the west and south through the East River—a fact difficult to prove before Col. Black's more recent gaugings were made.

Mr. Parsons. H. DE B. PARSONS, M. AM. SOC. C. E. (by letter).—The writer is pleased to note the close approximation between the percentages obtained by Mr. Hazen in 1906 and those shown in the paper, as indicated in Table 31.

Referring to Mr. Hazen's criticism of Table 32, the writer is of the opinion that the dips in the curves for February are due to the

FIG. 66.

Mr. Parsons.

salinometer readings being taken throughout the year 1909 and used in connection with the average monthly discharges of the rivers. If salinometer readings could have been taken for as many years as the stream-gauging record, the diagrams shown in the paper would have had smoother curves, and the corresponding tables would have shown less variation from month to month. It happened that February, 1909, was a month of great river discharge, and March, 1909, a month somewhat below the normal.

Mr. Hazen refers to an assumption made by the writer. This assumption, more correctly speaking, is a condition, namely, that the resultant flow of water passing any section, such as The Narrows, during each month, is the same as that of the land-water discharged during such month. The resultant flow is the difference between the ebb and flood volumes. This condition is self-evident. The only variation is the resultant flow of the East River, as explained in the paper, which will affect The Narrows.

Mr. Allen refers to a series of salinometer readings extending from the eastern end of Long Island Sound through the East River and Upper Bay. Fig. 66 shows graphically the results of these salinometer readings and the proportions of sea-water and land-water.

Paper No. 1279

KINETIC EFFECTS OF CROWDS.*

By C. J. Tilden, Assoc. M. Am. Soc. C. E.†

With Discussion by Messrs. Frazer C. Hilder, Henry H. Quimby, R. D. Coombs, J. B. French, and C. J. Tilden.

For nearly a century the accepted value for the weight of a dense crowd of people has been about 100 lb. per sq. ft., conservative designers often assuming a slightly higher figure, and their more daring brethren a considerably lower one.‡ The investigations of Stoney,§ Kernot,‖ and others, long ago showed that this was by no means the maximum value, and the elaborate work of Johnson,¶ published in 1904, showed that an intensity of 183 lb. per sq. ft. was within the range of possibility. The effect of Johnson's investigations was to raise slightly the load intensities prescribed by some specifications, but this effect was by no means general.

Thus far, the purely static effect of a crowd is the only one that has received careful study by engineers, and the "dead weight" is the loading assumed. The fact that this is not sufficient in considering the load that may come on a bridge or other structure was

recognized by Robert Stevenson in the early part of the last century. In his paper entitled "An Account of Suspension Bridges", published in 1821,* is the following interesting paragraph:

"But the effect we have to provide against in bridges of suspension, is not merely what is technically termed *dead weight*. A more powerful agent exists in the sudden impulses, or jerking motion of the load, * * *. The greatest trial, for example, which the timber bridge at Montrose, about 500 ft. in extent, has been considered to withstand, is the passing of a regiment of foot, marching in regular time. A troop of cavalry, on the contrary, does not produce corresponding effects, owing to the irregular step of the horses. The same observations apply to a crowd of persons walking promiscuously, or a drove of cattle," etc.

Stevenson, however, does not suggest any definite values for this "more powerful agent" which he recognizes and describes with such clear appreciation.

Shortly after Johnson's paper was published, a letter signed by Mr. R. Moreland appeared in London *Engineering*,† in which a suggestive experiment was reported:

"In 1900 my firm had a contract for the Manchester Racecourse for some large stands, and to gain information we put as many men as possible on our 10-ton weigh-bridge, and we found that we could get ninety men as close as possible into a space 14 ft. by 8 ft., or 112 square feet, and they weighed 115 cwt. 1 qr., which would equal 1 cwt. per square foot. We then asked them to jump, and the load went up to 1½ cwt.; they then ran four abreast across the machine, but no excess was recorded over the 1½ cwt. per square foot."

Details of this experiment are meager, but it is the only one, so far as the writer is aware, in which a determination is sought of the increased load effect due to motion in a group of human beings. In general, in structural work at least, this increase is assumed to be cared for by the "factor of safety", that pernicious and misnamed offspring of ignorance.

The study of kinetic effect is far more complex than that of static effect, for the movements of a crowd of people may take place in infinite variety, and each change of motion must be accompanied by some exertion of force other than the purely static condition. The problems suggested, therefore, are capable, at best, of only approximate solution. The following study is an attempt to throw some light on

* *Edinburgh Philosophical Journal*, No. 10, p. 253.

† Vol. LXXIX (April 28th, 1905), p. 551.

the question of determining and analyzing as far as possible the forces exerted by an individual under certain simple conditions of motion The extent to which such observations apply to crowds, and the limitations of such an application are then considered.

The subject is divided naturally into two parts: first, the vertical effect, as in the experiment described by Moreland and quoted above, manifested as an increase over the static or dead load; and, secondly, the horizontal effect which appears as a lateral force. The first is due to changes of motion in a vertical direction, the second to similar changes in a horizontal direction. The experiments described are simple and direct, and though the results may not be scientifically exact, they are at least instructive, and furnish a basis for modifying somewhat our views on the possible effect of crowds.

FIG. 1.

Vertical Effect.—1.—Rising Suddenly from a Crouching Posture.—In this experiment the subject was asked to assume a crouching position, as shown by Fig. 1, on an ordinary platform scale. His weight was determined and recorded. The counterpoise was then moved out on the scale-beam until it registered a load 40 or 50 lb. in excess of the static load, the hooked end of the scale-beam resting, of course, against the lower stop. The subject was then asked to rise smartly to a standing position, as shown by the dotted lines in Fig. 1, whereupon the scale-beam shot up momentarily, showing a sudden large increase in the downward load effect of the man, as a result of the upward acceleration given to his body. A somewhat larger load was then registered on the scale-beam and the operation repeated. A great deal of care was exercised to prevent the motion from becoming a jump, and the subject was warned not to let his feet leave the platform. The movement was smart and quick, however, occupying, per-

haps, ⅓ or ¼ sec. Each repetition of the movement was recorded, and the words "Raised" or "Not raised", referring to the scale-beam, were written after the number representing the load registered on the scales. The following is a sample of the record sheet kept of each experiment:

(Name of subject.) Static weight = 155 lb. (Date.)

Scales set at 220 lb. ..... Raised.
" " " 240 " ..... Raised.
" " " 260 " ..... Barely raised?
" " " 260 " ..... Raised.
" " " 265 " ..... Raised.
" " " 270 " ..... Raised.
" " " 275 " ..... Not raised.
" " " 275 " ..... Raised.
" " " 280 " ..... ?
" " " 280 " ..... Not raised.
" " " 280 " ..... Barely raised?

It is seen that this man, weighing 155 lb., exerted a momentary downward pressure of 275 lb., as shown by the scale-beam lifting from the stop, as a result of the movement described. As there was some question, even after three trials, as to whether 280 lb. had been exerted, the figure taken was 275 lb. or an increase of 77% over the static load. (See Line D, Fig. 2, I.) Eight experiments of this sort were tried on seven different men, weighing from 139 to 233 lb. The results are shown graphically by Fig. 2, I, in which the black portion of each line represents the static weight and the shaded portion the increase due to rising suddenly from a crouching position. It is interesting to note that the greatest increase recorded, 80%, occurs for the heaviest man, *G*, a former tennis champion who is very active on his feet.

The two lines marked *A* and A_x, one showing 58% increase and the other 67%, are for the same man. The result shown at *A* was obtained in the usual way, as illustrated by Fig. 1 and previously described. The case, A_x, differed from *A* in that a timber, about 11 in. deep and weighing 108 lb., was put on the scale platform on which the subject stood. While it is not likely that the interposition of this heavy mass had anything to do with the slight increase (from 58 to 67%) shown in A_x, it obviously did not tend to diminish the kinetic effect.

II.—Rising Suddenly from a Sitting Position.—This experiment was similar to I, and was conducted in the same manner, the only difference being that the subject rose suddenly from the chair in which he was seated, instead of getting up from a crouching position.

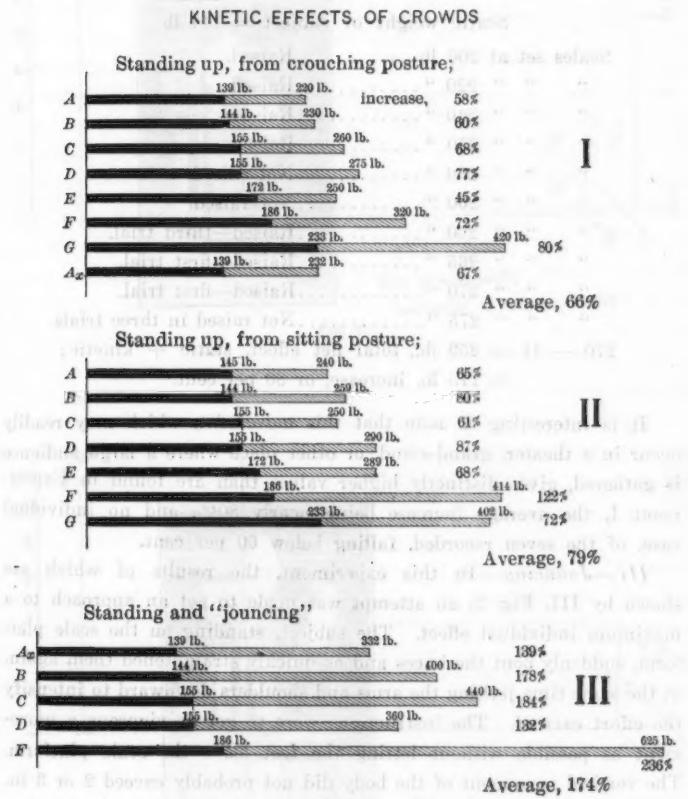

FIG. 2.

The movement is indicated clearly by the photographs, Figs. 3 and 4, in which the two successive positions of the subject are shown by a double exposure of the negative. The records were made in precisely the same manner as for Experiment I, with the results as shown in Fig. 2, II. The letters, *A*, *B*, *C*, etc., refer to the same in-

dividuals as in I. The following is a sample "log-sheet" for this experiment, being the record for *B:*

(Name of subject.) Scale reading = 155 lb. (Date.)
Weight of chair = 11 lb.

Static weight of subject = 144 lb.

Scales set at 200 lb.....Raised.
" " " 220 " .....Raised.
" " " 240 " .....Raised.
" " " 250 " .....Raised.
" " " 260 " .....Not raised.
" " " 260 " .....Not raised.
" " " 260 " .....Raised—third trial.
" " " 265 " .....Raised—first trial.
" " " 270 " .....Raised—first trial.
" " " 275 " .....Not raised in three trials.

270 — 11 = 259 lb., total net effect, static + kinetic;
= 115 lb. increase, or 80 per cent.

It is interesting to note that this movement, which may readily occur in a theater, grand-stand, or other place where a large audience is gathered, gives distinctly higher values than are found in Experiment I, the average increase being nearly 80%, and no individual case, of the seven recorded, falling below 60 per cent.

III.—Jouncing.—In this experiment, the results of which are shown by III, Fig. 2, an attempt was made to get an approach to a maximum individual effect. The subject, standing on the scale platform, suddenly bent the knees and as quickly straightened them again, at the same time jerking the arms and shoulders downward to intensify the effort exerted. The instructions were to get as vigorous a movement as possible without letting the feet leave the scale platform. The vertical movement of the body did not probably exceed 2 or 3 in. The experiment is interesting and suggestive, but hardly of much importance, as the time during which the greatest effort acts is necessarily exceedingly short. The effort is more in the nature of a quick blow. Its bearing in relation to I and II will be discussed later.

Horizontal Effect.—I.—Some idea of the horizontal effort exerted in Experiment II (rising from a sitting posture) may be obtained by

studying the movement of the center of gravity of the subject (Figs. 3 and 4). If the ratio of the movements, horizontal to vertical, is taken as measuring approximately the relative intensities of the respective forces, it gives a fairly good indication of the backward shove exerted by a man when he jumps up to cheer a spectacular play on the football field, or to shout welcome to his political favorite. In Fig. 3 the movement shown is from an erect sitting posture to a standing position; Fig. 4 shows a similar movement from a less alert sitting position. The first movement is probably more nearly typical than the second, but, in jumping up suddenly, as in Fig. 3, the final standing posture would probably have a somewhat greater forward inclination than is shown in the photograph, so that a ratio of horizontal to vertical motion of about 0.75 might fairly be assumed. Although this ratio of movements may not show the relative force values exactly, owing to complexities of motion not taken into account in the simple geometry of the figure, it is undoubtedly fairly indicative. On such a basis, taking the increase in vertical effect at about two-thirds of the static weight, it appears that, in rising suddenly from his seat, a man may exert a backward horizontal shove about one-half as great as his weight, say from 70 to 80 lb. for an ordinary man.

Figs. 5, 6, and 7 are introduced to show the method of determining the centers of gravity of the standing and sitting figures. For the standing figure (Figs. 3 and 4) the vertical centroidal line was readily drawn on the photograph by eye. The position of the horizontal centroidal line was then determined as in Fig. 5, by getting the reactions at head and heels on the two platform scales when the man was stretched out horizontally. A simple proportion between the two observed scale-weights then serves to fix the position of the line, and this is transferred to the photographs (Figs. 3 and 4) by the construction shown at the right of the figures. Similarly, for the sitting figure, a vertical centroidal line was obtained by the method shown in Fig. 6, and an inclined centroidal line as in Fig. 7, the angle of inclination of the latter being determined by the two measurements, 24 in. horizontal and 21 in. vertical, shown in the sketch. The intersection of these two lines, when properly transferred to the sitting figure in the photograph (geometrical construction on the right), locates the center of gravity of the seated man. The scale for the photographs was fixed by the two meter sticks seen clearly in Figs. 3 and 4, one laid

horizontally on the scale platform between the feet of the subject and the other standing vertically in the same plane. The vertical and horizontal components of the movement of the center of gravity were then measured directly on the photograph with this scale.

II.—Horizontal Forces Exerted by a Man Walking.—The motion of a man who is walking on a level floor, sidewalk, etc., at ordinary speed, is not perfectly uniform. The changes in velocity—whether acceleration or retardation—must be accompanied by some manifestation of horizontal force, this force urging the man forward when his velocity is being increased, and holding him back when it is being diminished. As these forces act on the man, his action (or reaction) on the floor must be equal and opposite to them; therefore, he will exert a backward horizontal push when his speed is increasing and a forward horizontal thrust when that speed is, for the moment, partly checked. The investigation which is summarized in Fig. 8 is an attempt to determine approximately what values these momentary forward and backward forces may have.

The twelve figures shown in the lower half of Fig. 8 were traced from a series of photographs, taken at intervals of $\frac{1}{12}$ sec., of an athlete walking.* The man walked directly in front of and parallel to a screen which was marked off by horizontal and vertical lines into squares of 5 cm. on a side. The subject was about 30 in. in front of this background, and the camera some 50 ft. from the subject, so that the distance interval covered in each interval of time might be determined with a close degree of approximation by counting the squares passed over by the man in each successive position. In making this count, the horizontal line, *AB*, was chosen as the base, as it passes very close to the center of gravity of the man for all positions, and the "reading" on the background squares was made at the intersection of this line with the buttocks of the naked figure. The total interval found in this way, from the first to the twelfth figure, was nearly 1.7 m., or about 5.5 ft., giving an average velocity of 6 ft. per sec. (a trifle more than 4 miles per hour) for the complete stride shown in the diagram. The average velocity during each interval ($\frac{1}{12}$ sec.) of

* This series of figures was traced from Plate 2 of Volume I of "Animal Locomotion," by Eadweard Muybridge (Philadelphia, 1887). This remarkable work, published in eleven great volumes, shows literally thousands of photographs of human beings and animals in great variety of motion. A smaller edition, containing a few of the series, much reduced in size, has been published under the title "The Human Figure in Motion." (London, Chapman and Hall, 1901.)

In interpreting and applying these results, the uncertainties attendant on their computation must be kept in mind; they give, however, an interesting and instructive indication of the way in which the velocity varies. Thus, the velocity is well below the average between Positions 3 and 4, well above between Positions 6 and 7 and well below again between Positions 9 and 10. This is shown graphically in the upper curve of Fig. 8, which gives the velocity-time curve drawn as indicated by the computed values, not exactly through the plotted points but "smoothed out" to give an even, continuous curve. The average velocity for the stride is shown by the heavy dotted line.

To measure the force exerted, it is necessary to know the acceleration, and this is obtained by differentiating graphically the velocity curve. This acceleration curve, or "first-derived" of the velocity curve, is shown immediately below the latter. The ordinates of the acceleration curve were obtained by actual geometric construction for the slope of the tangent to the velocity curve at a number of points. It is seen that the high and low points of this acceleration curve have values, plus and minus, respectively, of 16 or 18 ft. per sec. per sec., which would correspond to a horizontal accelerating or retarding force of

FIG. 8.

80 or 90 lb. for a man weighing about 160 lb.* These force values urge the man forward for the high points of the curve, and backward for the low points; note, in this connection, the backward shove or kick of the right foot in Positions 5 and 6 and of the left foot in Positions 11 and 12, and the forward thrust, retarding the body's motion, of the right foot in Positions 1 and 2 and of the left foot in Positions 7 and 8. Although these forces are impulsive in their nature and act for only a fraction of a second, there seems to be no doubt of their existence, and although the amount is not determinable exactly (varying as it must with different individuals and conditions), it may, apparently, equal or even exceed half the static weight of the man.

III.—Horizontal Forces Exerted by a Man Running Across a Bridge.—Approaching from a slightly different viewpoint this problem of horizontal force exerted, some experimental data were collected bearing on the lateral effect which may be produced on a bridge. At the time of a boat race, river pageant, or similar exhibition, a crowd of people will naturally gather on a bridge, ranging themselves along one side. As the spectacle moves under the bridge the entire crowd will cross to the other side (Fig. 9), and the motion is likely to be fairly rapid. What effect has it on the structure?

As in the previous cases, the experimenting was on an individual. The observer, with a stop-watch, noted the time of the subject as he turned from the rail on one side of the bridge and ran quickly to the other. This time included the start from rest at one rail and coming to rest again at the other. The suggestion was made that the subject imagine he was watching an exciting boat race, and did not want to miss any of it as the contestants pulled under the bridge. The tests were carried out on three bridges, in three different localities, the widths between rails being 17, 49½, and 68 ft., respectively, the second and third bridges having sidewalks on both sides. Three men took part as subjects, one a vigorous active man of sixty-seven, weighing 160 lb., another, thirty-nine years old, and weighing about 140 lb., and the third, twenty-six years old, and weighing 144 lb. The results are given in Table 2, and show, as might be expected, the higher average velocities for the wider bridges.

* Force (in pounds) = Mass × Acceleration, the mass being measured in "engineers' units" (1 unit = 32.2 lb.) and the acceleration in feet per second per second.

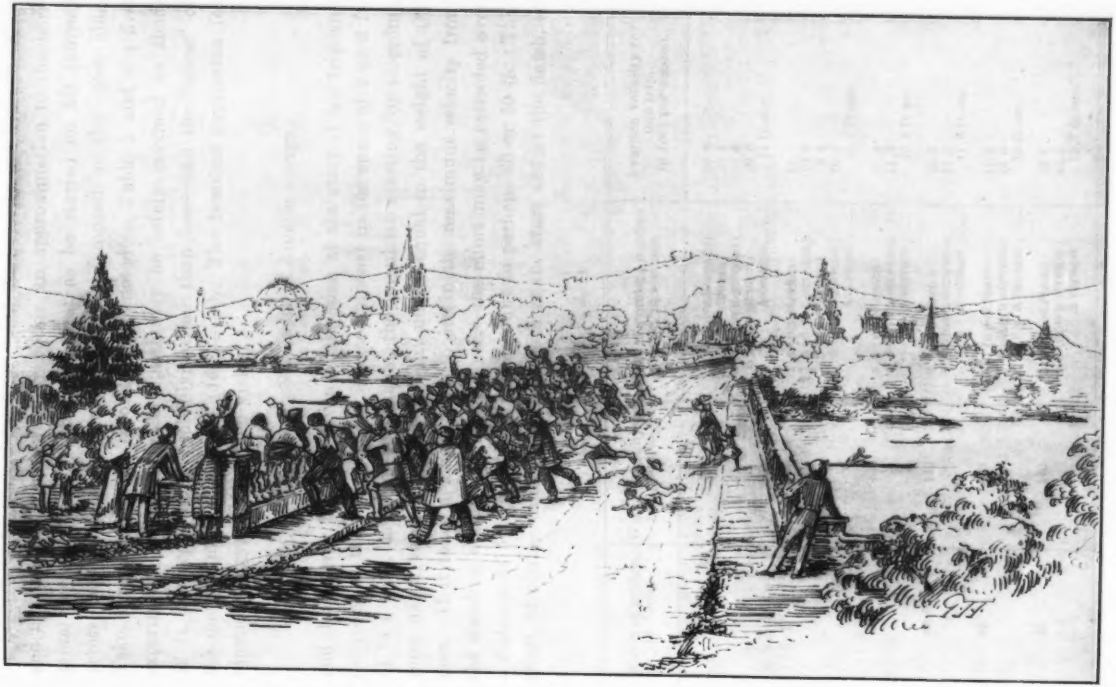

FIG. 9.—CROWD RUSHING FROM ONE SIDE OF A BRIDGE TO THE OTHER.

Remembering that these figures for the velocity are average values and not the maximum, we may obtain an approximation to the horizontal force exerted by the man, first as he started on his journey across the bridge and secondly when he stopped at the other side. Take, for example, the second bridge noted in Table 2 and the first experiment. The maximum speed may be safely assumed as about 12 ft. per sec.—more, probably, rather than less—and the "mass" of the moving man at 5 units ($160 \div g$). The familiar expression for kinetic energy, $\frac{1}{2} MV^2$, then yields,

$$\tfrac{1}{2} \times 5 \times 144 = 360 \text{ ft-lb. of kinetic energy,}$$

and this energy must be given to the man at the start of his trip and destroyed at the end. If this is accomplished in the space of 2 or 3 ft. ($\frac{1}{3}$ to $\frac{1}{4}$ sec.), as seems reasonable, the impulsive starting, or stopping, force has a value of about 150 lb., nearly equal to the weight of the man. If it takes a longer time to attain the maximum velocity from the standing start—say, about $\frac{1}{2}$ sec.—the effort may be extended over a distance of 5 or 6 ft., and will amount to perhaps 60 or 70 lb. This effort, of course, must be exerted both at the start and at the finish, as

the start is from rest and the subject comes to rest again at the opposite rail. If, as may happen when he brings up sharply against the rail, the whole amount of kinetic energy is destroyed in a space of 6 in. or 1 ft., the effort will amount to several hundred pounds.

In applying these experimental results to determine the probable effect of crowds, several points must receive careful consideration. In the first place, the object of the whole inquiry is to get some sort of answer to the question: Against what loads, horizontal and vertical, should an engineer design a structure which is likely to have to carry a dense crowd of human beings? It is with respect to their bearing on this question that the experiments will be discussed.

Direct multiplication of individual effect by the probable number of units in the crowd is, of course, wrong. In the first place, the forces exerted are impulsive in their nature, being exerted for only a small, though finite and measurable, fraction of a second. In order to get the full effect of such impulsive efforts from a crowd of people, it is necessary to have perfect synchronism of motion in every individual, a condition practically out of the question. Further, the denser a throng of people, the more individual motion is restricted, so that in the more closely packed crowds, giving the higher static loads per square foot, the increase resulting from kinetic effect is much reduced. On the other hand, that the static load only shall operate, perfect quiescence must be secured, a condition quite as impossible in any crowd as that of absolute synchronism in movement; and the duty of the engineer is to provide in every case for the maximum possible load-effect to which his structure may be subjected, a duty which is immeasurably emphasized when the safety of human beings is at stake.

The first experiment—that of rising from a crouching position—although suggestive and interesting, hardly has a practical bearing. That particular form of motion could take place only in a sparse crowd, and even then would be highly improbable. Its main value lies in showing rather strikingly the importance of some consideration of kinetic effect.

The case of a man rising suddenly from his seat, however, is of considerable importance. No one who has watched a grand-stand full of enthusiastic football "fans" can doubt that a spectacular play may bring nine-tenths of them to their feet with such a close approxi-

mation to unanimity of motion that the total kinetic effect must be considerable. However, if the usual allowance of 3 sq. ft. per sitting is made, and each spectator is assumed to weigh 165 lb., or 55 lb. per sq. ft. over the whole structure, an increase of 65 or 70% (over the 55 lb. per sq. ft.) may be assumed without reaching the static value of 100 lb. per sq. ft. for which such a stand would probably be designed. Provision against horizontal effect, however, is not commonly made, and the importance of some such provision is illustrated by the experiment. To be on the safe side, a backward horizontal impulse of 70 or 80 lb. for each sitting might wisely be guarded against.

The "jouncing" movement, while it has a high kinetic intensity and is possible in a much denser throng than are the motions of Experiments I and II, is nevertheless of much shorter duration; the effect is that of a rather sharp, quick blow. On this account, practically perfect synchronism of movement is necessary to get the maximum effect, and this, of course, is quite impossible in any ordinary crowd.

The horizontal effect resulting from a man walking is probably not of general importance, except in the case of a large number of men marching in cadence, as a body of soldiers. The evil effect of this on bridges has been recognized for generations, and the tactical requirement of "breaking step" during the passage of a bridge by infantry is well known.* Mention might be made of the obvious slight variations in vertical load effect during the phases of a stride (in Fig. 8 it is seen that 4 and 9 are high positions and 1, 6, and 12 are low positions of the man's center of gravity), but these movements are small compared with those of Figs. 1 and 3.

The experiment of running across a bridge is perhaps rather more difficult of application to a crowd. If a line of men, each weighing 150 lb., was distributed at intervals of, say, 18 in. along the railing of a bridge, and, at a given signal, turned and ran to the other side, bringing up sharply against the opposite rail, the lateral force exerted might even exceed the usual allowance made for wind. Something of the kind, undoubtedly, may occur under certain conditions, but to what extent it should be guarded against is again a matter of individual judgment based on the exigencies of a particular problem. A further application of this experiment, however, might be mentioned.

* See quotation from Robert Stevenson, cited previously.

A wharf or pier, used for excursion boats, may collect a large number of people who enter from the land singly or in groups and come to rest on the structure. In coming to rest a horizontal force is exerted, that is, kinetic energy is destroyed, tending to push the wharf out into the water; and this force is applied after the manner of a succession of blows, of varying magnitude, but all in the same direction.

The same is true of any elevated platform, or structure, built for the accommodation of men and women, the entrance to which is restricted to only one line of movement. Such a structure is bound to receive shocks or impulsive horizontal forces in the manner indicated. That these effects are generally so small as to be of no importance is quite true; but that they may also on occasion reach considerable proportions, and especially that the cumulative effect may be serious, seems to be equally beyond question. It may be that a bridge, or pier, or platform may be fully capable of carrying all ordinary loads, even to a densely packed crowd of people, but some day it gives way under a much less (static) load. Is it not possible that the failure may be due to a peculiar combination of movements, on the part of the individuals of the crowd, timed and synchronized so that a force effect is produced on the structure far greater than that of the mere dead load?

In conclusion, it may be said that the evidence submitted hardly warrants any dogmatic statement as to what loads should be considered in providing for the possible effects of motion in crowds of people. The results of the experiments are not scientifically exact, nor are the applications definite or precise; but that some provision should be made against effects which are shown to be probable in an excited gathering, there can be no doubt. It is a matter for the individual engineer to determine, in solving his particular problem. The facts, albeit with some uncertainties and many qualifications, are presented as they appeared in the actual experiments described. They should be interpreted and used in the light of sound common sense, fair and impartial engineering judgment, and, above all, a due sense of the responsibility that rests on the architect or engineer for the safety of those who must use his construction.

In closing, the writer would express his obligations to the friends and colleagues whose cordial assistance is recorded in Fig. 2 and in the tables. He is particularly indebted to his father, to whose virile pencil Figs. 1 and 9 and part of Fig. 8 are due.

DISCUSSION

Mr. Hilder.

FRAZER C. HILDER, ASSOC. M. AM. SOC. C. E. (by letter).—This paper is a valuable addition to the scanty data on the loads to be expected on a structure crowded with moving people. It would seem to the writer that more extended experiments along these lines might well be undertaken to determine the horizontal component of the kinetic effect produced by a crowd moving in unison on a grand-stand or similar structure. A considerable horizontal force is evidently exerted by a crowd of "rooters," not only by springing to their feet at the crucial moment of an exciting game, as considered by Mr. Tilden, but by moving rhythmically thereafter so as to produce and continually accentuate a rocking motion in the structure. The writer has in mind an instance coming under his observation where a wooden stand was dangerously racked by a crowd of excited students swaying in unison, from one leg to the other, as they sang. While such ebullitions might well be suppressed in the interests of safety, it is evident that in spite of precautions such movement may occur, and that the possibility should be considered in the design of a grand-stand, particularly for a college.

While such an investigation would indicate the need of excessively heavy bracing, if an ordinary factor of safety were used, it would seem that a structure of the class indicated might well be designed to resist the possible rocking or marching of a crowd, with a small factor of safety, as compared with that calculated for static loads.

Mr. Quimby.

HENRY H. QUIMBY, M. AM. SOC. C. E. (by letter).—Any suggestion of new forces to be provided for in the design of structures will awaken the interest of a structural engineer, and, therefore, the experiments described in this paper command attention. The statement that a man in rising suddenly from a seat may exert a horizontal effect or force equal to one-half his weight, is somewhat startling; and that a grand-stand should be figured for a horizontal force equal to one-half of all its vertical live load is a new proposition, which, if true, is important.

In order to test the proposition, the writer rigged up a means of measuring horizontal impulses by attaching adjustably loaded brackets to a light swinging platform; he also experimented with the swing disconnected from the loads, in order to observe the amount of the induced lateral movement.

The greatest backward horizontal force produced by a sudden rising from the seat with the consequent shifting forward of the center of gravity of the body, appeared to be 7% of the body weight, and the backward swing of the unrestrained platform indicated only 5% when the weight was multiplied by the tangent of the angle of incli-

Mr. Quimby.

nation of the suspenders. The latter is probably not at all reliable, because the amount of the lateral swing is not likely to be in direct proportion to the length of the suspenders, and, without doubt, the backward swing was always interrupted by the forward impulse.

It was immediately observed that the re-acting forward force was much greater than the rearward force. The unrestrained platform—disconnected from the apparatus and free to swing—would first swing backward about 4 in., and then about 8 in. forward of the neutral point. When it was restrained, the weight lifted by the second or return impulse was about twice as great as that lifted by the first or backward impulse, that is, about 14% of the vertical load.

These measurements seem to indicate that there is something wrong with the author's method of computing the horizontal effect. The error is probably in the assumption that the horizontal movement is as rapid as the vertical one. A study of the movement shows that either the center of gravity is thrown forward before rising, or the feet are drawn under the body and, after rising, the body steps forward, for the rise could not be made in the inclined direction without a "purchase" to the rear to push against. Speed of movement is essential to the development of kinetic energy.

The rearward impulse is succeeded so quickly by the forward one that the bracing of the structure has hardly time to feel it, and its energy must be largely absorbed by the inertia of the structure if the dead weight is at all considerable, and this is likely to be the case always. The platform used in the experiment described was very light—perhaps one-fifth of the live load—as probably was that of the scale used by the author in his work. Absorption of energy of a transitory force reduces the effect and the attending stress, as illustrated by the old magic of enduring a sledge-hammer blow on one's chest by interposing an anvil. It is suggested that the author repeat his rising experiment on the scale with its platform loaded with a dead weight equal to the live load, and report the result.

The fact that the second or forward impulse is greater than the rearward one, is probably due to the arrest of the movement being more sudden than its start. The energy expended in the movement must be divided between accelerating it and retarding it, but the kinetic effect will be proportioned to the quickness of each stage.

The stress, or the effect of stress, in a structure is not directly proportional to the speed of application of loads—it is not necessarily increased by so-called impact. Within limits, the rapid application of a load to almost any material will find a higher resistance than a slow application, and if the dead weight be equal to, say, the live load, much of any kinetic effect of sudden loading will be lost in the mass before reaching the bracing.

Mr. Quimby.

The effect of a crowd running across a bridge and against the railing is a more menacing force, and at least one case is recalled where a footbridge over a stream collapsed under a shifting crowd of spectators at a boat race. A well-designed bridge railing, however, will be competent to resist the pressure of a crowd, for if the strength of the rail and the posts be computed for 50 lb. per lin. ft. applied at the rail, the usual allowed unit stress will provide ample margin for a push against it. The kinetic effect of a crowd hurrying across the bridge would be spent in the floor and not on the railing, for only one rank of the runners could fetch up against the rail—at least, at one moment—and a bridge wide enough to permit a shifting crowd to get up any speed must have considerable mass or inertia, and is likely also to be stiff as a horizontal beam.

It would seem, therefore, that we hardly need to revise our practice in the design of structures to care for a new kind of impact. The suggestions in the paper, however, should be useful in directing attention to the necessity for intelligent design in the construction of all parapet railings, but the most formidable impact that railings are subject to nowadays seems to be that of straying trolley cars and automobiles, one of the former and half a dozen of the latter having come under the writer's notice recently, and engineers cannot well be expected to design for such contingencies.

Mr. Coombs.

R. D. Coombs, M. Am. Soc. C. E.—It seems to the speaker that the general application of the results of the experiments to specifications, by the addition of loading requirements, would be an unnecessary burden to structures which are calculated for wind load. Such structures, particularly if designed for the venerable loading of 30 lb. per sq. ft., would have a strength more than sufficient to care for the lateral stresses due to the movement of the live load. In fact, the calculated wind load would not occur while the structure was occupied, as the load presupposes a very violent wind velocity. Further, the usual so-called "wind loads" really include a vibration, or lateral impact loading.

Though some special provision for lateral and vertical impact forces may be proper for light temporary grand-stands, etc., which may not be designed for the usual wind loads, the speaker believes any such addition entirely unnecessary for first-class permanent work.

Mr. French.

J. B. French, M. Am. Soc. C. E.—The author's experiments are of interest, and merit discussion, but, as has been pointed out, the effect of these forces on structures is very largely dependent on the general character and dimensions of the structure, independent of its strength. If the intervals of time between the successive applications of even a very small force correspond to the rate of vibration

Mr. French. of the structure or structural member, the effect will be cumulative and may assume serious proportions.

The most extensive experiments on structures to determine the kinetic effect, as distinguished from the static effect, of moving loads, are undoubtedly those made by the American Railway Engineering Association by running trains across bridges, the length, weight, and speed of the trains, and the length of the bridges all being varied within considerable limits; and, in these experiments, it appeared to be demonstrated that the kinetic effect, or impact produced, depended largely on the relation of the span length to the speed and length of the train, and that the running of trains over bridges at a speed of less than 10 miles per hour produces no appreciable effect beyond that which would be produced by the train standing still.

The effect of the movement of crowds over bridges would certainly be dependent on similar laws, and it does not seem possible that a bridge designed to carry the automobile and heavy trucking traffic of to-day, and constructed with the solid floors which are now so common, could be appreciably affected by the dynamic effect of crowds of people.

In the case, however, of grand-stands filled with spectators of a football or similar game appealing to their enthusiasm, all might arise at one time and engage in regularly timed cheering or stamping, thereby, undoubtedly, producing a considerable effect, and this should be taken into account in the design of such structures. Even in this case, however, it is evident that the effect would be more dependent on the rigidity of the structure, or what might possibly be called its "vibratory pitch," than on its strength under static loads, or the weight of the spectators.

Mr. Tilden. C. J. TILDEN, M. AM. SOC. C. E. (by letter).—Mr. Hilder and Mr. French raise a question which is somewhat outside the scope of the paper, namely, that of vibrations set up in a structure by the movements of its living load. This, of course, is one possible result of the kinetic effect of crowds, and if the swaying motion of the crowd is in unison with the vibration period of the structure, disaster may follow. This phase of the question, however, has to do more with the building than with the load on it, and, therefore, was intentionally omitted from the original investigation. Nevertheless, the writer is glad to have the point raised, and does not by any means underestimate its importance.

The results reported by Mr. Quimby of his experiments with the swinging platform are not at all convincing. The existence of a backward-shoving force is clearly shown by the sudden backward swing of the platform, but to measure it by calling it equal to the force needed to hold the platform the same degree out of plumb, is surely a serious error. The immediate force-effect of a moving body on a freely swinging structure is very different from that of the same body,

moving in the same manner, on a practically rigid structure. The writer still believes that the maximum possible backward push on a grand-stand, or similar structure, is much more likely to be 50%, or more, of the static weight than the 7% suggested by Mr. Quimby. Referring to the writer's computation, Mr. Quimby says: "The error is probably in the assumption that the horizontal movement is as rapid as the vertical one." Mr. Tilden.

It is hard to see just where this "error" lies, as the two movements are made in precisely the same time, as a glance at Figs. 1 and 2, with their accompanying explanations, will show.

The absorption of a large part of these impulsive forces by "the inertia of the structure" is, of course, quite probable where the forces are isolated or result from the sudden movement of small and separated groups. It is when the movement is so general as to be practically unanimous that the resulting force on the entire structure may reach serious proportions. The experiment of interposing, between the man's feet and the scale platform, a mass nearly equal to the weight of the man, was tried by the writer, and the results reported in the last paragraph of page 2110 and the lines A_x of Fig. 2.

Mr. French is quite right in saying that a heavy modern bridge, with solid floor, could hardly be seriously affected by the movements of a crowd of people. Unfortunately, however, such bridges are a very small part of all the bridges in use. It is not the "first-class permanent work" (to quote Mr. Coombs' expression) which needs attention along the lines suggested by the paper, but the much more common, more or less flimsy structures, often hastily built, and sometimes without proper supervision.

The writer believes that a general increase in loading requirements—possibly even to the extent of 50 or 60%—for structures likely to carry people would be wise and proper. Such a ruling would not materially affect first-class design, but would decidedly benefit the lighter classes of work. It is certainly better to be safe than to be economical, where human lives are concerned.

Emphasis is lent to this view by the reports of accidents of various kinds which frequently appear in the press. Two recent cases are commented on briefly:* The first of these was the accident at Lawrence, Mass., on June 30th, when a dozen boys, from 9 to 15 years of age, lost their lives through the failure of a narrow, wooden walk leading to a municipal bath-house. The Associated Press report said "the boys were jumping up and down as they shouted to the keeper to open up." The second instance was that of the second floor piazza of a tenement house at Brookline, Mass., which collapsed under the weight (plus kinetic effect?) of fourteen children, three of whom were badly injured.

* *Engineering News*, July 10th, 1913, p. 90.

Mr. Tilden.

The recent failure of the floor of an amusement pier at Long Beach, Cal., resulting in the loss of 35 or 40 lives, was fully reported in the daily and engineering press. It is simply another instance in which it is not hard to imagine the kinetic effect, or impact, of the densely packed crowd as being at least a contributory cause of the collapse. At the ceremony of notifying Governor Marshall of his selection as Democratic candidate for Vice-President, which took place in Indianapolis in August, 1912, a grand-stand containing several hundred people gave way. Fortunately, no lives were lost, and the incident was passed over briefly by the press; but, here again, one may imagine movements in such a crowd, inspired by political enthusiasm, which might have much greater effect than the mere dead weight.

These are simply reports of facts, serious facts, involving the loss of many lives and the endangering of many more. It would be an easy matter to multiply instances, for scarcely a month passes that some accident of the kind is not reported. It is difficult, of course, to establish any direct and unquestioned connection between them and the subject of the paper. We naturally look for weakness in the structure rather than for excess in the load; but a more general recognition of the possible effects of motion in crowds would, the writer believes, result in safer and more rational design. Even practical builders, who might not be able to compute stresses and strains, would quickly "sense" the new requirements and build accordingly.

——*American Gas Light Journal*, v. 86, p. 847 (May 20, 1907).

——Depreciation; by Lawrence R. Dicksee. *Municipal Journal* (London), v. 16, pp. 323, 355 (April 19, 26, 1907).

——Editorials. Local Authorities and Depreciation. *Journal of Gas Lighting*, v. 98, p. 144 (April 16, 1907); *Electrical Review* (London), v. 60 p. 665 (April 26, 1907).

THE ACCURACY OF APPRAISALS; by Martin Schreiber. *Aera*, v. 1, p. 247 (Oct., 1912). (States that the principal point that the writer wishes to bring out is that any appraisal involving a comprehensive utility, founded principally on estimated values, is not entirely reliable for any business undertaking.)

THE APPRAISAL OF ELECTRIC PROPERTIES AND THE USES TO WHICH APpraisals May Be Put; by Halbert P. Gillette. *Engineering and Contracting*, v. 36, p. 506 (Nov. 8, 1911). (Address delivered before the Seattle Electric Club on general principles of valuation; one and one-half pages.)

——Abstract. *Electric Railway Journal*, v. 38, p. 948 (Oct. 28, 1911).

THE APPRAISAL OF INTANGIBLE VALUES IN PUBLIC UTILITIES. (Editorial.) *Electrical World*, v. 60, p. 866 (Oct. 26, 1912). (Review of a paper read by William J. Hagenah before the Northwest Electric Light and Power Association.)

APPRAISAL OF PLANTS FOR PUBLIC SERVICES; by Nicholas S. Hill, Jr. *Engineering Record*, v. 43, p. 546 (June 8, 1901). (On the fundamental principles of valuation; three pages.)

THE APPRAISAL OF PUBLIC SERVICE PROPERTIES AS A BASIS FOR THE Regulation of Rates; by C. E. Grunsky. *Transactions*, American Society of Civil Engineers, v. 75, p. 770 (Paper 1232. Dec., 1912). (Discussion of appraisal for rate-fixing purposes without deducting anything from the properly invested capital for depreciation.)

CLASSIFICATION OF OPERATING EXPENSES OF CARRIERS BY WATER AS Prescribed by the Interstate Commerce Commission. First Issue, Effective on Jan. 1, 1911. Government Printing Office, Washington, 1910. (Contains general instructions on reserves for depreciation and replacements.)

CLASSIFICATION OF REVENUES AND EXPENSES OF PIPE LINE COMPANIES as Prescribed by the Interstate Commerce Commission. First Issue, Effective on Jan. 1, 1911. Government Printing Office, Washington, 1910. (Gives general instructions in regard to depreciation, replacements and abandonments of property.)

COMPENSATION FOR CONDEMNATION OF PROPERTY; by Maguire and Mooney. *Electrical Review and Western Electrician*, v. 60, p. 709 (April 13, 1912). (Discusses value of land.)

CONCERNING FRANCHISE VALUES; by William H. Hodge. *Public Service*, v. 5, p. 111 (Oct., 1908). (One and one-half pages.)

THE CUSTODY OF DEPRECIATION FUNDS. (Editorial.) *Electrical World*, v. 59, p. 126 (Jan. 20, 1912). (One column.)

CUSTODY OF DEPRECIATION FUNDS. (Letter); by George L. Hoxie. *Electrical World*, v. 59, p. 367 (Feb. 17, 1912).

THE DEFICIT THEORY OF DEVELOPMENT EXPENSE OF PUBLIC SERVICE CORporations, and an Erroneous Application of the Theory by the Wisconsin Railroad Commission. (Editorial.) *Engineering and Contracting*, v. 35, p. 671 (June 14, 1911). (Editorial indicates alleged mistakes in the application of the deficit theory; one page.)

DEPRECIATION. (Editorial.) *Engineering*, v. 83, p. 585 (May 3, 1907). (Review of recent papers on this subject; refers especially to the papers of Robert Hammond, P. D. Leake, and Lawrence R. Dicksee.)

DEPRECIATION. (Editorials.) *Municipal Journal* (London), v. 12, pp. 818, 859, 939, 999, 1059 (Sept. 11, 25, Oct. 23, Nov. 13, Dec. 4, 1903).

——*Public Service*, v. 6, p. 122 (April, 1909).

——*Stone and Webster Public Service Journal*, v. 1, p. 16 (July, 1907). (Four pages.)

DEPRECIATION; by A. Winder. *Cassier's Magazine*, v. 35, p. 539 (Feb., 1909). (States that depreciation is made up of two elements, obsolescence and deterioration; two pages.)

DEPRECIATION; by C. N. Duffy. *Progressive Age*, v. 27, p. 686 (Sept. 1, 1909). (Paper read before the Western Gas Association.)

GENERAL—(*Continued*).

DEPRECIATION; by Edwin S. Mack. *American Gas Light Journal*, v. 88, p. 971 (June 8, 1908). (Paper read before the Wisconsin Gas Association.)

——*Progressive Age*, v. 26, p. 372 (June 15, 1908).

——*Public Service*, v. 7, p. 42 (Aug., 1909).

——Editorial. *Progressive Age*, v. 26, p. 362 (June 15, 1908).

DEPRECIATION; by Frederick Walmsley. *Municipal Journal* (London), v. 12, p. 932 (Oct. 23, 1903). (Abstract of paper read before the Society of Incorporated Accountants.)

——Editorial. *Municipal Journal* (London), v. 12, p. 939 (Oct. 23, 1903).

——Criticism. Ourselves or Our Successors. *Municipal Journal* (London), v. 16, p. 84 (Feb. 1, 1907).

DEPRECIATION; by George Johnson. *Electrical Review* (London), v. 66, p. 1048 (June 24, 1910). (Discusses methods of providing for shrinkage in value; two pages.)

DEPRECIATION; by H. E. McJilton. *Street Railway Journal*, v. 13, p. 288 (May, 1897). (Definition of the word depreciation; what should and what should not be charged to depreciation; abstract of paper read before the Association of Street Railway Accountants; very brief.)

DEPRECIATION; by Patterson J. Logan. *Municipal Journal* (London), v. 15, p. 93 (Jan. 26, 1906). (Depreciation as a factor in the accounts of municipalities and methods of making provision for it.)

DEPRECIATION; by Rowland Wilson. *Mechanical Engineer*, v. 27, p. 309 (March 10, 1911). (On depreciation in relation to works on factory buildings, machinery and plants; one paragraph.)

DEPRECIATION. (Letters); by Thomas G. Milner and Oswald W. Arnold. *Municipal Journal* (London), v. 12, p. 824 (Sept. 11, 1903). (Brief opinions in regard to depreciation in municipal undertakings.)

DEPRECIATION; by W. A. J. O'Meara. *Electrician*, v. 64, p. 1072 (April 8, 1910). (Discusses physical decay, obsolescence, inadequacy, tenure of holding, etc., and the life of machinery and other plant; three pages.)

DEPRECIATION: A PLEA FOR THE STUDY AND USE OF BETTER METHODS; by P. D. Leake. *Mechanical Engineer*, v. 20, pp. 117, 147, 179 (July 27, Aug. 3, 10, 1907). (A plea for better methods of measuring and providing for depreciation of industrial plants.)

DEPRECIATION AND APPRAISALS. (Editorial.) *Electrical Review and Western Electrician*, v. 59, p. 155 (July 22, 1911). (On method of providing for depreciation.)

DEPRECIATION AND PUBLIC SERVICE REGULATION; by Robert H. Whitten. *Engineering News*, v. 69, p. 942 (May 8, 1913). (Straight-line method, accrued depreciation deducted; uniform annual investment cost method, comparison of chief methods; diagram of combined interest and depreciation percentage under each method.)

DEPRECIATION AND RESERVES; by George Wilkinson. *Electric Railway Review*, v. 17, p. 491 (April 13, 1907). (Paper read before the Wharton School of Commerce and Finance.)

——Editorial. *Electric Railway Review*, v. 17, p. 481 (April 13, 1907).

DEPRECIATION AND SINKING FUNDS. (Editorial.) *Municipal Engineering*, v. 38, p. 33 (Jan., 1910). (Three pages.)

DEPRECIATION AND VALUES. (Editorial.) *Municipal Journal* (London), v. 16, p. 304 (April 12, 1907). (Statement by the Electrical Engineer at Southwark that depreciation allowances should be included in sinking fund.)

DEPRECIATION AS AFFECTING ENGINEERING STRUCTURES; by Horatio A. Foster. *Proceedings*, Engineers' Club of Philadelphia, v. 19, p. 330 (Oct., 1902). (Contains tables on effects of depreciation at different rates for term of years, sinking fund, reserve fund, etc; eighteen pages.)

DEPRECIATION ESTIMATES; by Edwin Gruhl. *Aera*, v. 1, p. 644 (March, 1913). (Advocates the necessity of securing actual data as to variation of life in service as a basis for estimating depreciation.)

DEPRECIATION IN ITS RELATION TO APPRAISALS; by Frank F. Fowle. *Electrical World*, v. 56, p. 796 (Oct. 6, 1910). (Address before the Electric Club of Chicago; one page.)

DEPRECIATION OF BUILDINGS AND MACHINERY. *Engineering Record*, v. 63, p. 159 (Feb. 11, 1911). (Two pages.)

THE DEPRECIATION OF FACTORIES, MINES AND INDUSTRIAL UNDERTAKINGS and Their Valuation; by Ewing Matheson. Edition 4. E. & F. N. Spon, Ltd., London, 1910. (Contains six chapters on valuation.)

GENERAL—(*Continued*).

THE DEPRECIATION OF PLANT, AND ITS RELATION TO GENERAL EXPENSE; by H. M. Norris. *Engineering Magazine*, v. 16, pp. 812, 957; v. 17, p. 76 (Feb., March, April, 1899). (On the depreciation of machinery and machine tools; contains a table on the effects of depreciation at different rates for a term of years.)

DEPRECIATION OF PLANT AND WORKS UNDER MUNICIPAL AND COMPANY Management; by Charles H. W. Biggs. *Transactions*, Society of Engineers, 1902, p. 271. (Considers capital, depreciation and maintenance.)

DEPRECIATION OF PUBLIC UTILITIES. *Municipal Journal and Engineer*, v. 22, p. 148 (Feb. 13, 1907). (Methods of allowing for depreciation; one column.)

THE DEPRECIATION PROBLEM; by John L. Bronson. *Cassier's Magazine*, v. 28, p. 190 (July, 1905). (A very short article.)

DEPRECIATION RESERVE. *Municipal Journal and Engineer*, v. 27, p. 772 (Nov. 24, 1909). (Census Bureau's definition of depreciation, and argument of a Public Accountant for a reserve fund derived from income.)

DEPRECIATION RESERVE AND THE PEOPLE. (Editorial.) *Public Service*, v. 5, p. 2 (July, 1908). (Effect of depreciation on rates.)

DEPRECIATION, SHALL SINKING FUND PERIODS BE EXTENDED? by S. H. Turner. *Municipal Journal* (London), v. 12, p. 833 (Sept. 18, 1903). (Abstract of paper read before the British Association.)

——Editorial. *Municipal Journal* (London), v. 12, p. 818 (Sept. 11, 1903).

DETERMINATION OF PHYSICAL VALUES; by Clinton S. Burns. *Engineering Record*, v. 52, p. 328 (Sept. 16, 1905). (Discusses the mathematical determination of values, with examples from water-works plants.)

——*Engineering News*, v. 52, p. 328 (Sept. 16, 1905).

DEVELOPMENT EXPENSE IN THE VALUATION OF PUBLIC SERVICE PROPERTIES. (Letter); by W. H. Winslow. *Engineering and Contracting*, v. 35, p. 697 (June 14, 1911). (Includes summary of case and editorial comments; one page.)

DIFFICULT PROBLEMS WHICH PUBLIC UTILITY COMMISSIONS ARE ENDEAVORing to Solve; by H. C. Abell. *Journal of Electricity, Power and Gas*, v. 22, p. 81 (Jan. 30, 1909). (Analysis of elements of valuation of public utilities.)

ELEMENTS OF A CONSTRUCTIVE FRANCHISE POLICY; by Delos F. Wilcox. *Engineering News*, v. 64, p. 615 (Dec. 8, 1910). (Abstract of paper read before the National Municipal League of Buffalo.)

ENGINEERING VALUATION OF PUBLIC UTILITIES AND FACTORIES; by Horatio A. Foster. D. Van Nostrand Co., New York, 1912. (Analysis of the elements of valuation; 345 pages.)

EQUITABLE RATE-MAKING BY PUBLIC SERVICE COMPANIES; by Dugald C. Jackson. *Technology Quarterly*, v. 31, p. 348 (Dec., 1908). (Considers depreciation in respect to "obsolescence" and "required reconstruction".)

——*Public Service*, v. 7, pp. 145, 189 (Nov., Dec., 1909).

——*Stone and Webster Public Service Journal*, v. 5, p. 104 (Dec., 1909).

ERROR IN FIGURING DEPRECIATION. (Letter); by C. J. West. *Engineering-Contracting*, v. 32, p. 506 (Dec. 8, 1909). (Depreciation in the Boston Municipal Machine Shop; one column.)

THE ETHICS OF ALLOWANCES FOR DEPRECIATION; by L. S. Randolph. *Engineering Magazine*, v. 39, p. 692 (Aug., 1910). (Discusses three possible general policies and their physical and financial effects; four pages.)

EXPENSE BURDEN, ITS INCIDENCE AND DISTRIBUTION; by Sterling H. Bunnell. *Transactions*, American Society of Mechanical Engineers, v. 33, p. 535 (1911). (Analysis of value of plant and equipment and cost-keeping.)

FACTORY DEPRECIATION, THE PROBLEM OF CORRECT VALUATION; by Ewing Matheson. *Cassier's Magazine*, v. 23, p. 140 (Nov., 1902). (Discussion of the principles involved in valuation.)

FINANCIAL COSTS THAT FREQUENTLY ARE UNDERESTIMATED. *Engineering and Contracting*, v. 37, p. 255 (March 6, 1912). (Organization, taxes, brokerage, interest and development costs or going value.)

FIVE IMPORTANT DECISIONS RELATING TO DEVELOPMENT EXPENSE OR Going Value Based on the Deficit Theory. (Editorial.) *Engineering and Contracting*, v. 36, p. 369 (Oct. 11, 1911). (One and one-half pages.)

FIXED CHARGES IN THE MACHINE SHOP AND DEPRECIATION OF MACHINE Tools; by Henry Spencer. *Engineer*, v. 114, p. 321 (Sept. 27, 1912).

FORM OF GENERAL BALANCE SHEET STATEMENT FOR CARRIERS BY WATER as Prescribed by the Interstate Commerce Commission, First Issue, Effective on Jan. 1, 1913. Government Printing Office, Washington, 1912.

GENERAL—(*Continued*).

GOING VALUE. (Editorial.) *Electrical Review and Western Electrician*, v. 59, p. 2 (July 1, 1911). (Largely extracts from an article by W. J. Hagenah published in *The Voter* entitled "The Regulation of Public Utilities".)

GOING VALUE; by Frank F. Fowle. *Journal*, Western Society of Engineers, v. 17, p. 147 (Feb., 1912). (Review and discussion of the more prominent methods of determining going value, with particular reference to their application to public utilities.)

——Abstract. *Electric Railway Journal*, v. 38, p. 1115 (Nov. 25, 1911).

GOING VALUE AS AN ELEMENT IN THE APPRAISAL OF PUBLIC UTILITY PROPERTIES; by William H. Bryan. *Journal*, Association of Engineering Societies, v. 43, p. 147 (Oct., 1909). (Discusses intangible values in appraisement of public utility plants; eleven pages.)

——Abstract. *Engineering-Contracting*, v. 32, p. 549 (Dec. 22, 1909).

GOING VALUE OF PUBLIC UTILITIES. (Editorial.) *Electrical World*, v. 57, p. 821 (April 6, 1911). (One page.)

HANDBOOK OF COST DATA FOR CONTRACTORS AND ENGINEERS; by Halbert P. Gillette. Edition 2. Myron C. Clark Publishing Co., Chicago, 1910. (Contains a chapter on principles of engineering economics and cost keeping.)

HEARINGS BEFORE THE COMMITTEE ON IRRIGATION OF ARID LANDS OF THE House of Representatives, April 23, June 1 and 8, 1910, p. 105. Government Printing Office, Washington, 1910. (Contains two and one-half pages on depreciation.)

THE IMPORTANCE OF DEPRECIATION ALLOWANCES. (Editorial.) *Engineering Record*, v. 55, p. 703 (June 15, 1907). (One page.)

INCOME TAX AND DEPRECIATION. *Municipal Journal* (London), v. 16, p. 744 (Aug. 13, 1907). (Allowance for depreciation of plant and machinery by municipalities.)

INTANGIBLE ASSETS OF PUBLIC UTILITIES; by N. I. Garrison. *Public Service*, v. 12, p. 105 (March, 1912). (On values that are not represented by physical property.)

AN INTANGIBLE VALUE. (Editorial.) *Electric Railway Journal*, v. 34, p. 1047 (Nov. 20, 1909). (Discussion of the values that should be allowed above the actual physical property of a public utility; one page.)

INVENTORY VALUATION OF MACHINERY PLANT; by Oberlin Smith. *Transactions*, American Society of Mechanical Engineers, v. 7, p. 433 (1886). (Cost, going value, obsolescence, cost of reproduction as factors in the valuation of machinery.)

THE JUST VALUE OF MONOPOLIES, AND THE REGULATION OF THE PRICES of Their Products; by Joseph Mayer. *Transactions*, American Society of Civil Engineers, v. 75, p. 455 (Paper 1225, Dec., 1912). (Valuation of enterprises supplying transportation, communication, light, heat and power.)

KEEPING DEPRECIATION RECORDS. (Editorial.) *Engineering Record*, v. 52, p. 82 (July 22, 1905). (One column.)

LECTURE NOTES ON SOME OF THE BUSINESS FEATURES OF ENGINEERING Practice, pp. 96, 133; by Alexander C. Humphreys. Stevens Institute of Technology, Hoboken, N. J., 1905. (Contains lectures on repairs and depreciation and on accounting as applied to depreciation.)

——Supplement No. 1, p. 41. Hoboken, N. J., 1905. (Contains supplementary note on depreciation.)

LORD AVEBURY AND DEPRECIATION. (Editorial.) *Municipal Journal* (London), v. 16, p. 112 (Feb. 8, 1907).

THE MAINTENANCE AND OBSOLESCENCE CHARGES. (Editorial.) *Engineering Record*, v. 55, p. 584 (May 11, 1907). (Statement that classification of items under this head might give rise to uncertainty, and example in report of United States Steel Corporation.)

MAY RESERVE FUND TO RENEW OBSOLETE EQUIPMENT. (Editorial.) *Electric Traction Weekly*, v. 6, p. 1473 (Dec. 3, 1910). (Decision of the Supreme Court on the valuation of special franchises.)

METHODS OF COMPUTING DEPRECIATION. (Letter); by Halbert P. Gillette. *Electrical World*, v. 60, p. 1273 (Dec. 14, 1912). (Refers to "unit-cost" depreciation problem.)

METHODS OF DETERMINING LIFE OF PUBLIC UTILITIES. *Engineering and Contracting*, v. 38, p. 448 (Oct. 23, 1912). (Based on a paper by Halford Erickson on depreciation, read before the Central States Water Works Association.)

GENERAL—(*Continued*).

METHODS OF MAKING COMPUTATIONS FOR DEPRECIATION IN PUBLIC UTILITY Plants. (Letter); by F. C. Finkle. *Engineering-Contracting*, v. 34, p. 590 (Oct. 12, 1910). (Challenging the statement that the sinking fund method is in common use to provide for depreciation of public utility plants.)

METHODS OF PROCEDURE UNDER THE WISCONSIN UTILITY LAW, BENEFITS and Restrictions of the Law. *Engineering and Contracting*, v. 38, p. 425 (Oct. 16, 1912). (Discusses methods of valuation, depreciation and business or going value; very brief.)

METHODS OF PROVIDING FOR AND RECORDING DEPRECIATION. *Engineering and Contracting*, v. 38, p. 506 (Nov. 6, 1912). (Various methods of providing for and recording depreciation with special reference to the practice of the Wisconsin Railroad Commission.)

METHODS OF WISCONSIN COMMISSION FOR THE VALUATION OF PUBLIC UTILities. *Electrical World*, v. 54, p. 600 (Sept. 9, 1909).

MUNICIPAL FRANCHISES, v. 2, p. 780; by Delos F. Wilcox. Engineering News Publishing Co., New York, 1911. (Contains a chapter on capitalization, capital value, appraisals and purchase price.)

MUNICIPAL LOAN PURPOSES AND PERIODS IN ENGLAND AND THE UNITED States. (Editorial.) *Engineering News*, v. 54, p. 462 (Nov. 2, 1905). (On depreciation of public properties; contains table; two pages.)

OBSOLESCENCE AND DECREPITUDE AS FACTORS IN DEPRECIATION. *Municipal Engineering*, v. 43, p. 100 (Aug., 1912).

OBSOLESCENCE IN PUBLIC UTILITY PLANTS. (Editorial.) *Municipal Engineering*, v. 42, p. 182 (March, 1912). (Two pages.)

OFFICIAL VALUATIONS OF PRIVATE PROPERTY; by Frederick W. Whitridge. *Electric Railway Journal*, v. 35, p. 110 (Jan. 15, 1910). (Abstract of an address presented before the American Economic Association; discusses methods of valuation; two and one-half pages.)

THE ORGANIZATION FOR AND METHODS AND RESULTS OF PHYSICAL VALUation in Nebraska; by E. C. Hurd. *Engineering and Contracting*, v. 36, p. 694 (Dec. 27, 1911). (Deals with the valuation of railroad and other public utility properties; two pages.)

OVERHEAD CHARGES; by Mortimer E. Cooley. *Proceedings*, American Electric Railway Accountants Association, v. 15, p. 169 (1911). (Discussion of the elements of value of a non-physical nature which are properly included in the appraisal of a public utility property; three pages.)

——Abstracts. *Electric Railway Journal*, v. 38, p. 877 (Oct. 14, 1911); *Canadian Engineer*, v. 22, p. 630 (May 9, 1912).

——Discussion. *Electric Railway Journal*, v. 38, p. 816 (Oct. 14, 1911).

——Editorial. *Electric Railway Journal*, v. 38, p. 897 (Oct. 21, 1911).

THE PHYSICAL VALUATION DEPARTMENT OF THE NEBRASKA STATE RAILway Commission. *Engineering News*, v. 68, p. 300 (Aug. 15, 1912). (Methods of valuation used by the Nebraska State Railway Commission.)

PHYSICAL VALUATION OF PUBLIC UTILITIES, DEPRECIATION IN ITS RELAtions to Investment, Earnings and Current Value; by R. S. Hale. *Engineering Magazine*, v. 45, p. 161 (May, 1913). (Gives general conclusions; five pages.)

PHYSICAL VALUATIONS; by O. T. Crosby. *Proceedings*, American Electric Railway Association, 1911, p. 368. (Discusses the services of the promoter, ways in which profit in public service enterprises have been limited, and some merits of watered stock.)

——Abstract. *Electric Railway Journal*, v. 38, p. 874 (Oct. 14, 1911). (Three pages.)

——Editorial. *Stone and Webster Public Service Journal*, Nov., 1911, p. 309.

A PRACTICAL DISCUSSION OF DEPRECIATION; by Frank F. Fowle. *Southern Electrician*, v. 42, p. 227 (June, 1911). (Difference of opinion about the theory of actual rate of depreciation.)

THE PRINCIPLES OF VALUING PROPERTY, WITH SPECIAL REFERENCE TO Industrial Enterprises; by Henry K. Rowell. *Journal*, American Society of Mechanical Engineers, v. 34, p. 1275 (Sept., 1912); v. 35, p. 285 (Feb., 1913). (This article has the following sub-divisions: Value of property; tax value; insurance value; fair cash value; commercial value; depreciation; capitalization, and method of valuing a plant.)

——Abstract. *Engineering and Contracting*, v. 38, p. 312 (Sept. 18, 1912).

PUBLIC SERVICE RATES AND DEPRECIATION. (Editorial.) *Electrical Review and Western Electrician*, v. 58, p. 67 (Jan. 14, 1911). (One page.)

QUASI-PUBLIC CORPORATION ACCOUNTING AND MANAGEMENT, pp. 77, 181; by John F. J. Mulhall. Corporation Publishing Co., Boston, 1905. (On depreciation; three pages.)

GENERAL—(*Continued*).

REGULATION, VALUATION AND DEPRECIATION OF PUBLIC UTILITIES; by Samuel S. Wyer. Sears & Simpson Co., Columbus, Ohio, 1913. (Contains selected bibliography.)

THE RELATION OF DEPRECIATION TO GROSS EARNINGS. *Engineering-Contracting*, v. 34, p. 130 (Aug. 10, 1910). (Comparison of the effects of depreciation charges upon annual income in the case of gas and electric companies as contrasted with water companies; comments on paper by Leonard Metcalf.)

REPAIRS, RENEWALS, DETERIORATION AND DEPRECIATION OF WORKSHOP Plant and Machinery; by James E. Darbishire. *Proceedings*, Institution of Mechanical Engineers, 1908, p. 797. (Method of treating depreciation, etc.)

***REPORT OF THE NEW YORK PUBLIC SERVICE COMMISSION, SECOND DISTRICT.** *Electric Railway Journal*, v. 37, p. 301 (Feb. 18, 1911). (Includes brief report on uniform system of accounts, including depreciation.)

***REPORT OF THE PUBLIC SERVICE COMMISSION FOR THE FIRST DISTRICT** of the State of New York for the Year Ending December 31, 1908, v. 1, p. 401. Albany, 1909. (Report upon uniform systems of accounts for public service corporations, basic principles established and treatment of depreciation and appreciation.)

***REPORT OF THE STATE BOARD OF EQUALIZATION FOR 1911-1912 (CALI**fornia), p. 75, and Supplement. Sacramento, 1912. (Contains general discussion of methods of valuation for public service corporations.)

***REPORT ON LEADING RAILROAD AND PUBLIC SERVICE COMMISSIONS;** by Max Thelen. California Railroad Commission, Sacramento, 1912. (On the organization and work of railroad commissions in Oregon, Washington, Nebraska, Minnesota, Wisconsin, New York, Massachusetts, Maryland, Georgia, Texas, and Oklahoma, including their work in physical valuation of property; very brief.)

RESPONSIBILITIES OF ELECTRICAL ENGINEERS IN MAKING APPRAISALS; by H. M. Byllesby. *Transactions*, American Institute of Electrical Engineers, v. 30, p. 1251 (1911). (Remarks on the rapid and wonderful development of electrical engineering and allied industries and discussion of the proper measurement of values in general.)

——Abstract. *Electric Railway Journal*, v. 38, p. 16 (July 1, 1911).

THE SALES METHOD OF APPRAISING LAND NOT UPHELD BY THE COURTS. (Editorial.) *Engineering and Contracting*, v. 36, p. 677 (Dec. 27, 1911). (One column.)

THE SALES METHOD OF APPRAISING REAL ESTATE. *Engineering and Contracting*, v. 35, p. 751 (June 28, 1911). (Statement to the Wisconsin State Railroad Commission of the use of this method made by W. D. Pence; one and one-half pages.)

THE SALES METHOD, THE EXPERT WITNESS METHOD AND THE CAPITALized Rental Method of Appraising Land. (Editorial.) *Engineering and Contracting*, v. 35, p. 733 (June 28, 1911). (One column.)

SINKING FUND CHARGES; by W. H. Booth. *Tramway and Railway World*, v. 13, p. 349 (April 9, 1903). (Allowance for depreciation and renewals.)

SOME CRITERIA OF VALUE IN PUBLIC SERVICE INDUSTRIES; by Clarence P. Fowler. *Engineering Magazine*, v. 42, p. 873 (March, 1912). (Discussion from the point of view of the investment banker.)

SOME PRINCIPLES ESTABLISHED BY THE WISCONSIN COMMISSION. *Electrical World*, v. 57, p. 221 (Jan. 26, 1911). (Paper by Edwin S. Mack presented to the convention of the Wisconsin Electrical Association; discusses actual total investment, cost of going value and good will.)

——*Electric Traction Weekly*, v. 7, p. 61 (Jan. 21, 1911).

——*Electric Railway Journal*, v. 37, p. 164 (Jan. 28, 1911).

SOMETHING ALONG THE LINE OF PHYSICAL AND INTANGIBLE VALUATION as Covered by Recent Legislation; by Robert B. Rifenberick. *Electric Railway Journal*, v. 41, p. 1163 (June 28, 1913). (Physical and other values, reproduction cost, overhead charges, depreciation, recent legislation and the Detroit appraisal; paper read before the Central Electric Railway Association.)

STATE REGULATION OF LIGHTING ENTERPRISES; by H. L. Doherty. *American Gas Light Journal*, v. 89, p. 92 (July 20, 1908). (Address before the Wisconsin Gas Association, discussing general principles in the valuation of public utilities.)

——Abstract. Doherty on Electrical Rates and Franchises. *Electrical World*, v. 52, pp. 170, 352 (July 25, Aug. 15, 1908).

——Editorial. Valuation of Lighting Systems. *Electrical World*, v. 52, p. 607 (Sept. 19, 1908).

GENERAL—(*Continued*).

TAXATION AND VALUATION; by Henry K. Rowell. *Transactions*, National Association of Cotton Manufacturers, No. 82, p. 175 (April, 1907). (Considers principles of common law relating to taxation, methods of determining values of property, and what may be admitted as evidence to establish values of property from its capacity for valuable use.)

THEORIES OF THE VALUATION OF PUBLIC SERVICE INDUSTRIES. *Municipal Engineering*, v. 43, p. 34 (July, 1912).

A TRUST WITNESS. (Editorial.) *Municipal Journal* (London), v. 12, p. 659 (July 17, 1903). (States that municipalities should be compelled to provide a depreciation fund in addition to a sinking fund; very brief.)

TWO CONFLICTING THEORIES OF VALUATION OF PUBLIC SERVICE COMPANIES; by Halbert P. Gillette. *Engineering and Contracting*, v. 38, p. 648 (Dec. 11, 1912). (Discusses theory of market value and investment value.)

——*Railroad Gazette*, v. 54, p. 55 (Jan. 10, 1913).

THE USE OF DEPRECIATION DATA IN RATE MAKING AND APPRAISAL PROBLEMS; by Halbert P. Gillette. *Engineering and Contracting*, v. 38, p. 476 (Oct. 30, 1912). (An attempt to make clear the radical difference between actual accrued depreciation and estimated prospective depreciation.)

——*Electrical World*, v. 60, p. 927 (Nov. 2, 1912).

——Editorial. Depreciation. *Electrical World*, v. 60, p. 909 (Nov. 2, 1912).

VALUATION, A FAIR RETURN, AND REASONABLE CAPITALIZATION; by Frederick Royce. *Stone and Webster Public Service Journal*, v. 9, p. 7 (July, 1911). (Seventeen pages.)

VALUATION OF LAND FOR RATE-MAKING PURPOSES. *Electrical Review*, v. 61, p. 1106 (Dec. 14, 1912). (Considers whether original cost or present value should be used in appraisal of land.)

VALUATION OF OPERATING PROPERTIES; by Edgar S. Nethercut. *Electric Railway Journal*, v. 35, p. 945 (May 28, 1910). (Paper read before the Central Electric Railway Association; very general statement; one and one-half pages.)

——Discussion. *Electric Railway Journal*, v. 35, p. 976 (June 4, 1910).

THE VALUATION OF PUBLIC SERVICE CORPORATION PROPERTY; by Henry Earle Riggs. *Transactions*, American Society of Civil Engineers, v. 72, p. 1 (Paper 1190. June, 1911). (300 pages.)

——Abstract. The Reasons For and Methods Employed in Appraising the Value of Railway Properties with Special Reference to the Michigan Valuation. *Engineering-Contracting*, v. 34, p. 534 (Dec. 14, 1910).

——Editorial. Method of Appraising Non-Physical Railway Values. *Engineering-Contracting*, v. 34, p. 517 (Dec. 14, 1910).

VALUATION OF PUBLIC SERVICE CORPORATIONS, LEGAL AND ECONOMIC Phases of Valuation for Rate Making and Public Purchase; by Robert H. Whitten. The Banks Law Publishing Co., New York, 1912. (Valuations made for Governmental purposes by official appraisers, commissions or courts; decisions and reports; bibliography of the subject.)

VALUATION OF PUBLIC SERVICE INDUSTRIES; by Henry C. Adams. *Electric Railway Journal*, v. 35, p. 314 (Feb. 19, 1910). (Abstract of paper read before the American Economic Association; one page.)

VALUATION OF PUBLIC SERVICE PROPERTIES; by L. R. Nash. *Stone and Webster Public Service Journal*, v. 11, p. 241 (Oct., 1912). (A summary of opinions, decisions and methods bearing on valuation.)

VALUATION OF PUBLIC UTILITIES; by Clinton S. Burns. *Municipal Journal and Engineer*, v. 29, p. 744 (Nov. 30, 1910). (Discusses depreciation and present value reducing formulas and explains a new method of appraisement.)

VALUATION OF PUBLIC UTILITIES; by Halford Erickson. no place, 1912. (Address before the Indiana Sanitary and Water Supply Association, Feb. 15, 1912.)

——Abstract. Principles of Valuation of Public Utilities. *Public Service Regulation*, v. 1, pp. 294, 370 (May, June, 1912). (Discussion of original, reproduction, going, franchise and earning values and abnormal conditions.)

VALUATION OF PUBLIC UTILITIES BY THE RAILROAD COMMISSION OF WISconsin. *Electric Railway Journal*, v. 34, p. 393 (Sept. 11, 1909). (Description of methods followed by the Commission; three pages.)

——Methods of Wisconsin Commission for the Valuation of Public Utilities. *Electrical World*, v. 54, p. 600 (Sept. 9, 1909).

VALUATION OF PUBLIC UTILITY PROPERTIES; by Henry Floy. McGraw-Hill Book Co., New York, 1912. (Summary of practice with typical examples.)

VALUATION OF THE PROPERTIES OF PUBLIC UTILITY CORPORATIONS; by Charles Gobrecht Darrach. The Bradford Press, Philadelphia, 1913. (Proposed method of estimating the value of public service companies' properties.)

GENERAL—(*Continued*).

THE VALUATION OF THE PROPERTY OF PUBLIC SERVICE CORPORATIONS. *Engineering Record*, v. 58, p. 274 (Sept. 5, 1908). (General article on methods of making valuations.)

VALUING THE PROPERTY OF PUBLIC UTILITIES; by Harold Almert. *Public Service*, v. 12, p. 65 (Feb., 1912). (General article on the appraisal of public utilities; one and one-half pages.)

WHERE A THEORY FAILS; by R. W. Child. *Stone and Webster Public Service Journal*, v. 2, p. 422 (June, 1911). (Discussion on depreciation of physical property.)

THE WISCONSIN PUBLIC UTILITIES LAW; by B. H. Meyer. *Electric Railway Journal*, v. 33, p. 103 (Jan. 16, 1909). (Discusses valuation in a general way; two pages.)

WISCONSIN PUBLIC UTILITY LAW: ITS OPERATION AND RESULTS; by Charles B. Salmon. *Proceedings*, American Water Works Association, v. 29, p. 168 (1909). (On valuation; two and one-half pages.)

——*Municipal Engineering*, v. 37, p. 27 (July, 1909).

***WORK OF THE JOINT ENGINEERING STAFF OF THE WISCONSIN TAX AND** Railroad Commissions; by William D. Pence. *Journal*, Western Society of Engineers, v. 14, p. 73 (Feb., 1909). (Describes fully the work of the staff in physical valuations of railways, street railways and other public utilities.)

——Abstracts. Valuation and Inspection Work of the Joint Engineering Staff of the Wisconsin Tax and Railroad Commissions; by William D. Pence. *Engineering News*, v. 61, p. 227 (March 4, 1909); *Railway Age Gazette*, v. 46, p. 67 (Jan. 8, 1909); *Electric Railway Journal*, v. 33, p. 22 (Jan. 2, 1909); *Engineering Record*, v. 59, pp. 10, 49, 73 (Jan. 2, 9, 16, 1909).

——Editorial. Valuation and Inspection of Public Service Corporation Properties by Engineers. *Engineering News*, v. 61, p. 244 (March 4, 1909).

WORKS MANAGEMENT, p. 82; by William Duane Ennis. McGraw-Hill Book Co., New York, 1911. (Contains a chapter on depreciation.)

GENERAL—UNVERIFIED REFERENCES.

ACCOUNTING OF INDUSTRIAL ENTERPRISES; by William M. Lybrand. *Journal of Accountancy*, v. 7, p. 224 (Jan., 1909). (Abstract of paper read before the American Association of Public Accountants.)

ACCOUNTS, THEIR CONSTRUCTION AND INTERPRETATION; by W. M. Cole.

ADDRESS BEFORE STREET RAILWAY ACCOUNTANTS ASSOCIATION OF AMERica (1903) Convention; by H. J. Davies. (Abstract.) *Street Railway Review*, v. 13, p. 724 (Sept. 20, 1903).

ANNUAL REPORT OF THE KANSAS CITY PUBLIC UTILITIES COMMISSION, 1911.

ARGUMENTS AS TO THE TRUE VALUE OF THE GENERAL PROPERTY IN WISconsin, Jan., 1904; by Frank P. Crandon, Thomas H. Brown, Arthur S. Dudley, W. W. Baldwin, Thomas A. Polleys. Madison, Wis., 1904.

CAPITALIZATION AND DEPRECIATION IN MUNICIPAL PLANTS; by Forrest F. Barker. *Inter-Nation*, v. 1, p. 76 (April, 1907). (Address before the Incorporated Public Service Accountants of Massachusetts.)

CARING FOR DEPRECIATION; by Earl A. Saliers. *Journal of Accountancy*, April, 1912, p. 241.

COMPULSORY DEPRECIATION CHARGE. *Journal of Accountancy*, Dec., 1912, p. 431.

CORPORATION ACCOUNTING AND AUDITING; by Keister.

CORPORATION ACCOUNTING AND LAW; by Rahill.

COST ACCOUNTING; by J. R. Weidman. *Journal of Accountancy*, Nov., 1910.

THE COST OF PRODUCTION; by B. C. Bean.

DEFERRED CHARGES TO OPERATING; by Walter A. Staub. *Journal of Accountancy*, v. 8, p. 401 (Oct., 1909).

DEPRECIATION. (Editorial.) *Light Railway and Tramway Journal*, v. 14, p. 210 (April 6, 1906).

——*Michigan Investor* (Detroit), March 13, 1909.

DEPRECIATION; by Edwin S. Mack. *Water and Gas Review*, v. 20, p. 29 (Aug., 1909). (Abstract of paper read before the Wisconsin Gas Association.)

DEPRECIATION; by H. W. Wilmot. *Journal of Accountancy*, v. 9, p. 104 (Dec., 1909).

DEPRECIATION; by Max Teichmann. *Journal of Accountancy*, v. 3, p. 101 (Dec., 1906).

DEPRECIATION AND OBSOLESCENCE. *Light Railway and Tramway Journal*, Sept. 6, 1912, p. 791.

DEPRECIATION AND OTHER RESERVES; by Alfred Knight. *Journal of Accountancy*, v. 3, pp. 189, 201 (Jan., 1908). (Paper read before the Cincinnati College of Finance, Commerce and Accounts.)

DEPRECIATION AND RESERVE ACCOUNTS; by H. D. Grant. *Journal of Accountancy*, v. 9, p. 352 (March, 1910).

DEPRECIATION AND RESERVE FUNDS; by Lawrence R. Dicksee. 1903. (80 pages.)

DEPRECIATION AT DETROIT. *Finance* (Cleveland, Ohio), v. 15, p. 201 (Feb. 16, 1907).

DEPRECIATION ESTIMATING; by William B. Jackson. *Steam*, v. 7, p. 103 (April, 1911).

DEPRECIATION IN ENGINEERING WORKS; by R. E. Neale. *Mechanical World*, Serial beginning Feb. 7, 1913.

DEPRECIATION IN VALUATIONS OF PUBLIC SERVICE CORPORATIONS FOR Various Purposes; by E. A. Saliers. *Journal of Accountancy*, v. 15, p. 106 (Feb., 1913).

DEPRECIATION OF CAPITAL; by Lawrence R. Dicksee.

DEPRECIATION, RENEWAL AND REPLACEMENT ACCOUNTS; by Herbert G. Stockwell. (Paper read at the Annual Meeting of the American Association of Public Accountants at Denver, Colo., Oct. 18-22, 1909.)

——Abstract. *Journal of Accountancy*, v. 9, pp. 89, 189 (Dec., 1909, Jan., 1910).

DETERMINATION OF GOING VALUE; METHODS OF FIXING VALUE OF INTANgible Utility Assets; by Morris Knowles. *Public Service*, Oct., 1912, p. 812.

DISTRIBUTION OF URBAN LAND VALUES; by Richard M. Hurd. *Yale Review*, v. 11, p. 124 (Aug., 1902).

ETHICAL AND ECONOMIC ELEMENTS IN PUBLIC SERVICE VALUATION; by James E. Allison. *Quarterly Journal of Economics*, Nov., 1912, p. 998.

GOING VALUE RECOGNIZED IN NEW JERSEY. *Gas Record*, Feb. 10, 1913, p. 137.

HISTORY OF RENEWAL FUNDS. *Proceedings*, International Street Railway Congress, 1904, p. 167.

IMPORTANCE OF DEPRECIATION. *Zeitschrift für Werk-Zeug*, Dec. 13, 1908.

INCOME TAX AND ALLOWANCE FOR DEPRECIATION. *Light Railway and Tramway Journal* (London), v. 21, pp. 18, 28 (July 2, 1909).

INCOME TAX ASSESSMENT. *Tramway and Railway World*, v. 26, p. 66 (July 17, 1909).

INCREMENT VERSUS RATES; by Ward Prouty. *Public Service Regulation*, March, 1912.

LAND VALUES AND PUBLIC UTILITY RATES. *The Public*, Sept. 29, 1911, p. 995. (Testimony of Edward W. Bemis in the Des Moines gas case.)

LEGAL BASIS OF RATE REGULATION; by E. C. Bailey. *Columbia Law Review*, June, 1911, p. 532; Nov., 1911, p. 639.

LOGICAL BASIS FOR VALUATION; by Charles Griffith Young. New York, 1911. (Paper read before Central Electric Railway Association, Jan. 19, 1911.)

MAINTENANCE AND DEPRECIATION IN PUBLIC SERVICE CORPORATIONS; by Harvey Stuart Chase. *Journal of Accountancy*, v. 4, p. 1 (May, 1907). (Paper read before Incorporated Public Accountants of Massachusetts.)

MODERN ACCOUNTING; by H. R. Hatfield.

THE NATURE OF CAPITAL AND INCOME; by Irving Fisher.

OFFICIAL VALUATION OF PRIVATE PROPERTY; by Frederick Wallingford Whitridge. New York, 1910. (Paper read before the American Economic Association, Dec. 30, 1909.)

ORIGIN OF THE PECULIAR DUTIES OF PUBLIC SERVICE COMPANIES; by Charles K. Burdick. *Columbia Law Review*, June, 1911, p. 514; Nov. 1911, p. 616.

PHYSICAL APPRAISAL IN RELATION TO ACCOUNTANCY, EXAMINATION OF Some of the Basic Fallacies Regarding Plant Valuation; by R. K. Woodbury. *Journal of Accountancy*, Dec., 1910.

PLANT VALUATIONS; by W. D. Scott. *Journal of Electricity, Power and Gas*, Dec. 9, 1911, p. 549.

PROPER BASIS OF CAPITALIZATION; by Bruce Wyman. In "Public Service Corporations," v. 2, pp. 1080-1112, 1911.

QUESTION OF DEPRECIATION. *Zeitschrift für Werk-Zeug*, March 15, 1909.

RENEWAL AND REPLACEMENT ACCOUNTS; by E. G. Stockwell. *Journal of Accountancy*, Jan., 1910.

GENERAL—UNVERIFIED REFERENCES—(*Continued*).

SINKING FUND RESERVES; by Warren S. Pangborn. *Journal of Accountancy*, Aug., 1911.

THE SOMERS SYSTEM OF REALTY VALUATION; by H. L. Lutz. *Quarterly Journal of Economics*, v. 25, p. 172 (Nov., 1910).

STANDARDS OF DEPRECIATION; by Harvey Stuart Chase. *Boston Evening Transcript*, April 12, 1907.

TREATMENT OF DEPRECIATION IN CONNECTION WITH THE FEDERAL CORporation Tax. *Journal of Accountancy*, March, 1912, p. 213.

VALUATION OF PUBLIC SERVICE UTILITIES. In American Economic Association, Publication, 3d series, v. 2, pp. 184-195 (April, 1910).

THE VALUATION OF PUBLIC UTILITIES; by Clinton S. Burns. *City Hall-Midland Municipalities*, v. 22, p. 50 (Nov., 1911).

VALUATION OF PUBLIC UTILITIES; by Henry A. Lardner. In Public Utilities Act of California, p. 28; compiled by Louis Sloss & Company, San Francisco, 1912.

VALUATION OF PUBLIC UTILITIES FOR PURPOSES OF COMPENSATION; by F. H. Bell. *Canadian Law Times*, Jan., 1911.

VALUATION OF PUBLIC UTILITY PROPERTY; by Horatio A. Foster. *Bulletin*, Thropp Polytechnic Institute, Jan., 1911, p. 17.

VALUING PUBLIC UTILITIES. *Commercial and Financial Chronicle*, Aug. 3, 1912, p. 266.

ELECTRIC LIGHT AND POWER—GENERAL.

ACCOUNTING FOR DEPRECIATION; by H. M. Edwards. National Electric Light Association, Thirty-fourth Convention, 1911, Papers, Reports and Discussions, v. 2, p. 179. (How the amount to be reserved for depreciation should be determined and how the reserve should be treated.)

ADEQUATE DEPRECIATION OF CAPITAL EXPENDITURE BY MUNICIPAL ELECtricity Undertakings; by J. Horace Bowden and Fred Tait. *Electrical Review* (London), v. 60, pp. 1021, 1064 (June 21, 28, 1907). (Serial giving full discussion of the subject, including physical valuation.)

ANALYSIS OF CENTRAL-STATION COSTS. *Electrical World*, v. 52, p. 1239 (Dec. 5, 1908). (Elements of cost of service to the consumer.)

COMMENTS ON FIXED COSTS IN INDUSTRIAL POWER PLANTS; by John C. Parker. *Proceedings*, American Institute of Electrical Engineers, v. 30, p. 469 (March 30, 1911). (Two and one-half pages on depreciation.)

COMMERCIAL DEPRECIATION IN ELECTRIC PLANTS. *Street Railway Bulletin*, v. 7, p. 431 (Aug., 1908). (States that allowance should be made for machinery out of date in addition to allowance of 10% for ordinary wear and tear.)

COMMERCIAL DEPRECIATION IN ELECTRIC PLANTS; by Judson H. Boughton. *Public Service*, v. 5, p. 7 (July, 1908). (One-half page.)

DEPRECIATION; by C. N. Duffy. *Electrical World*, v. 51, p. 217 (Feb. 1, 1908). (The treatment of depreciation is confined to broad general questions briefly touched upon as applicable to electric lighting; abstract of paper read before the Northwestern Electrical Association.)

——*Electric Railway Review*, v. 19, p. 83 (Jan. 18, 1908).

——*Electrical Review* (London), v. 63, p. 374 (Sept. 4, 1908).

——*Street Railway Journal*, v. 31, p. 169 (Feb. 1, 1908).

——Editorial. Depreciation. *Electrical World*, v. 51, p. 207 (Feb. 1, 1908).

DEPRECIATION; by Robert Hammond. *Journal*, Institution of Electrical Engineers, v. 39, p. 270 (1907). (The question of depreciation in all its bearings as applicable to electricity supply undertakings.)

——Abstracts. *Electrician*, v. 59, p. 51 (April 26, 1907); *Electrical Review* (London), v. 60, p. 744 (May 3, 1907); *Electric Railway Review*, v. 17, p. 716 (June 1, 1907); *Progressive Age*, v. 25, p. 305 (June 1, 1907); *Engineering Magazine*, v. 33, p. 636 (July, 1907); *Engineering Record*, v. 55, p. 703 (June 15, 1907); *Electrical Review* (Chicago), v. 50, p. 828 (May 25, 1907); *Municipal Journal* (London), v. 16, pp. 411, 435 (May 10, 17, 1907); *Street Railway Bulletin*, v. 6, p. 382 (June, 1907); *Tramway and Railway World*, v. 21, p. 497 (June 6, 1907).

——Editorials and discussions. *Electrician*, v. 59, pp. 100, 103 (May 3, 1907); *Engineering Record*, v. 55, p. 703 (June 15, 1907).

DEPRECIATION. (Letter); by S. Fred Smith. *Electrical World*, v. 54, p. 489 (Aug. 26, 1909). (Depreciation of property of electrical corporations; general.)

ELECTRIC LIGHT AND POWER—GENERAL—(*Continued*).

DEPRECIATION ACCOUNTING FOR SMALL COMPANIES; by George E. Claflin. National Electric Light Association, Thirty-second Convention, 1909, Papers, Reports and Discussions, v. 3, p. 165. (Classification for depreciation of electrical works; tangible property; wear and tear; obsolescence; inadequacy; extraordinary casualties.)

——Abstract. *Electric Railway Journal*, v. 33, p. 1078 (June 12, 1909). (Very brief.)

THE DEPRECIATION AND MAINTENANCE OF ELECTRICAL EQUIPMENT; by George W. Cravens. *Electrical Review* (New York), v. 56, p. 853 (April 23, 1910). (Considers the different methods of accounting in use and advocates the sliding scale method; four pages.)

DEPRECIATION AND REPAIRS. (Editorial.) *Electrical Review and Western Electrician*, v. 53, p. 807 (Nov. 28, 1908). (Allowance made for electric lighting plants for annual depreciation and repairs.)

DEPRECIATION AND RESERVE FUNDS OF ELECTRICAL PROPERTIES; by William B. Jackson. *Journal*, Western Society of Engineers, v. 15, p. 587 (September, 1910). (Discusses methods of estimating the amount to be charged for depreciation and reserve fund and how the principle should be applied; thirty-two pages.)

——Abstracts. *Engineering-Contracting*, v. 33, p. 487 (May 25, 1910); *Electric Railway Journal*, v. 35, p. 903 (May 21, 1910).

DEPRECIATION AND RESERVES FOR ANTIQUATION AND OBSOLESCENCE FROM an Engineering Standpoint; by C. H. Yeaman. *Electrician*, v. 59, p. 475 (July 5, 1907). (Contains table of estimated life of electrical appliances for loan purposes.)

——*Electrical Engineer* (London), v. 40, p. 46 (July 12, 1907).

——*Electrical Review* (London), v. 61, p. 44 (July 12, 1907).

DEPRECIATION AS RELATED TO ELECTRICAL PROPERTIES; by Henry Floy. *Proceedings*, American Institute of Electrical Engineers, v. 30, p. 1267 (1911). (A long article, subdivided under application of terms, classes of depreciation, absolute and theoretical depreciation, depreciation accounts or reserve funds, 50% method, depreciation of contingent percentages and summary and conclusions.)

——Abstracts. *Electric Railway Journal*, v. 38, p. 21 (July 1, 1911); Depreciation. *Engineering-Contracting*, v. 36, p. 359 (Oct. 4, 1911); Notes on Depreciation. *Engineering Record*, v. 64, p. 282 (Sept. 2, 1911).

——Comments. Absolute and Theoretical Depreciation. *Engineering Record*, v. 64, p. 333 (Sept. 16, 1911); Depreciation; by H. C. D. Nutting. *Electrical World*, v. 58, p. 323 (Aug. 5, 1911).

DEPRECIATION OF COMPANIES' ASSETS. (Letter.) *Electrician*, v. 59, p. 146 (May 10, 1907). (On depreciation of electric light plants; very brief.)

DEPRECIATION OF ELECTRIC LIGHT PLANTS; by Alexander C. Humphreys. *Municipality*, v. 8, p. 72 (March, 1908). (The elements of obsolescence, inadequacy and actual decay.)

DEPRECIATION OF ELECTRIC LIGHT PLANTS; by Robert Hammond. *Municipality*, v. 8, p. 69 (March, 1908). (An attempt to secure data on actual depreciation, rather than methods used in appraisal.)

DEPRECIATION OF ELECTRIC LIGHT PLANTS; by William H. Bryan. *Municipality*, v. 8, p. 74 (March, 1908). (Brief abstract of paper read before the Engineers' Club of St. Louis.)

THE DEPRECIATION OF ELECTRICAL PROPERTIES; by G. W. Bissell. *Electrical Age*, v. 36, p. 459 (June, 1906). (The allowance that should be made for depreciation.)

DEPRECIATION OF POWER-PLANT EQUIPMENT. (Letter); by Everard Brown. *Electrical World*, v. 60, p. 268 (Aug. 3, 1912). (On decrepitude and obsolescence of machinery in electrical power plants.)

DEPRECIATION OF POWER PLANT EQUIPMENT; by F. H. Neely. *Power*, v. 30, p. 1028 (June 8, 1909). (Concerning depreciation in private and municipal plants and provision which should be made against it.)

DEPRECIATION ON ELECTRIC LIGHT AND POWER PLANTS. *Electric Railway Journal*, v. 40, p. 60 (July 13, 1912). (Analysis of depreciation on different elements of physical property; brief.)

ELECTRIC LIGHTING RATES AND DEPRECIATION; by H. H. Crowell. *Municipal Journal and Engineer*, v. 23, p. 698 (Dec. 18, 1907). (Table of estimated life of apparatus, depreciation due to wear, obsolescence and inadequacy.)

ELECTRICAL UNDERTAKINGS AND THE LAW OF RATING. (Serial.) *Electrical Review* (London), v. 66, p. 84 (Jan. 21, 1910). (The first part discusses the rating of electric light and power companies.)

ELECTRIC LIGHT AND POWER—GENERAL—(*Continued*).

ELEMENTS AFFECTING THE FAIR VALUATION OF PLANT AND PROPERTY; by W. F. Wells. National Electric Light Association, Thirty-fourth Convention, 1911, Papers, Reports and Discussions, v. 1, p. 271. (Analysis of valuation classification of electrical properties.)

ESTIMATING THE COST OF AN ELECTRIC PLANT. *Journal*, Franklin Institute, v. 165, p. 397 (May, 1908). (Gives years of life as estimated by different engineers for various parts of the plant.)

MAKING RATES FOR ELECTRIC PLANTS; by Halford Erickson. *Public Service Regulation*, v. 1, p. 579 (Sept., 1912). (Principles of valuation; going value, depreciation, operating expenses, rates, effect of demand on cost, etc.)

THE OBSOLESCENCE OF ELECTRIC LIGHTING PLANT; by F. Fernie. *Electrical Review* (London), v. 63, p. 516 (Sept. 25, 1908). (Discusses rate of depreciation and necessity for an insurance fund.)

RATE-MAKING FOR PUBLIC UTILITIES; by Halford Erickson. *Electric Railway Journal*, v. 33, p. 775 (April 24, 1909). (Relation between investment and output of electrical plants; paper read before the Wisconsin Electric and Interurban Railway Association.)

RATE REGULATION OF ELECTRIC POWER; by S. S. Wyer. *Cassier's Magazine*, v. 35, p. 410 (Jan., 1909). (Considers replacement value and depreciation.)

RATES AND RATE MAKING; by John F. Druar. *Journal*, Association of Engineering Societies, v. 50, p. 221 (May, 1913). (Discusses the valuation of a combined electrical and gas property to determine the legitimate capital, on which capital a certain return should be received.)

STANDARD HANDBOOK FOR ELECTRICAL ENGINEERS, p. 668. Edition 3. McGraw-Hill Book Co., New York, 1910. (Contains brief data on cost and depreciation of electric plants.)

UNIFORM SYSTEM OF ACCOUNTING. (Letter); by F. E. Haskell. *Electrical World*, v. 53, p. 928 (April 15, 1909). (Rule adopted to provide for monthly charge to cover wear and tear, obsolescence and inadequacy, etc.)

UPKEEP CHARGES ON LARGE ELECTRIC GENERATING SETS; by Robert J. Burstall. *Electrical Engineer* (London), v. 39, p. 866 (June 21, 1907). (Paper read before the Engineering Conference, Institution of Civil Engineers; allowance for repairs and renewals.)

——*Engineering*, v. 83, p. 834 (June 21, 1907).

VALUATION OF ELECTRIC PLANTS. (Editorial.) *Engineering Record*, v. 58, p. 365 (Oct. 3, 1908). (One and one-half columns.)

ELECTRIC LIGHT AND POWER—SPECIAL CASES.

Aberdeen, Scotland.

ABERDEEN AND DEPRECIATION. *Municipal Journal* (London), v. 12, p. 943 (Oct. 23, 1903). (Comparison of allowance for depreciation of electrical plants at Aberdeen, Glasgow, and Bolton.)

Beloit, Wis.

***CITY OF BELOIT VS. BELOIT WATER, GAS AND ELECTRIC COMPANY;** Decided July 17, 1911. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 7, p. 216. Madison, Wis., 1912. (Details of the valuation of the power plant and going value.)

FIXING NORMAL OPERATING COSTS; by Frank A. Newton. *Engineering Record*, v. 65, p. 258 (March 9, 1912). (Comments on the decision of the Wisconsin Railroad Commission in the case of the City of Beloit *vs.* Beloit Water, Gas & Electric Co.)

Boonville, N. Y.

AMORTIZATION RULE OF THE NEW YORK PUBLIC SERVICE COMMISSION OF the Second District. *Electrical World*, v. 54, p. 1162 (Nov. 11, 1909). (Computation of amortization of property of the Board of Light Commissioners of Boonville, N. Y.)

Bristol, England.

REPORT BY SIR WILLIAM PREESE ON PROBABLE LIFE OF PLANT AT BRISTOL. *Electrician*, v. 57, p. 704 (Aug. 17, 1906). (Details of estimated life of electrical plants; figures given for various items are those used by L. R. Dicksee in his report.)

——Editorial. Depreciation. *Electrician*, v. 57, p. 702 (Aug. 17, 1906).

Burkhardt Milling & Electric Power Co.

***E. G. ROSS ET AL. VS. BURKHARDT MILLING AND ELECTRIC POWER COM**pany; Decided April 8, 1910. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 5, p. 139. Madison, Wis., 1911. (The value of property and the method of determining values are discussed.)

ELECTRIC LIGHT AND POWER—SPECIAL CASES—(*Continued*).

California.

***UNIFORM CLASSIFICATION OF ACCOUNTS FOR ELECTRIC CORPORATIONS** prescribed by the Railroad Commission of the State of California; Adopted Oct. 23, 1912, Effective Jan. 1, 1913. Sacramento, 1912.

Cardiff, Wales.

DEPRECIATION: INTERESTING REPORT FROM CARDIFF. *Municipal Journal* (London), v. 16, p. 1083 (Dec. 20, 1907). (Allowance for depreciation considered to represent fair wear and tear.)

DEPRECIATION OF CARDIFF ELECTRIC TRAMWAY AND LIGHTING UNDERtakings. *Electric Railway Review*, v. 19, p. 16 (Jan. 4, 1908). (Details of rates of depreciation of equipment are given.)

Cashton, Wis.

***IN RE DETERMINING AND FIXING JUST COMPENSATION TO BE PAID TO THE** Cashton Light and Power Company by the Village of Cashton for the Taking of the Property of the Said Company Actually Used and Useful for the Convenience of the Public in Accordance With the Provisions of Chapter 499, Laws of 1907; Submitted Oct. 14, 1908, Decided Nov. 28, 1908. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 3, p. 67. Madison, Wis., 1910. (Discusses going value of public utility plants.)

Chippewa Falls, Wis.

***T. J. CUNNINGHAM ET AL. VS. CHIPPEWA FALLS WATER WORKS AND** Lighting Company; In Re Investigation by the Railroad Commission of Wisconsin of Rates Charged by the Chippewa Falls Water Works and Lighting Company; In Re Valuation of the Property of the Chippewa Falls Water Works and Lighting Company; Decided June 14, 1910. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 5, p. 302. Madison, Wis., 1911. (Contains data on the value of the electric plant.)

Chippewa Valley Ry., Light & Power Co.

***IN RE APPLICATION OF THE CHIPPEWA VALLEY RAILWAY, LIGHT AND** Power Company for Authority to Change its Rates; Submitted Feb. 19, 1908, Decided Mar. 18, 1908. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 2, p. 311. Madison, Wis., 1909. (Refers to valuation of electric plant.)

Darlington, Wis.

***IN RE APPLICATION OF THE DARLINGTON ELECTRIC LIGHT AND WATER** Power Company for Power to Increase Rates; In Re Darlington Electric Light and Water Power Company, Valuation of Property; Submitted Sept. 2, 1909, Decided June 17, 1910. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 5, p. 397. Madison, Wis., 1911.

District of Columbia.

***UNIFORM SYSTEM OF ACCOUNTS FOR GAS CORPORATIONS AND ELECTRIC** Corporations in the District of Columbia as Prescribed by the Interstate Commerce Commission, pp. 29, 47, 55, 67. Washington, 1909. (Provision for amortization of plant, which includes monthly charges of the amount estimated to be necessary to cover wear, tear and obsolescence.)

Dodgeville, Wis.

***CITY OF DODGEVILLE VS. DODGEVILLE ELECTRIC LIGHT AND POWER COM**pany; Submitted May 4, 1908, Decided June 2, 1908. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 2, p. 392. Madison, Wis., 1909. (Data relating to valuation of plant.)

Edinburgh, Scotland.

DEPRECIATION, ETC., ON ELECTRICITY SUPPLY UNDERTAKINGS. *Electrician*, v. 57, pp. 231, 350 (May 25, June 15, 1906). (Report on present condition of electric light and machinery plant of the Edinburgh Corporation.)

Fareham, England.

DEPRECIATION. (Editorial.) *Electrician*, v. 62, p. 709 (Feb. 19, 1909). (Depreciation in connection with a loan for an electrical plant at Fareham, England.)

Greenwood, Miss.

REPORT OF THE APPRAISERS SELECTED TO ESTIMATE THE VALUE OF property of the Greenwood Light and Water Company to the City of Greenwood and the Greenwood Light and Water Co., March 22, 1904. Greenwood, Miss., 1904. (Eight pages.)

Groton, Mass.

A VALUABLE MUNICIPAL RATE DECISION. (Editorial.) *Engineering Record*, v. 66, p. 2 (July 6, 1912). (Comments on decision by the Massachusetts Gas and Electric Light Commission on electrical rates at Groton, Mass; very brief.)

ELECTRIC LIGHT AND POWER—SPECIAL CASES—(*Continued*).

Kaukauma, Wis.

*IN RE DETERMINING AND FIXING THE JUST COMPENSATION TO BE PAID to the Kaukauma Gas, Electric Light and Power Company by the City of Kaukauma; Submitted Feb. 6, 1911; Decided Dec. 26, 1911. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 8, p. 409. Madison, Wis., 1912. (Physical value and going value of the property and value of the water-power lease.)

La Crosse, Wis.

*IN RE APPLICATION OF THE LA CROSSE GAS AND ELECTRIC COMPANY FOR Authority to Increase Its Rates; Decided Nov. 17, 1911. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 8, pp. 138, 156, 170, 179, 202, 224. Madison, Wis., 1912. (Physical value of plants, original cost and effect of allowance of going value.)

*IN RE APPLICATION OF THE LA CROSSE GAS AND ELECTRIC COMPANY FOR Authority to Increase Rates; Submitted Aug. 16, 1907, Decided Sept. 19, 1907. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 2, p. 3. Madison, Wis., 1909. (Gives method of estimating cost of plant before physical examination can be made.)

*THE MEANING OF "ACTUAL STATION OPERATING COSTS." *Engineering Record*, v. 65, p. 191 (Feb. 17, 1912). (Decision of the Railroad Commission of Wisconsin in the case of the La Crosse Gas & Electric Co.)

Madison, Wis.

RATE MAKING FOR PUBLIC UTILITIES, THE MADISON CASE; by Percy H. Thomas. *Electric Journal*, v. 7, p. 560 (July, 1910). (Discusses the decision of the Railroad Commission of Wisconsin in the case of the State Journal Printing Co. *vs.* the Madison Gas & Electric Co., rendered March 8, 1910.)

Manitowoc, Wis.

*CITY OF MANITOWOC VS. MANITOWOC ELECTRIC LIGHT COMPANY; Submitted Sept. 30, 1908, Decided June 14, 1910. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 5, p. 361. Madison, Wis., 1911. (A tentative valuation of the physical property of the respondent was made; the income accounts and operating expenses for a term of years are analyzed.)

Marinette, Wis. See Menominee, Wis.

Marquette, Mich.

A STUDY IN CENTRAL-STATION FINANCES AND OPERATION FROM MARQUETTE, Mich. *Electrical World*, v. 53, p. 403 (Feb. 11, 1909). (Gives estimates of depreciation for an electric light and power plant.)

Massachusetts.

DISTRIBUTION COSTS IN SEVEN CENTRAL-STATION SYSTEMS. *Electrical World*, v. 52, p. 1014 (Nov. 7, 1908). (Figures deduced from returns to the Massachusetts Board of Gas and Electric Light Commissioners.)

Menominee, Wis.

*IN RE VALUATION OF ELECTRIC LIGHT PLANT OF MENOMINEE AND MARInette Light and Traction Company; In Re Application of Menominee and Marinette Light and Traction Company for Authority to Equalize Rates; In Re Menominee and Marinette Light and Traction Company, Investigation of Rates on Motion of the Commission; Decided Aug. 3, 1909. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 3, p. 778. Madison, Wis., 1910. (Data on valuation of electric light and power plant.)

Merrill Ry. & Lighting Co.

*IN RE APPLICATION OF THE MERRILL RAILWAY AND LIGHTING COMPANY for Authority to Change Its Rates for Electric Lighting; Submitted Sept. 17, 1907, Decided Dec. 10, 1907. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 2, p. 148. Madison, Wis., 1909. (Discusses value of the plant, including water power and dam, electric light plant, and railway plant.)

Minneapolis, Minn.

ELECTRIC RATES FOR MINNEAPOLIS, A LONG CONTROVERSY OVER BASING Rates on Expert Analysis or Unreasonable Comparisons; by William G. Deacon. *Public Service*, v. 5, p. 107 (Oct., 1908). (Contains very brief data on valuation.)

MINNEAPOLIS LIGHT AND POWER RATES. *Electrical World*, v. 51, p. 651 (March 28, 1908). (Brief data on the elements of cost of plant.)

ELECTRIC LIGHT AND POWER—SPECIAL CASES—(*Continued*).

New York City.

ACCOUNTING FOR DEPRECIATION; by H. M. Edwards. *Electric Railway Journal*, v. 37, p. 972 (June 3, 1911). (Method used by the New York Edison Co.)

REGULATED ELECTRIC LIGHT ACCOUNTING; by H. M. Edwards. National Electric Light Association, Thirty-fifth Convention, 1912, Papers, Reports and Discussions, v. 4, p. 106. (On the uniform system of accounts for electrical corporations as prescribed by the Public Service Commission, State of New York, First District, and the petition to modify it.)

——Abstract. *Electric Railway Journal*, v. 39, p. 1029 (June 15, 1912).

New York State.

NEW YORK PUBLIC SERVICE COMMISSION TENTATIVE ACCOUNTS FOR ELECtrical and Gas Corporations. *Electric Railway Review*, v. 19, p. 532 (May 2, 1908). (Classification for accounts prepared by W. J. Meyers; abstract of some features of the system.)

PETITION FOR CHANGES IN TREATMENT OF DEPRECIATION IN NEW YORK. *Electrical World*, v. 58, p. 1420 (Dec. 9, 1911). (Petition filed by various lighting companies with New York Public Service Commission, Second District; one page.)

STANDARD ACCOUNTING CONFERENCE. *Progressive Age*, v. 26, p. 267 (May 1, 1908). (On report of classification of accounts, gas and electric companies, by the Public Service Commission, State of New York, Second District.)

*STATE OF NEW YORK, SECOND ANNUAL REPORT OF THE PUBLIC SERVICE Commission, Second District, for the Year Ending Dec. 31, 1908; v. 2, Uniform System of Accounts. Albany, 1909. (Classification of accounts for street railroads, gas and electrical corporations; general amortization account, including amount estimated for wear, tear and obsolescence of plant.)

Pacific Gas & Electric Co.

PACIFIC GAS RATE VALUATION; by John A. Britton. *Progressive Age*, v. 30, p. 330 (April 15, 1912). (Includes cost of electric energy, depreciation and administration.)

Pasadena, Cal.

PASADENA MUNICIPAL LIGHTING PLANT. *Municipal Engineering*, v. 44, p. 505 (June, 1913). (Capitalization, depreciation allowance, etc., in relation to rate regulation.)

Red Cedar Valley, Wis.

*IN RE APPLICATION OF THE RED CEDAR VALLEY ELECTRIC COMPANY FOR Authority to Increase its Rates; Decided June 14, 1911. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 6, p. 717. Madison, Wis., 1912. (Contains Company's statement of the value of the physical property of the plant.)

Ripon, Wis.

*CITY OF RIPON VS. RIPON LIGHT AND WATER COMPANY; Decided March 28, 1910. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 5, p. 1. Madison, Wis., 1911. (Data on vaulation of the water, light and electric plants.)

St. Louis, Mo.

REPORT OF ST. LOUIS PUBLIC SERVICE COMMISSION TO THE MUNICIPAL Assembly of St. Louis on Rates for Electric Light and Power. St. Louis, 1911. (Contains description of methods of appraisal of the property of the Union Electric Light & Power Co.)

San Francisco, Cal.

UNIT GENERATING AND DISTRIBUTION COSTS OF THE PACIFIC GAS & ELECtric Company in San Francisco. *Electrical World*, v. 59, p. 790 (April 13, 1912).

Sheboygan, Wis.

*CITY OF SHEBOYGAN VS. SHEBOYGAN RAILWAY AND ELECTRIC COMPANY; Submitted Oct. 18, 1910, Decided Feb. 3, 1911. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 6, p. 353. Madison, Wis., 1912. (Company's estimate of investment and annual expenses chargeable to street lighting.)

Superior Water, Light & Power Co.

*ESTIMATING THE RATE OF "REASONABLE RETURN" FOR A PUBLIC UTILITY. *Engineering and Contracting*, v. 39, p. 482 (April 30, 1913). (Argument submitted to the Wisconsin Railroad Commission, for the Superior Water, Light & Power Co., giving analysis of the rate of fair return for capital invested.)

ELECTRIC LIGHT AND POWER—SPECIAL CASES—(*Continued*).

***PUBLIC SERVICE COMMISSION NEWS.** *Electrical World*, v. 60, p. 1136 (Nov. 30, 1912). (Basis of valuation of electric plant in investigation of the revenues of the Superior Water, Light & Power Co.)

Wakefield, Mass.

DEPRECIATION OF MUNICIPAL LIGHTING PLANTS. (Editorial.) *Electrical Review and Western Electrician*, v. 53, p. 493 (Oct 3, 1908). (Inadequacy of allowance for depreciation in plant at Wakefield, Mass.)

Waupaca, Wis.

***IN RE JOINT APPLICATION OF THE WAUPACA ELECTRIC LIGHT AND RAILway Company and the City of Waupaca to the Effect that the Railroad Commission Act as Arbitrator in Certain Matters Pertaining to Street Lighting in the City of Waupaca; Submitted Dec. 15, 1910, Decided Feb. 21, 1912. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 8, p. 586. Madison, Wis., 1912.** (Total reproduction cost, present value and cost of operation were ascertained and apportioned between street lighting and all other service.)

West Ham, England.

IS DEPRECIATION AS SUCH, NEEDED? (Editorial.) *Municipal Journal* (London), v. 12, p. 699 (July 31, 1903). (Relates to West Ham Corporation electric lighting plant.)

Wisconsin.

***ADJUSTMENT OF ELECTRIC LIGHTING RATE.** *Power*, v. 35, p. 498 (April 9, 1912). (Extracts from the reports of the Wisconsin Railway Commission regarding the influence of various fixed charges upon the rates.)

METHODS OF OBTAINING COST OF ELECTRIC LIGHTING SERVICE TO CONsumers Based on Decisions of the Wisconsin Railroad Commission. *Engineering and Contracting*, v. 37, p. 48 (Jan. 10, 1912). (Four pages.)

***UNIFORM CLASSIFICATION OF ACCOUNTS FOR ELECTRIC UTILITIES PREscribed by the Railroad Commission of Wisconsin, Dec., 1908. Edition 3. Madison, Wis., 1912.** (Treats of tangible and intangible property, reserve accounts, etc.)

WISCONSIN CLASSIFICATION OF ELECTRIC ACCOUNTS. *Electrical World*, v. 53, p. 503 (Feb. 25, 1909). (Classification prepared by the Wisconsin Railroad Commission.)

Worcester, Mass.

THE APPRAISAL OF STREET LIGHTING SERVICE. *Engineering Record*, v. 66, p. 104 (July 27, 1912). (Decision by the Massachusetts Gas and Electric Light Commission in the Worcester street lighting case.)

York, England.

DEPRECIATION IN ELECTRIC LIGHTING. (Editorial.) *Municipal Journal* (London), v. 12, p. 12 (Jan. 2, 1903). (Policy of York Corporation; very brief.)

GAS-WORKS—GENERAL.

DEPRECIATION; by John A. Britton. *Progressive Age*, v. 26, p. 379 (June 15, 1908). (Depreciation as an item to be considered in fixing gas rates.)

DEPRECIATION ALLOWANCE FOR INCOME-TAX. (Editorial.) *Journal of Gas Lighting*, v. 108, p. 517 (Nov. 23, 1909). (Protest against action of Inland Revenue authorities on depreciation in gas plants.)

DEPRECIATION: AN ITEM IN THE MANUFACTURE AND SALE OF GAS; by Royal Schacklette. *American Gas Light Journal*, v. 93, p. 106 (July 8, 1910). (Considers depreciation in the various parts of the plant.)

DEPRECIATION AND INCOME-TAX. *Journal of Gas Lighting*, v. 118, p. 886 (June 18, 1912). (Refers to depreciation in gas plants.)

DEPRECIATION AND INCOME-TAX, THE CASE OF MUNICIPAL UNDERTAKINGS. *Journal of Gas Lighting*, v. 121, p. 48 (Jan. 7, 1913). (Methods of allowing for depreciation in gas, water and electric lighting undertakings.)

DEPRECIATION AND KINDRED MATTERS; by Charles H. Armstrong. *Journal of Gas Lighting*, v. 102, p. 223 (April 28, 1908). (A paper read at a meeting of the North of England Gas Managers' Association.)

DEPRECIATION IN GAS PLANTS; by John I. Beggs. *American Gas Light Journal*, v. 89, p. 5 (July 6, 1908). (Address before the Wisconsin Gas Association.)

——Maintenance of Plant; by John I. Beggs. *Progressive Age*, v. 26, p. 427 (July 15, 1908).

GAS-WORKS—GENERAL—(*Continued*).

DEPRECIATION IN GAS PLANTS; by R. W. Prosser. *American Gas Light Journal*, v. 76, p. 767 (May 26, 1902). (Gives tables of life of apparatus of a gas works and annual charge for depreciation; one and one-half pages.)

DEPRECIATION IN GAS WORKS. *Progressive Age*, v. 30, p. 870 (Oct. 15, 1912).

INAUGURAL ADDRESS OF THE PRESIDENT; by Alexander Wilson. *Transactions*, Institution of Gas Engineers, 1911, p. 51. (Takes up the question of depreciation; four pages.)

——Abstract. *Journal of Gas Lighting*, v. 114, p. 728 (June 13, 1911).

THE PRESENT AND GROWING NEED FOR THE GENERAL ADOPTION OF A Uniform System of Records and Accounts; by A. C. Humphreys. *Proceedings*, New England Association of Gas Engineers, 1907, p. 146.

RATES AND RATE MAKING; by John F. Druar. *Journal*, Association of Engineering Societies, v. 50, p. 221 (May, 1913). (Discusses the valuation of a combined electrical and gas property for determining the legitimate capital, upon which capital a certain return should be received.)

REASONABLE GAS RATES AND THEIR DETERMINATION; by C. L. Cory. *Progressive Age*, v. 30, p. 964 (Nov. 15, 1912). (Discusses rates of return and value of gas plant.)

REVIEW OF RECENT DECISIONS OF PUBLIC SERVICE COMMISSIONS WHICH Affect Gas Companies; by A. E. Forstall. *Proceedings*, American Gas Institute, v. 5, p. 460 (1910). (Discusses methods of valuation considering physical value, cost of reproduction, depreciation, etc.)

——*American Gas Light Journal*, v. 94, p. 148 (Jan. 3, 1911).

GAS-WORKS—SPECIAL CASES.

Baltimore, Md.

STOCK AND FAIR VALUE. *Public Service Regulation*, v. 1, p. 550 (Aug., 1912). (Baltimore gas and electric rate hearing, before the Maryland Commission.)

Beloit, Wis.

BELOIT UTILITY DECISION BY RAILROAD COMMISSION OF WISCONSIN. *American Gas Light Journal*, v. 95, p. 162 (Sept. 11, 1911). (Gives estimate in valuation of the property of the Beloit Water, Gas & Electric Co.)

***CITY OF BELOIT VS. BELOIT WATER, GAS AND ELECTRIC COMPANY;** Decided July 19, 1911. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 7, p. 220. Madison, Wis., 1912. (Value of gas plant is given.)

FIXING NORMAL OPERATING COSTS; by Frank A. Newton. *Engineering Record*, v. 65, p. 258 (March 9, 1912). (Comments on the decision in the case of the City of Beloit *vs.* the Beloit Water, Gas & Electric Co.)

Brooklyn, N. Y.

PAVING OVER GAS MAINS AND CAPITALIZATION OF PROFITABLE CONTRACTS as Elements in Rate Making: Decision of the New York Public Service Commission in the Kings County Lighting Case. *Engineering News*, v. 66, p. 604 (Nov. 16, 1911). (Discusses paving over mains and capitalization of contracts as factors in the valuation of the property, citing Supreme Court decisions.)

***RE MAYHEW V. KINGS CO. LIGHTING CO. (CASE 1273).** Reports of Decisions of the Public Service Commission for the First District of the State of New York, v. 2, p. 659. New York, 1912. (Details of valuation of property of the Kings County Lighting Co. and methods of estimating it.)

California.

PACIFIC GAS RATE VALUATION; by John A. Britton. *Progressive Age*, v. 30, p. 330 (April 15, 1912). (Cost of gas in holder, 1911, cost of gas distribution, cost of administration and depreciation, and cost of electric energy, depreciation and administration, Pacific Gas & Electric Co.)

***UNIFORM CLASSIFICATION OF ACCOUNTS FOR GAS CORPORATIONS PRE**scribed by the Railroad Commission of the State of California; Adopted Oct. 23, 1912, Effective, Jan. 1, 1913. Sacramento, 1912. (Classification of intangible and tangible capital, including franchise, patent rights, physical property, etc.)

Cedar Rapids, Iowa.

FAIR RATES FOR PUBLIC SERVICE. (Letter.) *Engineering Record*, v. 59, p. 699 (May 29, 1909). (Decision of Iowa Supreme Court on valuation of the Cedar Rapids Gas Light Co.)

GAS-WORKS—SPECIAL CASES—(*Continued*).

Chicago, Ill.

APPRAISAL OF GAS PROPERTIES IN CHICAGO, AND INVESTIGATION AS TO Reasonable Rates for Gas: Valuation of Physical Property; by William J. Hagenah. *Engineering and Contracting*, v. 35, p. 572 (May 17, 1911). (Twelve pages.)

——Editorial. The Chicago Gas Appraisal. *Engineering and Contracting*, v. 35, p. 557 (May 17, 1911). (One column.)

INVESTIGATION OF THE PEOPLES GAS LIGHT AND COKE COMPANY FOR THE Council Committee on Gas, Oil and Electric Light, Chicago; by William J. Hagenah. Journal of the Proceedings of the Council of Chicago, July 10, 1911, p. 840. (Gives full report on the valuation of the Company; 89 pages.)

PRICE OF GAS IN CHICAGO. Journal of the Proceedings of the City Council of Chicago, July 10, 1911, p. 820. (Report of Edward W. Bemis commenting on report by W. J. Hagenah.)

——Editorial. Gas Rates in Chicago. *Municipal Engineering*, v. 41, p. 206 (Sept., 1911).

Chippewa Falls, Wis.

*T. J. CUNNINGHAM ET AL. VS. CHIPPEWA FALLS WATER WORKS AND LIGHTing Company: In Re Investigation by the Railroad Commission of Wisconsin of Rates Charged by the Chippewa Falls Water Works and Lighting Company; In Re Valuation of the Property of the Chippewa Falls Water Works and Lighting Company; Decided June 14, 1910. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 5, p. 302. Madison, Wis., 1911. (Contains data on the value of the Gas Department.)

District of Columbia.

*UNIFORM SYSTEM OF ACCOUNTS FOR GAS CORPORATIONS AND ELECTRIC Corporations in the District of Columbia as Prescribed by the Interstate Commerce Commission, pp. 29, 47, 55, 67. Washington, 1909. (Provision for amortization of plant, which includes monthly charges of the amount estimated to be necessary to cover wear, tear and obsolescence.)

Galesburg, Ill.

THE GAS FIGHT AT GALESBURG. *Public Service*, v. 4, p. 67 (March, 1908). (Report by Bylesby & Co. on the valuation of the gas plant at Galesburg, Ill.)

La Crosse, Wis.

DEPRECIATION AS A FACTOR IN RATES. (Editorial.) *Electric Railway Review*, v. 18, p. 752 (Nov. 9, 1907). (Petition of La Crosse Gas & Electric Co.)

*IN RE APPLICATION OF THE LA CROSSE GAS AND ELECTRIC COMPANY FOR Authority to Increase Its Rates; Decided Nov. 17, 1911. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 8, pp. 138, 156, 170, 179, 195, 224. Madison, Wis., 1912. (Physical value of plant, original cost and effect of allowance for going value.)

*THE MEANING OF "ACTUAL STATION OPERATING COSTS." *Engineering Record*, v. 65, p. 191 (Feb. 17, 1912). (Decision of the Railroad Commission of Wisconsin in the case of the La Crosse Gas & Electric Co.)

Madison, Wis.

THE APPRAISAL OF THE MADISON GAS AND ELECTRIC CO. *Engineering and Contracting*, v. 35, p. 747 (June 28, 1911). (Appraisal made by the Wisconsin State Railroad Commission; three pages.)

GOING VALUE OF PUBLIC SERVICE CORPORATIONS, AS DETERMINED BY THE Wisconsin Railroad Commission in the Madison Gas and Electric Case. *Engineering and Contracting*, v. 35, p. 691 (June 14, 1911). (On the decision rendered in the case of the State Journal Printing Co. *et al. vs.* the Madison Gas & Electric Co.; four pages.)

*IMPORTANT DECISION BY WISCONSIN COMMISSION ON CENTRAL-STATION Valuation and Rate-Making. *Electrical World*, v. 55, p. 675 (March 17, 1910). (Decision by the Wisconsin Railroad Commission on "going value", rate of return, etc., in the case of State Journal Printing Co. *et al. vs.* Madison Gas & Electric Co.)

*IN RE INVESTIGATION, ON MOTION OF THE COMMISSION, OF THE RATES, Rules and Regulations of the Madison Gas and Electric Company; Decided July 5, 1911. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 7, p. 152. Madison, Wis., 1912. (Gives cost of reproduction new and existing value of the Madison gas and electric lighting plant.)

REASONABLE RATES FOR GAS AND ELECTRICITY AS DETERMINED BY THE Wisconsin Railroad Commission for the City of Madison. *Engineering News*, v. 63, p. 380 (March 31, 1910). (State Journal Printing Co. *vs.* Madison Gas & Electric Co.; gives the method of valuation and related investigations.)

GAS-WORKS—SPECIAL CASES—(*Continued*).

***STATE JOURNAL PRINTING COMPANY ET AL. VS. MADISON GAS AND ELEC**tric Company; Decided March 8, 1910. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 4, p. 501. Madison, Wis., 1910. (Method of arriving at valuation of gas and electric plants; also method of valuing real estate.)

Manitowoc, Wis.

***IN RE APPLICATION OF THE MANITOWOC GAS COMPANY FOR AUTHORITY** to Equalize Rates; Submitted Sept. 28, 1908, Decided Dec. 17, 1908. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 3, p. 163. Madison, Wis., 1910. (Data on the physical valuation of the property.)

***PHILOSOPHY OF GAS RATES, DECISION OF WISCONSIN RAILROAD COMMIS**sion Authorizing Manitowoc Gas Company to Increase Its Rates. *Public Service*, v. 6, p. 58 (Feb., 1909). (Contains brief reference to depreciation.)

Neenah, Wis.

***CITY OF NEENAH VS. THE WISCONSIN TRACTION, LIGHT, HEAT AND POWER** Company; Decided Aug. 4, 1911. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 7, p. 479. Madison, Wis., 1912. (Contains a tentative valuation of the physical property of the Gas Department of the Wisconsin Traction, Light, Heat & Power Co.)

New Jersey.

***GAS RATE DECISIONS IN NEW JERSEY.** *Electric Railway Journal*, v. 41, p. 35 (Jan. 4, 1913). (Decision of New Jersey Public Utilities Commission; relates to valuation of property of the Public Service Gas Co. in the Passaic District.)

***GOING CONCERN VALUE.** (Editorial Note.) *American Gas Light Journal*, v. 98, p. 208 (March 31, 1913). (Brief extract from decision by the Board of Public Utility Commissioners of New Jersey.)

New York City.

***DECISION OF THE SUPREME COURT OF THE UNITED STATES, THE PUBLIC** Service Commission *vs.* the Consolidated Gas Company of New York. National Electric Light Association, Thirty-second Convention, 1909, Papers, Reports and Discussions, v. 3, pp. 319, 324. (Considers valuation of franchises and value of the Company's property.)

THE EIGHTY-CENT GAS DECISION OF THE SUPREME COURT. (Editorial.) *Engineering Record*, v. 59, p. 31 (Jan. 9, 1909).

FULL TEXT OF THE OPINION OF THE SUPREME COURT OF THE UNITED STATES in the Matter of the New York Legislature's Order Fixing the Gas Rates in New York City at 80 Cents per 1 000 Cubic Feet. *American Gas Light Journal*, v. 90, p. 99 (Jan. 18, 1909). (Considers value of property and franchise; three pages.)

New York State.

***NEW YORK PUBLIC SERVICE COMMISSION TENTATIVE ACCOUNTS FOR ELEC**trical and Gas Corporations. *Electric Railway Review*, v. 19, p. 532 (May 2, 1908). (Classification prepared by W. J. Meyers; abstract of some features of the system.)

***STANDARD ACCOUNTING CONFERENCE.** *Progressive Age*, v. 26, p. 267 (May 1, 1908). (On report of classification of accounts, gas and electric companies, by Public Service Commission, State of New York, Second District.)

***STATE OF NEW YORK, SECOND ANNUAL REPORT OF THE PUBLIC SERVICE** Commission, Second District, for the Year Ending Dec. 31, 1908; v. 2, Uniform System of Accounts. Albany, 1909. (Classification of accounts for street railroads, gas and electrical corporations; general amortization account, including amount estimated for wear, tear and obsolescence of plant.)

Passaic, N. J.

PUBLIC SERVICE GAS COMPANY RATE CASE; by Frank Bergen. *Aera*, v. 1, p. 465 (Jan., 1913). (Valuation of the property of the Passaic Division of the Public Service Gas Co., and discussion of methods.)

Peoria, Ill.

IN THE CIRCUIT COURT OF THE UNITED STATES, NORTHERN DISTRICT OF Illinois, Southern Division, Peoria Gas and Electric Company, Complainant, *vs.* City of Peoria, Defendant, in Chancery for Injunction, Etc.: Special Master's Report. Barnard & Miller, Chicago, 1903. (Contains data on methods of valuation of gas plants.)

Queens Borough Gas & Electric Co.

***RATES OF THE QUEENS BOROUGH GAS AND ELECTRIC CO.: THE FIRST COM**modity-Rate Case of the Public Service Commission for the First District of New York. *Engineering News*, v. 66, p. 266 (Aug. 31, 1911). (Method of appraisal of property; land appraisal, development costs, working capital, going value, unimpaired investment and annual depreciation.)

GAS-WORKS—SPECIAL CASES—(*Continued*).

***RE RATES OF QUEENS BOROUGH GAS AND ELECTRIC COMPANY (CASES 1224 and 1225).** Reports of Decisions of the Public Service Commission of the First District of the State of New York, v. 2, p. 544. New York, 1912. (Methods of determining value of gas property.)

Racine, Wis.

***CITY OF RACINE VS. RACINE GAS LIGHT COMPANY;** Decided Jan. 27, 1911. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 6, p. 229. Madison, Wis., 1912. (A tentative valuation of the physical property of the Racine Gas Light Co., including land, breakwater, mains and paving, and the going value of the plant.)

DECISION OF THE RAILROAD COMMISSION OF WISCONSIN IN THE RACINE Case. *American Gas Light Journal*, v. 94, p. 547 (March 20, 1911). (Gives valuation of the Racine Gas Light Co.'s plant.)

Saginaw, Mich.

SAGINAW GAS DECISION. *Progressive Age*, v. 26, p. 722 (Dec. 15, 1908). (Contains data on the valuation of the gas plant.)

St. Paul, Minn.

THE FAIR PRICE OF GAS AT ST. PAUL; by R. S. Feurtado. *Public Service*, v. 3, p. 173 (Dec., 1907). (Valuation of the plant of the St. Paul Gas Light Co.)

San Francisco, Cal.

THE COST OF GAS IN SAN FRANCISCO, REPORT TO THE BOARD OF SUPERvisors, May 18, 1908; by C. D. Stuart. *Public Service*, v. 5, p. 20 (July, 1908). (On the valuation of the gas plant.)

Sheboygan, Wis.

THE SHEBOYGAN, WIS., GAS CASE. *Public Service Regulation*, v. 1, p. 695 (Oct., 1912). (Opinion in case of Sheboygan Gas Light Co., *re* valuation of the property.)

Superior, Wis.

***ESTIMATING THE RATE OF "REASONABLE RETURN" FOR A PUBLIC UTILITY.** *Engineering and Contracting*, v. 39, p. 482 (April 30, 1913). (Analysis of the rate of return; argument submitted to the Wisconsin Railroad Commission by the Superior Water, Light & Power Co.)

***WISCONSIN RATES.** *Progressive Age*, v. 30, p. 1075 (Dec. 16, 1912). (Decision of the Railroad Commission of Wisconsin in the application of the Superior Commercial Club *et al. vs.* the Superior Water, Light & Power Co.)

GAS-WORKS—UNVERIFIED REFERENCES.

DEPRECIATION USED FOR UNIFORM ACCOUNTS. *Public Service*, v. 2, p. 147 (May, 1907). (On depreciation in gas plants.)

DES MOINES GAS CO. VS. CITY OF DES MOINES ET AL.; In the District Court of the United States in and for the Southern District of Iowa, Central Division: Complainant's Brief on Exception to Master's Report.

PRIVILEGE BECOMES PROPERTY UNDER THE FOURTEENTH AMENDMENT: The Consolidated Gas Decision; by Jesse F. Orton. *Independent*, p. 719 (Oct. 12, 1911).

MINING.

AMERICAN IRON-ORE RESERVES; by Edwin C. Eckel. *Engineering Magazine*, v. 44, p. 7 (Oct., 1912). (Bases for valuation of iron-ore properties.)

***APPRAISAL OF MINING PROPERTIES OF MICHIGAN BY THE STATE BOARD** of Tax Commissioners. Lansing, Mich., 1911, James H. Thompson, Chairman, State Board of Tax Commissioners. (Gives inventory and appraisal of all the mining properties of the State; eighty-two pages.)

DEPRECIATION AS AFFECTING COLLIERIES AND IRON WORKS; by H. A. Foster. *Iron and Coal Trades Review*, v. 65, p. 1303 (Nov. 21, 1902). (Some of the methods of treating the subject of depreciation.)

STOCK VALUE AND MINE VALUE; by Alfred C. Lane. *Canadian Mining Journal*, v. 32, pp. 691, 729, 775 (Nov. 1, 15, Dec. 1, 1911). (Elements to be considered in the valuation of mines; return, stability, marketability, activity and control.)

THE VALUATION OF MINES; by T. A. Rickard. *Mining and Scientific Press*, v. 106, p. 766 (May 24, 1913).

RAILROADS—GENERAL.

ACCOUNTING DEPRECIATION. *Railroad Age Gazette*, v. 45, p. 415 (July 3, 1908). (On the relation of valuation to depreciation; one column.)

AMERICAN TRANSPORTATION QUESTION, p. 81; by Samuel O. Dunn. D. Appleton & Co., New York, 1912. (On the theory of railroad valuation; forty-two pages.)

AN AMERICAN TRANSPORTATION SYSTEM, p. 316; by George A. Rankin. G. P. Putnam's Sons, New York, 1909. (Contains a discussion of the appraisement of railroads; seventeen pages.)

APPORTIONMENT BETWEEN STATE AND INTERSTATE TRAFFIC OF RAILway Property Devoted to the Public Service; by Thomas D. O'Brien. *Proceedings*, Annual Convention of the National Association of Railway Commissioners, 1909, p. 306. (Method of valuation by reproduction cost; three pages.)

APPRAISED VALUE OF THE RAILWAYS IN FIVE STATES AND THE PROBABLE Cost of Reproducing All Railways in America. *Engineering-Contracting*, v. 34, p. 89 (Aug. 3, 1910). (Results and comparisons of State valuations.)

THE ARBITRARY DEPRECIATION CHARGE; by F. A. Delano. *Railroad Gazette*, v. 44, p. 681 (May 15, 1908). (A paragraph from the *Wall Street Journal*.)

ASSIGNMENT OF STEAM AND ELECTRIC LOCOMOTIVES, PASSENGER AND Freight Train Cars and Work Equipment Cost to the Several States and to Operating Divisions Within States. *Engineering and Contracting*, v. 39, p. 724 (June 25, 1913). (Abstract of paper by A. I. T. Thompson read before the Mississippi Valley States Conference.)

THE ASSIGNMENT OF VALUATION OF FACILITIES TO MORE THAN ONE STATE. *Engineering and Contracting*, v. 39, p. 726 (June 25, 1913). (A plan for apportioning value of general railroad shops between States; abstract of paper by Hugh H. Bryant read before the Mississippi Valley States Conference.)

BASIS OF VALUATION AS BETWEEN INTRASTATE AND INTERSTATE BUSINESS. *Railway Age Gazette*, v. 46, p. 319 (Feb. 12, 1909). (One paragraph.)

COMMERCIAL VALUATION OF RAILWAY OPERATING PROPERTY IN THE United States, 1904; by Henry C. Adams. U. S. Bureau of the Census, Bulletin No. 21, Washington, 1905. (Reports by Prof. Henry C. Adams, Prof. B. H. Meyer, William J. Meyers and others; eighty-eight pages.)

——Abstract. Railroads Valuations in State Reports. *Railroad Gazette*, v. 39, p. 226 (Sept. 8, 1905).

——Editorial. The Census Office Railroad Valuation. *Railroad Gazette*, v. 39, p. 194 (Sept. 1, 1905).

——Criticism on Bulletin No. 21 Issued by the Census Bureau, Assuming to Give the Commercial Value of Railroads; by E. Frederick Browne. Omaha, 1905.

A COMPARATIVE STATEMENT OF PHYSICAL VALUATION AND CAPITALIZA-tion; by the Bureau of Railway Economics. Washington, 1911. (Compares valuations made by States of Washington, South Dakota, Michigan and Minnesota.)

CONCERNING RAILWAY VALUATION. (Letter); by E. Gray, Jr. *Railway and Engineering Review*, v. 53, p. 105 (Feb. 1, 1913). (Criticism of paper by D. F. Jurgensen on Reproduction Costs.)

COST, CAPITALIZATION AND ESTIMATED VALUE OF AMERICAN RAILWAYS: An Analysis of Current Fallacies; by Slason Thompson. Edition 3. Bureau of Railway News, Chicago, 1908. (Aims to show that the value of railway properties in the United States exceeds their total net capitalization.)

——Editorial. Cost, Capitalization and Values of American Railways. *Railway Age*, v. 44, p. 710 (Nov. 22, 1907).

THE CROSBY BILL ON RATE REGULATION. *Electric Railway Journal*, v. 40, p. 94 (July 20, 1912). (The author suggests a method of valuation of the properties of public service carriers, and outlines a suggested scale for a rate of return for new and old capital.)

DEDUCTIONS FOR OBSOLESCENSE JUSTIFIED. *Railway Age Gazette*, v. 49, p. 1093 (Dec. 2, 1910). (Decision of the Supreme Court of New York regarding the value of franchises and allowance for depreciation in taxation.)

DEPRECIATION; by S. M. Hudson. *Railway Age*, v. 44, p. 175 (Aug. 9, 1907). (General discussion of depreciation; one and one-half pages.)

DEPRECIATION IN RAILWAY ACCOUNTING. *Railway Age*, v. 43, p. 728 (May 10, 1907). (Recommendations of Interstate Commerce Commission; one page.)

DEPRECIATION IN RAILWAY ACCOUNTING. *Railway Age*, v. 45, p. 623 (May 1, 1908). (On equipment depreciation accounts; two pages.)

DEPRECIATION IN STEAM RAILWAY ACCOUNTING. *Electric Railway Journal*, v. 32, p. 748 (Oct. 3, 1908). (Memorandum compiled by Special Committee on Relations with Interstate Commerce Commission of the American Railway Association; one page.)

RAILROADS—GENERAL—(*Continued*).

DETERMINING A REASONABLE RATE. (Editorial.) *Railway World*, v. 56, p. 344 (April 19, 1912). (Comments on opinion of Judge Thomas G. Jones, of Alabama, on the cost of reproduction of a railroad, the basis for reasonable rates.)

DEVELOPMENT OF THE FREIGHT RATE HEARING REGARDING THE PHYSICAL Valuation of Railways. (Editorial.) *Engineering-Contracting*, v. 34, p. 263 (Sept. 28, 1910). (One and one-half columns.)

DISCUSSION OF REPORT OF COMMITTEE ON RATES AND RATE MAKING; by M. R. Maltbie. *Proceedings*, Annual Convention of the National Association of Railway Commissioners, 1910, pp. 200, 204. (On "market value," depreciation, and methods of making valuation; five pages.)

THE ECONOMICS OF RAILROAD CONSTRUCTION, p. 41; by Walter Loring Webb. John Wiley & Sons, New York, 1906. (Contains a chapter on the valuation of railway property.)

EQUIPMENT ACCOUNT FOR EACH CAR AND LOCOMOTIVE. *Railway Age Gazette*, v. 43, p. 640 (Nov. 29, 1907). (Method of keeping a depreciation account.)

ESTIMATING THE VALUE OF RAILROAD PROPERTY. *Railroad Gazette*, v. 37, p. 289 (Sept. 2, 1904). (On general principles of valuation; two columns.)

FAIR RETURN ON THE VALUE OF PROPERTY: A FALLACIOUS STANDARD. *Railway Age Gazette*, v. 48, p. 1129 (May 6, 1910). (From an address by Walker D. Hines before the Traffic Club of Pittsburgh.)

FEDERAL REGULATION OF RAILROAD SECURITIES AND VALUATION OF RAIL-road Properties; by Henry Fink. *Railway World*, v. 55, p. 390 (May 19, 1911). (Further extracts from statement to the Railway Securities Commission.)

GOVERNMENT SUPERVISION OF RAILWAY ACCOUNTS; by Henry C. Adams. *Electric Railway Review*, v. 19, p. 43 (Jan. 11, 1908). (Abstract of paper read before the Association of American Government Accountants.)

HEARINGS OF THE RAILROAD SECURITIES COMMISSION. (Editorial.) *Railway and Engineering Review*, v. 50, p. 1175 (Dec. 24, 1910). (Refers to question whether valuation of railroad should be used as a basis for issuing new securities.)

HENRY C. ADAMS ON RAILWAY VALUATION. *Railway World*, v. 51, p. 467 (June 7, 1907). (A brief analysis of the elements of valuation.)

HENRY FINK ON DANGER OF RAILWAY VALUATION. *Railway Age*, v. 43, p. 680 (April 26, 1907). (Declares there is no relation between valuation and rate regulation.)

INCOME ACCOUNT OF RAILWAYS. (Letter); by Frank May. *Railway Age*, v. 45, p. 560 (April 17, 1908). (How depreciation charges should be made.)

INITIAL COST, COST OF MAINTENANCE AND DEPRECIATION OF WOODEN Passenger Cars. *Engineering-Contracting*, v. 34, p. 215 (Sept. 7, 1910). (Rate of depreciation per year of different classes of cars.)

LET THE GOVERNMENT GO AHEAD AND PROSECUTE AND APPRAISE THE Railways. (Editorial.) *Railway Age Gazette*, v. 49, p. 566 (Sept. 30, 1910). (Relation between valuation and rates.)

MAINTENANCE CHARGES AND DIVIDENDS. (Editorial.) *Engineering Record*, v. 55, p. 86, (Jan. 26, 1907). (Alludes to comparison of repair costs in relation to traffic; one column.)

MAY RESERVE FUND TO RENEW ABSOLUTE EQUIPMENT. (Editorial.) *Electric Traction Weekly*, v. 6, p. 1473 (Dec. 3, 1910). (Decision by Supreme Court; article states that this is a new principle on valuation of special franchises.)

A METHOD OF APPRAISING NON-PHYSICAL RAILWAY VALUES. (Editorial.) *Engineering-Contracting*, v. 34, p. 517 (Dec. 14, 1910). (Comments on paper by Henry Earle Riggs on valuation of public utilities and on the method employed by Prof. Henry C. Adams in valuation of railroads.)

MR. HANSEL ON VALUATION OF RAILWAYS. (Editorials.) *Railway Age*, v. 44, pp. 71, 277 (July 19, Aug. 30, 1907). (On "State Valuation of Railways", by Charles Hansel in *North American Review* for July 5, 1907.)

——Letter. State Valuation of Railroads; by Carl Tombo. *Railway Age*, v. 44, p. 348 (Sept. 13, 1907).

——Letter. State Valuation of Railroads; by Charles Hansel. *Railway Age*, v. 44, p. 281 (Aug. 30, 1907).

NATIONAL VALUATION CONVENTION URGED, CONCERTED ACTION SHOULD BE Taken to Make Appraisal of Railways Economical, Intelligent and Just; by H. Bortin. *Railway Age Gazette*, v. 54, p. 836 (April 11, 1913).

THE NECESSITY OF DEPRECIATION RESERVES; by Henry L. Gray. *Railway Age Gazette*, v. 48, p. 1297 (May 27, 1910). (Two pages.)

RAILROADS—GENERAL—(*Continued*).

——Editorial. Depreciation Reserves. *Railway Age Gazette*, v. 48, p. 1290 (May 27, 1910).

——Letters. Depreciation Reserves. *Railway Age Gazette*, v. 49, p. 66 (July 8, 1910).

NOTES ON THE APPLICATION OF A DEPRECIATION CHARGE IN RAILWAY Accounting; by Frederic A. Delano. *Railway Age*, v. 45, p. 471 (March 27, 1908). (Depreciation of equipment, track, bridges, buildings, shop tools, etc., of the plant as a whole and limit of depreciation.)

OBSOLESCENCE AND DEPRECIATION FOR LOCOMOTIVES. (Editorial.) *Electric Railway Journal*, v. 41, p. 997 (June 7, 1913). (Comparison between steam and electric locomotives.)

PHYSICAL VALUATION AND CAPITALIZATION. *Railway Age Gazette*, v. 50, p. 121 (Jan. 20, 1911). (A statement of Prof. F. H. Dixon, which is said to refute a statement made by Clifford Thorne to the effect that railways in the States where valuations have been made are over-capitalized.)

PHYSICAL VALUATION AND CAPITALIZATION. *Railway World*, v. 55, p. 88 (Feb. 3, 1911). (Material prepared by the Bureau of Railway Economics; four pages.)

PHYSICAL VALUATION OF AMERICAN RAILWAYS. In Railway Library, 1910, p. 395; edited by Slason Thompson. Bureau of Railway News and Statistics, Chicago, 1911.

PHYSICAL VALUATION OF RAILROADS; by William J. Wilgus. *Proceedings*, American Society of Civil Engineers, v. 39, p. 1109 (May, 1913). (Discusses basic principles, land values, inventorying and pricing measureable items, overhead cost, interest during construction, working capital and depreciation.)

——Abstract. Valuation of Steam Railroads. *Railway Age Gazette*, v. 67, pp. 654, 692 (June 14, 21, 1913).

PHYSICAL VALUATION VERSUS RAILROAD RATES; by Henry Fink. *Railway World*, v. 55, p. 288 (April 14, 1911). (Extracts from statement made to the Railway Securities Commission.)

PHYSICAL VALUATIONS AND CAPITALIZATION OF RAILWAYS; by Slason Thompson. *Railway World*, v. 55, p. 1011 (Dec. 16, 1910). (Gives actual appraisals made in various States.)

——*Railway and Engineering Review*, v. 50, p. 1159 (Dec. 17, 1910).

THE PROBLEM OF RAILWAY VALUATION; by Logan G. McPherson. *Railway Age Gazette*, v. 54, p. 1131 (May 23, 1913). (The change in the attitude of the public toward the carriers, and the various difficult questions it has raised.)

PROGRESS OF VALUATION OF RAILWAYS. *Railway Age*, v. 45, p. 103 (Jan. 24, 1908). (Considers the progress in methods of valuation; one page.)

PROPOSED VALUATION OF RAILROAD PROPERTY. (Editorial.) *Railway Age Gazette*, v. 42, p. 293 (March 8, 1907). (Concerning valuation as a basis for rate-making; one and one-half columns.)

RAILROAD ACCOUNTING AND THE HEPBURN LAW; by Arthur C. Graves. *Railroad Age Gazette*, v. 45, pp. 1543, 1597; v. 46, p. 18 (Dec. 11, 18, 1908; Jan. 1, 1909). (A protest against the requirements of the Government in railroad accounting.)

RAILROAD ACCOUNTING UNDER GOVERNMENT SUPERVISION; by M. P. Blauvelt. *Railway Age*, v. 45, p. 702 (May 15, 1908). (Discusses depreciation of equipment and replacement accounts.)

THE RAILROAD PROBLEM, RATES, UNIT COSTS AND EFFICIENCY; by F. Lincoln Hutchins. *Engineering Magazine*, v. 42, pp. 488, 709 (Jan., Feb., 1912). (The paper contains the following divisions: rate-making, unit costs and efficiency, capitalization and regulation.)

RAILROAD TAXATION AND VALUATION; by C. F. Staples. *Proceedings*, Annual Convention of the National Association of Railway Commissioners, 1909, p. 375. (Discusses gross earning and stock and bond methods of valuation; eight pages.)

RAILROAD VALUATION; by William J. Ripley. Ginn & Co., Boston, 1907. (Thirty-three pages.)

RAILROAD VALUATION, REPRODUCTION COST NEW AS A SOLE BASIS FOR Rates; by D. F. Jurgensen. *Journal*, Association of Engineering Societies, v. 49, p. 294 (Dec., 1912). (On method to be used in the valuation of railroads.)

RAILWAY ATTITUDE TOWARD VALUATION OF RAILWAYS. *Railway Age Gazette*, v. 49, p. 1137 (Dec. 16, 1910). (Arguments against a mere physical valuation; one page.)

RAILROADS—GENERAL—(*Continued*).

RAILWAY CAPITAL AND REAL VALUE; by Darius Miller. *Railway World*, v. 55, p. 28 (Jan. 13, 1911). (An article by the President of the Chicago, Burlington & Quincy R. R., in which he gives his views as to the relation between capitalization and rates.)

RAILWAY DEPRECIATION ACCOUNTS; by C. L. Sturgis. *Proceedings*, Annual Convention of the National Association of Railway Commissioners, 1909, p. 392. (Considers depreciation and depreciation accounts in relation to the question of railway regulation.)

——*Railway Age Gazette*, v. 48, p. 944 (April 8, 1910).

——Abstract. *Electric Railway Journal*, v. 34, p. 1224 (Dec. 18, 1909).

RAILWAY DEPRECIATION ACCOUNTS; by W. J. Meyers. *Proceedings*, Annual Convention of the National Association of Railway Commissioners, 1909, p. 403. (Charging repairs and replacements as made, importance of formal depreciation account and consideration of depreciation by companies affected.)

——Abstract. *Electric Railway Journal*, v. 34, p. 1146 (Dec. 4, 1909).

RAILWAY VALUATION AGAIN. *Railway and Engineering Review*, v. 50, p. 1172 (Dec. 24, 1910). (Comments on statement of Judson C. Clements before the Railways Securities Commission; from *New York Sun*, Dec. 3, 1910.)

RAILWAY VALUATION BY THE CENSUS OFFICE. *Railway Age*, v. 37, p. 1103 (June 17, 1904). (On methods of valuation advocated by the Interstate Commerce Commission; one page.)

REPAIRS, RENEWALS, DETERIORATION AND DEPRECIATION OF WORKSHOP Plant and Machinery; by James Edward Darbishire. *Proceedings*, Institution of Mechanical Engineers, 1908, Pts. 3-4, pp. 812, 879. (The discussion of this paper includes remarks upon the depreciation of railway workshops and rolling stock.)

REPORT OF COMMITTEE ON LIFE OF RAILWAY PHYSICAL PROPERTY. *Proceedings*, American Electric Railway Accountants Association, 1912, p. 189. (Contains bibliography on life of physical property of railways and table of depreciation estimates.)

REPORT OF COMMITTEE ON RAILROAD TAXES AND PLANS FOR ASCERTAINing Fair Valuation of Railroad Property. *Proceedings*, Annual Convention of the National Association of Railway Commissioners, 1903, p. 13; 1904, p. 50; 1905, p. 55; 1906, p. 33; 1908, p. 174; 1909, p. 321; 1910, p. 138; 1911, p. 61; 1912, p. 34. (Reports and discussions of varying length on taxation and the best methods of valuation.)

——Abstract of report for 1905. *Railway Age*, v. 40, p. 289 (Sept. 8, 1905).

——Abstract of report for 1910. *Electric Railway Journal*, v. 36, pp. 1062, 1192 (Nov. 26, Dec. 17, 1910); *Railway and Engineering Review*, v. 50, p. 1130 (Dec. 10, 1910).

——Abstract of report for 1911. *Electric Railway Journal*, v. 38, p. 1026 (Nov. 11, 1911).

——Abstract of report for 1912. *Electric Railway Journal*, v. 40, p. 1065 (Nov. 23, 1912). (Treats of allowance for contingencies, interest during construction, basis for valuation, cost of reproduction new and original investment and fair value.)

——Editorials on report for 1912. Railway Valuation. *Electric Railway Journal*, v. 40, p. 1051 (Nov. 23, 1912); Valuation by the National and the State Governments. *Electric Railway Journal*, v. 40, p. 1139 (Dec. 7, 1912).

REPORT OF THE COMMITTEE ON FEDERAL RELATIONS. *Proceedings*, American Electric Railway Association, 1911, p. 310. (Contains a page on physical valuation of railways.)

——Abstract. *Electric Railway Journal*, v. 38, p. 812 (Oct. 13, 1911).

REPORT OF THE HADLEY SECURITIES COMMISSION. *Railway Age Gazette*, v. 51, p. 1210 (Dec. 15, 1911). (Two pages.)

——Editorial. The Usefulness of a Physical Valuation. *Railway Age Gazette*, v. 51, p. 1203 (Dec. 15, 1911).

SOME DISPUTED POINTS IN RAILWAY VALUATION. (Editorials.) *Railway Age Gazette*, v. 54, pp. 1056, 1118, 1164, 1208 (May 16, 23, 30, June 6, 1913). (On right of way, investment from earnings, depreciation and intangible values.)

——Criticism. Mr. Loweth on Depreciation in Valuation. (Letter); by C. F. Loweth. *Railway Age Gazette*, v. 54, p. 1536 (June 20, 1913). (Criticism on editorial in issue of May 30th, 1913.)

——Editorial. Depreciation in Railway Valuation. *Railway Age Gazette*, v. 54, p. 1535 (June 20, 1913).

SOME NEGLECTED FACTORS OF FAIR VALUATION. (Editorial.) *Railway Age Gazette*, v. 46, p. 441 (March 5, 1909). (Concerning the relation between physical valuations as made by State Commissions and rate regulation.)

RAILROADS—GENERAL—(*Continued*).

STATISTICS AS TO THE LIFE OF STEEL RAILWAY BRIDGES. *Engineering-Contracting*, v. 30, p. 227 (Oct. 7, 1908). (Reference to depreciation of bridges and table showing life of ten railway bridges.)

AN UNSEEN FACTOR IN RAILWAY VALUATION. (Editorial.) *Railway Age Gazette*, v. 50, p. 821 (April 7, 1911). (In regard to the element which represents investment extinct and destroyed in the various railway re-organizations.)

USEFULNESS OF A PHYSICAL VALUATION. (Editorial.) *Railway Age Gazette*, v. 51, p. 1203 (Dec. 15, 1911). (Comments on the report and recommendations of the Hadley Securities Commission; one page.)

THE VALUATION OF AMERICAN RAILWAYS. (Editorial.) *Railway World*, v. 51, p. 410 (May 17, 1907). (Discusses value regarded as original or reproduction cost and as capitalization on the net earnings of the road.)

VALUATION OF PUBLIC SERVICE CORPORATIONS; by W. H. Williams. American Economic Association, New York, 1909. (Discusses the valuation of railroad taxes, rates, capitalization, etc.; fifty-one pages.)

——Abstract. *Electric Railway Journal*, v. 35, p. 76 (Jan. 8, 1910).

VALUATION OF RAILROAD PROPERTY; by Henry Fink. *Railway Age Gazette*, v. 45, pp. 587, 627 (July 24, 31, 1908). (Discusses physical valuation, capitalization and rate-making.)

VALUATION OF RAILROAD PROPERTY FOR LOCAL TAXATION. (Letter.) *Railroad Gazette*, v. 29, p. 863 (Dec. 10, 1897). (Decisions on valuation of railroads, based on opposing principles, cost of reproduction and earning capacity.)

VALUATION OF RAILROADS. (Editorial.) *Railway Age Gazette*, v. 42, p. 730 (May 31, 1910). (History of attempts to fix value of railroad properties, and statement that this cannot be done on a physical basis; one page.)

VALUATION OF RAILWAY PROPERTIES; by Robert Yates. *Railway Age Gazette*, v. 47, p. 975 (Nov. 19, 1909). (Considers a few of the principal elements of construction showing the cost value and depreciated value.)

VALUATION OF RAILWAYS. *Railway Age Gazette*, v. 46, pp. 173, 219, 261, 312 (Jan. 22, 29, Feb. 5, 12, 1909). (Full discussion of valuation in relation to State Railway Commissions, rates, etc.)

VALUATION OF THE RAILWAYS IN THE UNITED STATES; by B. H. Meyer. *Proceedings*, Annual Convention of the National Association of Railway Commissioners, 1904, p. 46. (General principles of valuation; four pages.)

——Abstract. Valuation of the Railways of the United States. *Railway Age*, v. 38, p. 729 (Nov. 18, 1904).

VALUE OF THE RAILROADS AND THEIR CAPITALIZATION; by H. T. Newcomb. *Railroad Gazette*, v. 34, p. 671 (Aug. 29, 1902). (Argues that the capital stock of a railroad does not represent its real value; one page.)

VALUING RAILROAD PROPERTY; by Charles Hansel. *Traffic World*, v. 7, p. 735 (April 22, 1911). (Consideration of earning power, franchise and real value as elements of appraisal; address before the Southern Commercial Congress.)

WHAT IS THE VALUE OF A RAILROAD FOR PURPOSES OF TAXATION? by Charles Hansel. *Railroad Gazette*, v. 33, p. 271 (April 19, 1901). (On the work of Prof. M. E. Cooley, who was selected to examine the railroads in the State of Michigan, and on the subject of valuation in general; one page.)

United States Interstate Commerce Commission.

ACCOUNTING FOR DEPRECIATION OF EQUIPMENT. (Editorial.) *Railway Age*, v. 44, p. 36 (July 12, 1907). (Comments on the proposal to require railways to make formal depreciation accounts as outlined in Accounting Circular, No. 8, United States Interstate Commerce Commission.)

ACCOUNTING FOR DEPRECIATION OF EQUIPMENT. (Letter); by W. A. Worthington. *Railway Age*, v. 44, p. 245 (Aug. 23, 1907). (On the classification of the Interstate Commerce Commission.)

CLASSIFICATION OF ACCOUNTS FOR INTERSTATE STEAM ROADS. *Electric Railway Journal*, v. 32, p. 348 (July 25, 1908). (New classifications as of July 1, 1908, supplements to the revised issues prescribed for the fiscal year beginning July 1st, 1907.)

CLASSIFICATION OF OPERATING EXPENSES AS PRESCRIBED BY THE INTERstate Commerce Commission. Third Revised Issue. Government Printing Office, Washington, 1911. (Gives annual per cent. allowed for depreciation.)

CLASSIFICATION OF OPERATING EXPENSES AS PRESCRIBED BY THE INTERstate Commerce Commission for Steam Roads. Third Revised Edition, Effective July 1st, 1908. Government Printing Office, Washington, 1908. (Contains condensed classification of account for small carriers and extended classification for large carriers.)

——Supplement. Government Printing Office, Washington, 1908.

RAILROADS—GENERAL—(*Continued*).

DEPRECIATION AND RENEWALS ACCOUNTS MODIFIED. (Editorial.) *Railway Age*, v. 44, p. 308 (Sept. 6, 1907). (Discussion of Circular 13, Accounting Series, United States Interstate Commerce Commission.)

DEPRECIATION IN RAILWAY ACCOUNTING. (Letter); by H. A. Dunn. *Railway Age*, v. 45, p. 756 (May 29, 1908). (Comments on methods of accounting recommended by the Interstate Commerce Commission.)

EVALUATION OF RAILROADS; by Walter S. McCormack. *Traffic World*, v. 8, p. 511 (Sept. 23, 1911). (States that carriers should be represented in work of the Interstate Commerce Commission.)

FORM OF GENERAL BALANCE SHEET STATEMENT AS PRESCRIBED BY THE Interstate Commerce Commission for Steam Roads. First Revised Issue, Effective June 15th, 1910. Government Printing Office, Washington, 1910.

HEARING ON DEPRECIATION OF EQUIPMENT ACCOUNTS BY INTERSTATE COMmerce Commission. *Electric Railway Journal*, v. 32, p. 236 (July 4, 1908). (Opinion of a Committee of the American Railway Association.)

——Editorial. Depreciation of Equipment Accounts. *Electric Railway Journal*, v. 32, p. 193 (July 4, 1908).

INTERSTATE COMMERCE COMMISSION DESIRE INFORMATION CONCERNING Treatment of Depreciation Accounts. *Railway Age*, v. 45, p. 221 (Feb. 14, 1908). (Questions which should be considered in keeping account of depreciation; abstract of Circular No. 7, Special Report Series.)

OBJECTIONS TO THE DEPRECIATION CHARGE. *Railroad Age Gazette*, v. 45, p. 1050 (Oct. 2, 1908). (A summary of views expressed by railroad officers on depreciation; memorandum of the American Railway Association's Special Committee to the Interstate Commerce Commission.)

——Depreciation in Steam Railway Accounting. *Electric Railway Journal*, v. 32, p. 748 (Oct. 3, 1908).

——Editorial. Proposed Valuation and Rates. *Railway Age*, v. 43, p. 268 (March 1, 1907).

PROTEST OF PENNSYLVANIA RAILROAD AGAINST CLASSIFICATION OF ADDItions and Betterments. *Electric Railway Journal*, v. 34, p. 908 (Oct. 23, 1909). (Formal protest to the Interstate Commerce Commission against required classification of accounts.)

QUESTIONS PERTAINING TO DEPRECIATION. *Railway Age*, v. 44, p. 805 (Dec. 6, 1907). (Abstracts of Circulars 12 and 12*a*, Accounting Series, United States Interstate Commerce Commission.)

STATE VALUATION OF RAILWAYS; by Darius Miller. *Railway and Engineering Review*, v. 50, p. 1027 (Nov. 5, 1910). (Statements made at the rate hearing of the Interstate Commerce Commission.)

United States Railway Valuation Act.

THE BILL FOR PHYSICAL VALUATION. *Railway and Engineering Review*, v. 53, p. 169 (Feb. 22, 1913). (The text of the Railway Valuation Act.)

——Bill for Physical Valuation of Railways. *Railway Age Gazette*, v. 52, p. 811 (April 5, 1912). (Full text of the Adamson Bill for the physical valuation of railways by the Interstate Commerce Commission.)

CAN ENGINEERS BE TRUSTED TO ARBITRATE FAIRLY AND INTELLIGENTLY Between the Public Interests and the Property Interests? (Editorial.) *Engineering News*, v. 69, p. 1187 (June 5, 1913.) (On statement of Senator Robert M. La Follette that railroad valuation work should be placed in charge of an economist and not of an engineer.)

HEARING ON PROPOSED FEDERAL RAILROAD APPRAISAL. *Railway and Engineering Review*, v. 53, p. 140 (Feb. 15, 1913).

A HUGE PIECE OF ENGINEERING WORK. (Editorial.) *Engineering News*, v. 69, p. 476 (March 6, 1913). (Comments on the Railway Valuation Act.)

PHYSICAL VALUATION OF RAILROADS. (Editorial.) *Railway Age Gazette*, v. 45, p. 1029 (Oct. 2, 1908). (Recommendation for Federal valuation of railroads by Henry C. Adams, Statistician of the Interstate Commerce Commission; one and one-half columns.)

PLAN FOR PHYSICAL VALUATION OF RAILWAY PROPERTIES. *Railway Age*, v. 43, p. 286 (March 1, 1907). (Abstract of a memorandum by H. C. Adams submitted to the President by the Interstate Commerce Commission.)

THE PLANK IN THE DEMOCRATIC PLATFORM PLEDGING THE APPRAISAL OF All Railways. (Editorial.) *Engineering and Contracting*, v. 38, p. 562 (Nov. 20, 1912). (Estimates the cost of a railway appraisal to range from $2.50 per mile, for very rough inventory, to $25 per mile for a very thorough appraisal, or about 50 cents per $1 000 of physical property appraised.)

PROPOSED NATIONAL VALUATION CONVENTION. (Letter); by L. C. Fritch. *Railway Age Gazette*, v. 54, p. 1536 (June 20, 1913). (Objections to holding convention.)

RAILROADS—GENERAL—(*Continued*).

——The Railway Valuation Act. *Engineering News*, v. 69, p. 482 (March 6, 1913). (Text of the law passed by Congress ordering the valuation of railroad properties.)

THE RAILWAY VALUATION ACT. (Letter); by Alex. C. Humphreys. *Engineering News*, v. 69, p. 688 (April 3, 1913). (The doubtful value of the provision of the law which requires the appraisers to analyze past financial transactions of railroads.)

STATE RAILWAY COMMISSIONERS AND FEDERAL VALUATION; by D. F. Jurgensen. *Railway and Engineering Review*, v. 53, p. 529 (June 7, 1913). (States that the Federal valuation is a contest between carriers and public, with the Interstate Commerce Commission as umpire.)

VALUATION OF THE RAILROADS. (Editorial.) *Engineering Record*, v. 67, p. 283 (March 15, 1913). (On the Railway Valuation Act.)

THE VALUE OF VALUATION. (Editorial.) *Electric Railroad Journal*, v. 41, p. 667 (April 12, 1913). (Doubt expressed as to the usefulness of the valuation of railroads provided for by Congress.)

RAILROADS—SPECIAL CASES.

Atchison, Topeka & Santa Fé R. R.

WHY RAILROADS NEED HIGHER RATES, p. 88; by E. P. Ripley. Chicago (?), 1910. (Takes up the physical value of the Santa Fé R. R. in testimony before the Interstate Commerce Commission, Chicago, 1910.)

Beaumont & Great Northern R. R.

VALUATION OF THE RAILWAYS OF TEXAS. *Engineering-Contracting*, v. 33, p. 370 (April 20, 1910). (Detailed value of the Beaumont & Great Northern R. R., with brief comments.)

Boston & Maine R. R.

*EVIDENCE AS TO THE VALUE OF NEW HAMPSHIRE ROADS EMBRACED IN the Boston & Maine System. In the Report of the Public Service Commission of New Hampshire on an Investigation of Railroad Rates, p. 300. Concord, N. H., 1912. (Discussion of formula for determining the value of railroad properties: Original cost; amount and market value of stocks and bonds; present as compared with original cost of construction; probable earning capacity.)

California.

*INSTRUCTIONS TO ASSISTANT ENGINEERS FOR INSPECTING RAILWAY PROPerty for Inventory and Appraisal, California Railroad Commission. *Engineering and Contracting*, v. 37, p. 619 (May 29, 1912).

Chicago, Milwaukee & St. Paul R. R.

*A. E. BUELL VS. CHICAGO, MILWAUKEE & ST. PAUL RAILWAY COMPANY; Submitted July 1, 1906, Decided Feb. 16, 1907. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 1, pp. 337, 478. Madison, Wis., 1908. (Discusses what constitutes a fair valuation of a railroad.)

ITEMIZED COST OF THE C., M. & ST. P. R. R. IN SOUTH DAKOTA. *Engineering-Contracting*, v. 28, p. 56 (July 24, 1907). (Estimates given in the Spokane rate case.)

Great Britain.

THE SERVICEABLE LIFE AND COST OF RENEWALS OF PERMANENT WAY OF British Railways; by R. Price-Williams. *Journal*, Iron and Steel Institute, v. 80, p. 183 (1909, Pt. 2). (Gives actual figures and diagrams of cost of maintenance on British railways for a number of years.)

Great Northern Ry.

ITEMIZED COST OF THE GREAT NORTHERN RAILWAY SYSTEM AS ESTIMATED by Its Chief Engineer. *Engineering-Contracting*, v. 29, p. 271 (May 6, 1908). (Estimates given in testimony before the Interstate Commerce Commission in the Spokane rate case.)

ORIGINAL COST AND COST OF REPRODUCTION OF THE GREAT NORTHERN Railway (768 Miles) in the State of Washington. *Engineering-Contracting*, v. 32, p. 496 (Dec. 8, 1909). (Data as to the original cost, given by Halbert P. Gillette before the Railroad Commission.)

Kansas.

*KANSAS RAILWAY VALUATION, REPORT OF THE WORK OF THE ENGINEERing Department, Public Utilities Commission, from Date of Establishment to Nov., 1912; by C. C. Witt. *Public Service Regulation*, v. 2, p. 217 (May, 1913).

RAILROADS—SPECIAL CASES—(*Continued*).

Kansas City Southern Ry.

ACCOUNTING FOR ABANDONED PROPERTY. *Electric Railway Journal*, v. 39, p. 247 (Feb. 10, 1912). (Reply of Interstate Commerce Commission to the suit brought by the K. C. S. Ry., in regard to manner of accounting for value of property abandoned in the reconstruction of track.)

Louisiana.

***REPORT MADE BY THE STATE BOARD OF APPRAISERS SHOWING THE** Assessments Made of Property Employed in the Railway, Telegraph, Telephone, Sleeping Car, and Express Business for the Year 1899. (On the methods of valuation, and actual valuations made.)

Massachusetts.

THE FRANCHISE IN CAPITALIZATION. (Editorial.) *Railroad Gazette*, v. 37, p. 269 (Aug. 26, 1904). (Discussion of bill presented to Massachusetts Legislature allowing a new corporation to capitalize on a basis of market value of absorbed companies and to capitalize the franchises.)

Michigan.

EXPERT VALUATION OF RAILWAY AND OTHER CORPORATE PROPERTY IN Michigan. *Engineering News*, v. 44, p. 430 (Dec. 20, 1900). (Full account of the valuation made by the Michigan Board of State Tax Commissioners, describing organization for the work.)

RAILROAD TAXATION; by Robert H. Shields. In Sixth Report of the Board of State Tax Commissioners, Dec. 15, 1910, p. 53. Lansing, Mich., 1911. (Discusses several theories for valuation of railroads.)

RAILWAY CAPITAL AND VALUES; by W. H. Williams. *Railway Age Gazette*, v. 46, pp. 761, 805, 845, 903 (April 2, 9, 16, 23, 1909). (Outlines the methods used to obtain a physical valuation of railroad property in Michigan.)

——Abstract. *Railway and Engineering Review*, v. 48, p. 1047 (Dec. 26, 1908).

Minneapolis, St. Paul & Sault Ste. Marie Ry.

***IN RE INVESTIGATION ON MOTION OF THE COMMISSION OF PASSENGER** Rates Charged by the Minneapolis, St. Paul & Sault Ste. Marie Railway Company: Submitted April 9, 1907, Decided June 1, 1907. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 1, pp. 543, 581. Madison, Wis., 1908. (Contains brief reference to valuation of the road.)

Minnesota.

CURRENT RAILWAY PROBLEMS; by Samuel O. Dunn. Railway Age Gazette, New York, 1911. (Contains an article on valuation of railways with special reference to the physical valuation in Minnesota.)

***FORMS USED IN COMPILING INFORMATION IN THE 1906 APPRAISAL OF THE** Railways of Minnesota. *Engineering and Contracting*, v. 37, p. 52 (Jan. 10, 1912). (Four pages.)

JUDGE SANBORN ON STATE INTERFERENCE WITH INTERSTATE COMMERCE and Valuation of Railways. *Railway Age Gazette*, v. 50, p. 987 (April 28, 1911). (Opinions of the U. S. Circuit Judge in the Minnesota rate case; abstract of the discussion on the correct basis for the valuation of railways and a "fair return")

THE MINNESOTA COMMISSION'S VALUATION FORMS. *Public Service Regulation*, v. 1, p. 301 (May, 1912). (Showing headings of some of the blanks used for detailed railway inventory and valuation in Minnesota, contributed by D. F. Jurgensen, Engineer.)

THE MINNESOTA RATE CASE; by Charles E. Otis. In Railway Library, 1910, p. 31; edited by Slason Thompson. Bureau of Railway News and Statistics, Chicago, 1911. (Contains analysis of valuation of property devoted to public service.)

THE MINNESOTA RATE CASES, OPINION OF THE SUPREME COURT OF THE United States. (63d Congress, 1st Sess., Senate Doc. No. 54). Washington, D. C., 1913. (Opinion of Justice Hughes of the Supreme Court on the valuation of railways.)

——Abstracts. Decision of the Supreme Court in the Minnesota Rate Cases. *Electric Railway Journal*, v. 41, p. 1064 (June 14, 1913); Railway Evaluation and Depreciation. *Engineering Record*, v. 67, p. 687 (June 21, 1913); The Supreme Court's Comments on Railway Valuation. *Railway Age Gazette*, v. 54, p. 1537 (June 20, 1913).

——Editorials. Construction Expenses in the Minnesota Rate Decision. *Electric Railway Journal*, v. 41, p. 1101 (June 21, 1913); *Railway Age Gazette*, v. 54, p. 1304 (June 13, 1913); The Minnesota Rate Decision. *Engineering Record*, v. 67, p. 679 (June 21, 1913); The United States Supreme Court on Principles of Railway Valuation. *Engineering News*, v. 69, p. 1338 (June 26, 1913).

RAILROADS—SPECIAL CASES—(*Continued*).

MINNESOTA RATE LAWS VOID. *Traffic World*, v. 7, p. 646 (April 15, 1911). (Statement is made that apportionment on the basis of revenue to the various classes of its business in order to determine the reasonableness of its rate, is the most reasonable and equitable method of assigning the value of a railroad property in a State, used for transportation; decision in case Shepard *vs.* Northern Pacific *et al.*, etc., United States Circuit Court.)

***TWENTY-THIRD ANNUAL REPORT OF THE RAILROAD AND WAREHOUSE** Commission of Minnesota to the Governor for the Year Ending November 30, 1907, p. 14. St. Paul, 1908. (On method of making valuation; six pages.)

*——24th, 1908, p. 12. Minneapolis, 1909. (Contains report on valuation of the railways of the State.)

——Abstracts. An Analysis of the Appraisal of the Railways of Minnesota with Comments on the Same. *Engineering-Contracting*, v. 31, p. 172 (March 3, 1909); Valuation of Railways in Minnesota. *Railway Age Gazette*, v. 46, p. 225 (Jan. 29, 1909).

*——26th, 1910, p. 94. Minneapolis, 1911. (Contains findings and report on rate cases by Charles E. Otis, including valuations of property devoted to public service.)

——Abstract. *Railway and Engineering Review*, v. 49, p. 297 (March 13, 1909).

VALUATION OF RAILROAD PROPERTY IN MINNESOTA; by A. S. Cutler. *Year Book*, Engineers' Society, University of Minnesota, v. 16, p. 69 (1908). (Method of making valuation of railroad property in Minnesota; seven and one-half pages.)

VALUATION OF RAILWAYS IN MINNESOTA. *Railway Age Gazette*, v. 44, p. 877 (Dec. 20, 1907). (Describes methods of making valuation.)

VALUATION OF RAILWAYS IN MINNESOTA. *Railway Age Gazette*, v. 46, p. 269 (Feb. 5, 1909). (Describes the work of the Minnesota Railroad Commission.)

——Editorial. *Railway Age Gazette*, v. 46, p. 245 (Feb. 5, 1909).

Nebraska.

***FOURTH ANNUAL REPORT OF THE NEBRASKA STATE RAILWAY COMMIS**sion to the Governor, Year Ending November 30, 1911, p. 446. Omaha, 1911. (Includes statements of physical value of the various railroad and transportation facilities of the stock yards properties within the State of Nebraska, being the initial appraisal of July 1st, 1909.)

——State Railway Valuation: Nebraska Commission Reports Progress on State-Wide Appraisal of Physical Values. *Public Service Regulation*, v. 1, p. 445 (July, 1912).

ORGANIZATION FOR AND METHODS AND RESULTS OF PHYSICAL VALUATION in Nebraska; by E. C. Hurd. *Engineering and Contracting*, v. 36, p. 694 (Dec. 27, 1911). (Two pages.)

VALUATION OF RAILWAY PROPERTY—THE NEBRASKA METHOD. *Railway Age*, v. 37, p. 1219 (June 24, 1904). (Valuation for purposes of taxation; one page.)

New Jersey.

THE APPRAISAL OF THE RAILWAYS OF NEW JERSEY, AND PROGRESS IN Other States. *Engineering and Contracting*, v. 35, p. 701 (June 21, 1911). (One column.)

***PROGRESS REPORT OF THE BOARD TO RE-APPRAISE RAILROADS AND** Canals in This State, March 9th, 1910. Trenton, N. J. (Gives organization, methods, and some data on actual values.)

RAILROAD APPRAISAL AND TAXATION IN NEW JERSEY; by Charles Hansel. *Engineering News*, v. 68, p. 334 (Aug. 22, 1912). (Defense of the method of appraisal of railroads for taxation in New Jersey.)

***REPORT ON REVALUATION OF RAILROADS AND CANALS, NEW JERSEY, 1911;** by Charles Hansel. Trenton, 1912. (Treats of value of property, including the franchise, bonds and stocks, organization, operating cost, real estate, tangible personal property, depreciation, etc.)

THE VALUATION OF RAILROADS IN NEW JERSEY; by Charles Hansel. *Engineering Record*, v. 63, p. 594 (May 27, 1911). (Four pages.)

VALUATION OF RAILWAYS IN NEW JERSEY. *Railway Age Gazette*, v. 53, p. 243 (Aug. 9, 1912). (Methods adopted by Charles Hansel to ascertain value in accordance with State statute; results obtained by the work.)

New York, New Haven & Hartford R. R.

DEPRECIATION FUNDS OF THE NEW YORK, NEW HAVEN AND HARTFORD Railroad. (Editorial.) *Railway Age*, v. 43, p. 133 (Feb. 1, 1907). (One paragraph.)

RAILROADS—SPECIAL CASES—(*Continued*).

THE NEW HAVEN VALUATION. *Railway Age Gazette*, v. 50, p. 461 (March 10, 1911). (Review of the valuation of the N. Y., N. H. & H. R. R. properties just completed under the order of the Massachusetts Legislature.)

PRICES EMPLOYED IN THE PHYSICAL VALUATION OF THE NEW YORK, NEW Haven & Hartford R. R. *Engineering and Contracting*, v. 37, p. 220 (Feb. 21, 1912). (The unit prices adopted were based on the average ruling prices of the various elements for the last few years and on prices actually paid by the Railway Company; one column.)

THE PRINCIPLES GOVERNING A RAILROAD APPRAISAL OF AN UNUSUAL NAture. *Engineering Record*, v. 65, p. 174 (Feb. 17, 1912). (Gives an outline of the views of George F. Swain on the valuation of the N. Y., N. H. & H. R. R.)

RAILROAD REVALUATION—WITH AN EXAMPLE. (Editorial.) *Railway Age Gazette*, v. 45, p. 1081 (Oct. 9, 1908). (On the valuation of the N. Y., N. H. & H. R. R.)

——Letter. Scientific Valuation in Wisconsin; by Dwight C. Morgan. *Railway Age Gazette*, v. 45, p. 1242 (Oct. 30, 1908). (Criticism of editorial of Oct. 9, 1908.)

***REPORT OF THE BOARD OF RAILROAD COMMISSIONERS, THE TAX COMMIS**sioner and the Bank Commissioner, Sitting as a Commission, Relative to the Assets and Liabilities of the New York, New Haven & Hartford Railroad Company. Wright & Potter Printing Co., Boston, 1911. (Contains extensive reports by George F. Swain and Stone & Webster on the valuation of the railroad.)

VALUATION OF THE SOUTH STATION, BOSTON. (Editorial.) *Railway Age Gazette*, v. 48, p. 1243 (May 20, 1910). (On the revaluation of the South Station at Boston, made by J. F. Stevens, for the N. Y., N. H. & H. R. R. Co.; one-half column.)

Northern Pacific Ry.

AVERAGE COST OF REPAIRING LOCOMOTIVES IN AMERICA, COMPARED WITH the Cost on the Northern Pacific, Together with Comments on Plant Depreciation and Repairs. *Engineering-Contracting*, v. 30, p. 150 (Sept. 2, 1908). (Discusses depreciation of locomotives.)

FINDINGS OF THE INTERSTATE COMMERCE COMMISSION AS TO THE COSTS of Constructing the Northern Pacific and Great Northern Railways, and Its Decision in the Spokane Rate Case. *Engineering-Contracting*, v. 31, p. 217 (March 24, 1909). (Discusses a decision of the Interstate Commerce Commission regarding rate reduction on the N. P. and G. N. Rys.)

ITEMIZED COST OF THE NORTHERN PACIFIC RAILWAY SYSTEM AS ESTImated by Its Chief Engineer. *Engineering-Contracting*, v. 29, p. 226 (April 15, 1908). (Estimates given in the Spokane rate case.)

***ORIGINAL COST AND COST OF REPRODUCTION OF THE NORTHERN PACIFIC** Railway (1,645 Miles) in the State of Washington. *Engineering-Contracting*, v. 33, p. 44 (Jan. 12, 1910). (Data as to the cost given by Halbert P. Gillette, before the Railroad Commission.)

See also Minnesota.

Oklahoma.

***BEFORE THE CORPORATION COMMISSION, STATE OF OKLAHOMA:** *In Re* Proposed Order to Promulgate Rates on Wheat, etc., No. 1350. Oklahoma City, 1912. (Opinion of George A. Henshaw, Commissioner; contains an extended discussion of the proper elements in valuation.)

Oregon.

***ANNUAL REPORT OF THE RAILROAD COMMISSION OF OREGON, 1908, p. 20;** 1909, p. 25. Salem, Ore., 1909-10. (Speaks briefly of the methods used and describes the organization of the force.)

Oregon R. R. & Navigation Co.

***VALUATION OF THE OREGON RAILROAD & NAVIGATION COMPANY.** *Railway Age Gazette*, v. 45, p. 1357 (Nov. 13, 1908). (Actual figures; one paragraph.)

South Dakota.

***NINETEENTH ANNUAL REPORT OF THE BOARD OF RAILROAD COMMISSION**ers of the State of South Dakota for the Year Ending June 30, 1908, p. 24. Huron, S. Dak., 1908. (On method of making valuation of railroads; three and one-half pages.)

THE PHYSICAL VALUATION OF THE RAILROADS IN SOUTH DAKOTA. *Engineering Record*, v. 63, p. 174 (Feb. 11, 1911). (Contains a table giving appraised value per mile of all railways in South Dakota, reproduction value new, condition per cent. and present value.)

RAILROADS—SPECIAL CASES—(*Continued*).

***SOUTH DAKOTA RAILROAD APPRAISAL AS OF JUNE 30, 1909: REPORT OF** Carl C. Witt, Engineer, to the Board of Railroad Commissioners of the State of South Dakota. In Twenty-First Annual Report of the Board of Railroad Commissioners of the State of South Dakota for the Fiscal Year ending June 30, 1910, p. 25. Sioux Falls, S. Dak., 1910. (Actual valuation and general explanatory notes.)

Southern Pacific Co.

EQUIPMENT DEPRECIATION AND RENEWAL; by William Mahl. *Railroad Gazette*, v. 43, p. 418 (Oct. 1, 1907). (Compiled from data published in Annual Report of the S. P. Co.)

——*Railway Age Gazette*, v. 48, p. 440 (March 4, 1910).

——Editorial. *Railroad Gazette*, v. 43, p. 406 (Oct. 11, 1907).

EQUIPMENT DEPRECIATION AND REPLACEMENT; by William Mahl. *Railway Age Gazette*, v. 48, p. 1249 (May 20, 1910). (Statement of the per cent. of cost of equipment vacated to total original cost on the S. P. Co.)

——Abstract. Equipment Depreciation and Renewal of Railways. *Engineering-Contracting*, v. 34, p. 193 (Aug. 31, 1910).

Texas.

***ANNUAL REPORT OF THE RAILROAD COMMISSION OF THE STATE OF TEXAS** for the Year 1908, pp. 32, 457. Austin, Tex., 1908. (Gives a detailed statement of the value of the different railroads.)

ESTIMATING THE VALUE OF A RAILWAY. *Engineering News*, v. 31, p. 308 (April 12, 1894). (On the work of the Texas Railroad Commission; one column.)

——Editorial. *Engineering News*, v. 31, p. 302 (April 12, 1894).

***METHOD USED BY THE RAILROAD COMMISSION OF TEXAS, UNDER THE** Stock and Bond Law, in Valuing Railroad Properties; by R. A. Thompson. *Transactions*, American Society of Civil Engineers, v. 52, p. 328 (Paper 974. June, 1904). (Thirty-six pages.)

RAILROAD FRANCHISE VALUES IN TEXAS; by W. H. Coverdale. *Railroad Gazette*, v. 36, p. 115 (Feb. 12, 1904). (Remarks on the methods of the Texas Commission in the valuation of railroads.)

STATE REGULATION AND VALUATION OF RAILWAYS IN TEXAS. *Engineering News*, v. 33, p. 152 (March 7, 1895). (On the work of the Railroad Commission; one page.)

WORK OF THE TEXAS STATE RAILWAY COMMISSION. *Engineering News*, v. 35, p. 273 (April 23, 1896). (On the valuation work of the Texas Commission; one page.)

Union Pacific R. R.

REPORT OF THE COMMISSION AND OF THE MINORITY COMMISSIONER AP-pointed Under the Act of Congress, Approved March 3d, 1887, Entitled, "An Act Authorizing an Investigation of the Books, Accounts and Methods of Railroads Which Have Received Aid from the United States, and for Other Purposes"; also Report of the Inspecting Engineer and Accountants. Washington, 1887. (Valuation of the U. P. Ry.)

TESTIMONY TAKEN UNDER THE ACT OF CONGRESS APPROVED MAR. 3d, 1887, Entitled. "An Act Authorizing an Investigation of the Books, Accounts and Methods of Railroads Which Have Received Aid from the United States and for Other Purposes." Washington, 1887. (50th Congress, 1st Sess., Senate Doc. No. 51.) (Testimony taken in the valuation of the U. P. Ry.)

Washington.

***CLASSIFICATION OF UNITS INVOLVED IN CONSTRUCTION, AND ADDITIONS** and Betterments, Railroad Commission of Washington, 1909. Olympia, Wash., 1910.

DISCUSSION ON RATES AND RATE MAKING; by J. C. Lawrence. *Proceedings*, Annual Convention of the National Association of Railway Commissioners, 1910, p. 164. (Method of the Railroad Commission of Washington in determining the reasonableness of rates.)

***STATE OF WASHINGTON, SECOND AND THIRD ANNUAL REPORTS OF THE** Railroad Commission of Washington to the Governor Covering the Period from December 31, 1906, to December 31, 1907, and from December 31, 1907, to December 31, 1908, pp. 13, 41, 127. Olympia, Wash., 1909. (Contains report of H. P. Gillette on valuation of railways of the State of Washington.)

——Abstract. Report of H. P. Gillette to the Washington Railroad Commission on the Valuation of Railways in Washington. *Engineering-Contracting*, v. 31, p. 266 (April 7, 1909).

RAILROADS—SPECIAL CASES—(*Continued*).

VALUATION OF RAILWAYS IN WASHINGTON; by J. C. Lawrence. *Railway Age Gazette*, v. 48, p. 358 (Feb. 18, 1910). (Reasonable railway rates and how they are determined.)

——Editorial. Valuation and Rate Regulation. *Railway Age Gazette*, v. 48, p. 437 (March 4, 1910).

——(Correction.) *Railway Age Gazette*, v. 48, p. 859 (April 1, 1910).

VALUATION OF WASHINGTON RAILWAYS. *Railway Age*, v. 45, p. 113 (Jan. 24, 1908). (Review of the work of the Washington Railroad Commission.)

Wisconsin.

THE APPRAISEMENT OF THE PHYSICAL VALUE OF WISCONSIN RAILWAYS for the Purpose of Taxation; by W. D. Taylor. *Wisconsin Engineer*, v. 8, p. 1 (Dec., 1903). (Concerning valuation made by the Wisconsin State Tax Commission, giving method, organization, etc.)

——Abstract. *Engineering News*, v. 51, p. 314 (March 31, 1904).

AVERAGE COST PER MILE OF RAILWAYS IN WISCONSIN AND MICHIGAN AS Determined by State Commissions. *Engineering-Contracting*, v. 27, p. 285 (June 26, 1907). (One page.)

*FIRST BIENNIAL REPORT OF THE WISCONSIN TAX COMMISSION TO THE Governor and Legislature, p. 91. Edition 2. Madison, Wis., 1901. (Contains data on the method of determining the value of railroads.)

*——2d, p. 182. Madison, Wis., 1903. (Elements of value of railroad property, earnings as a basis of valuation, market value, value of land grants, etc.)

*——3d, p. 267. Madison, Wis., 1907. (Report of Prof. William D. Taylor, on the "Appraisal of the Physical Properties of Wisconsin Railways, 1903"; twenty-six pages.)

*——4th, p. 121. Madison, Wis., 1909. (Report by William D. Pence on the "Appraisal of the Physical Properties of Wisconsin Railroads, 1908"; twenty-three pages.)

*——5th, p. 185. Madison, Wis., 1911. (Contains a report submitted by W. D. Pence on "Appraisal of Physical Properties of Wisconsin Steam and Electric Railroads for the Year ending June 30, 1910".)

WISCONSIN RAILWAY TAXATION BILL. *Railway Age*, v. 35, p. 364 (March 13, 1903). (Discussion of the proposal of the State of Wisconsin to base taxation of railroads on their valuation, and of the methods of valuation by stock and bond prices and capitalized net earnings.)

THE ANATOMY OF A RAILROAD REPORT AND TON-MILE COST; by Thomas Francis Woodlock. New York, 1909. (Nelson's Wall Street Library, Vol. 2.)

APPRAISING RAILROAD VALUES; by J. D. Evans. *Moody's Magazine*, v. 4, p. 135 (July, 1907). (States no fair and just plan yet devised; also impracticable to fix rates by cost of service; railroads not over-capitalized.)

AN ARGUMENT AGAINST OFFICIAL VALUATION OF RAILROAD PROPERTIES; by Joseph P. Cotton. In American Economic Association Bulletin, 3d Series, No. 1 (April, 1910), pp. 253-258.

ARGUMENTS AS TO THE FAIR TAXABLE VALUE OF THE RAILWAY PROPerty in Wisconsin of the Chicago & Northwestern Railway, the Chicago, Milwaukee & St. Paul Railway and the Chicago, Burlington & Quincy Railroad Companies; Submitted by Frank P. Crandon and others to State Board of Assessment of Wisconsin. Madison, Wis., 1904.

CIRCULAR NO. 7, SPECIAL REPORT SERIES, UNITED STATES INTERSTATE COMmerce Commission. (Depreciation blanks sent out by the Interstate Commerce Commission.)

CIRCULAR NO. 13, ACCOUNTING SERIES, UNITED STATES INTERSTATE COMmerce Commission. (Prof. H. C. Adams discusses the equipment depreciation and renewals account.)

CIRCULAR NO. 20, ACCOUNTING SERIES, UNITED STATES INTERSTATE COMmerce Commission.

COST, CAPITALIZATION AND ESTIMATED VALUE OF AMERICAN RAILWAYS. *Railway News*, Jan. 4, 1908.

DEPRECIATION IN RAILWAY ACCOUNTING; by J. F. Calvert. *Journal of Accountancy*, v. 6, p. 229 (Aug., 1908).

RAILROADS—UNVERIFIED REFERENCES—(*Continued*).

THE ECONOMICS OF RAILWAY MAINTENANCE OF WAY; by W. M. Cunningham. *Journal of Accountancy*, v. 9, p. 358 (March, 1910).

FURTHER HARDSHIPS FOR THE RAILROADS. *Commercial and Financial Chronicle*, June 8, 1912, p. 1537.

JUDICIAL TEST OF A REASONABLE RAILROAD RATE AND ITS RELATION TO a Federal Valuation of Railway Property; by Charles G. Fenwick. *Michigan Law Review*, April, 1910.

THE LAW RELATING TO THE ASSESSMENT AND VALUATION OF RAILWAYS and Stations for Rating Purposes; by Walter B. Clode and Francis H. Cripps-Day. London, 1899.

LIFE OF PHYSICAL RAILWAY PROPERTY, TRACK AND WAY STRUCTURES; by W. J. French. *Street Railway Bulletin*, Jan., 1912, p. 42.

METHODS OF ESTIMATING RAILROAD VALUATION; by Carl Snyder. In "American Railways as Investments," 1907, pp. 15-66.

THE MICHIGAN RAILROAD APPRAISAL; by Henry Carter Adams. Ann Arbor, 1901.

MICHIGAN RAILROAD APPRAISAL; by Mortimer E. Cooley and Henry C. Adams. Michigan Political Science Association Publication, June 1901, p. 65.

MINNESOTA RAILWAY VALUATION; by G. O. Virtue. *Quarterly Journal of Economics*, May, 1909. (Six pages.)

NECESSITY FOR DEPRECIATION CHARGES ON RAILWAYS; by Arthur F. Dodd. *Encyclopedia of Accountancy*, v. 5, p. 423.

THE NEEDS OF THE RAILROADS; by Logan G. McPherson. *Political Science Quarterly*, v. 23, p. 440. (Refers to capitalization as affected by railroad development.)

NOTES ON DEPRECIATION ON RAILWAYS; by Frederic A. Delano. *Journal of Political Economy*, v. 16, p. 585 (Nov., 1908).

OFFICIAL VALUATION OF RAILROAD PROPERTIES: DISCUSSION; by Edward B. Whitney, Victor Rosewater, Charles F. Matthewson, A. C. Playdell, B. H. Meyer. American Economic Association Quarterly, v. 11, 3d Series, pp. 259-289 (April, 1910).

OUGHT THE RAILROADS TO ADVANCE THE RATES? by Samuel O. Dunn. *Review of Reviews*, Sept., 1910, p. 338. (Gives tables showing comparative costs of equipment, 1900 and 1910, and comparative cost of material in 1900, 1907, and 1910.)

OUR RAILROADS; by Harry P. Robinson. St. Paul, 1890. (A statement of the value and earnings of railroads of the Western States; forty-one pages.)

PHYSICAL VALUATION OF RAILWAYS; by William Z. Ripley. *Nation*, v. 86, p. 209 (March 5, 1908).

RAILROAD CAPITALIZATION AND FEDERAL REGULATION; by Franklin K. Lane. *American Review of Reviews*, v. 37, p. 711 (June, 1908).

RAILROAD RATE REGULATION. Beale and Wyman, 1906.

RAILROAD RATES; by Noyes.

RAILROAD VALUATION; by Ivy Ledbetter Lee. New York, 1907.

SOME PHASES OF THE AMERICAN RAILWAY PROBLEM. *Government*, v. 1, p. 7 (July, 1907). (Valuation of railroads, pp. 7-18.)

STATE VALUATION OF RAILROADS, SOME OF THE PROBLEMS; by Charles Hansel. *North American Review*, July 5, 1907, pp. 185, 485.

THE TAXATION OF CORPORATE PROPERTY AS SEEN IN THE TAXATION OF Michigan Railroads; by Robert H. Shields. *Proceedings*, Minnesota Academy of Sciences, 1907, pp. 40-58.

LES VALEURS DES CHEMINS DE FER AUX ETATS-UNIS; by F. Bernard. Paris, 1894.

VALUATION AND TAXATION OF RAILROADS IN PENNSYLVANIA; by the Pennsylvania Tax Conference. 1894. (Eighteen pages.)

VALUATION OF RAILROAD PROPERTY, REGULATION OF RATES AND SERvices, the Arguments and Votes Upon the Same in the Senate of the United States, May 9, 12, 14 and 18, 1906; by Robert M. La Follette.

VALUATION OF RAILROADS IN MICHIGAN; Report of the Michigan Tax Commissioner, 1900, p. 66; 1902, p. 50.

VALUATION OF RAILWAY PROPERTY NECESSARY TO FIX REASONABLE Rates, Amendments to the Interstate Commerce Act, Speech in the Senate, May 25, 26 and 31, 1910; by R. M. La Follette. *Congressional Record*, 61st Congress, 2d Sess., May 31, 1910, v. 45, pp. 7, 139-144, 6882-6913.

VALUATION OF RAILWAYS; by Lawrence J. Laughlin. In "Latter-Day Problems." New York, 1909. (Reprinted from *Scribner's Magazine*, April, 1909.)

VALUATION OF RAILWAYS, WITH SPECIAL REFERENCE TO THE PHYSICAL Valuation in Minnesota; by Samuel O. Dunn. *Journal of Political Economy*, v. 17, p. 189 (April, 1909). (Sixteen pages.)

***VALUATION OF TERMINAL LANDS;** by John Earl Baker. *Journal of Accountancy*, v. 8, p. 237 (Aug., 1909). (Supplement to Annual Report, Minnesota Railroad and Warehouse Commission, 1908; thirteen pages.)

VALUE OF RAILROAD PROPERTY; by W. S. Harries. American Railroad Management, 1907. (Abstract of paper read before the American Railway Association.)

VALUING THE RAILROADS. *American Review of Reviews*, v. 39, p. 379 (March, 1909).

WHAT ARE RAILROADS WORTH? by Henry L. Gray. *Saturday Evening Post*, June 17, 1911.

STEAM POWER.

COMMERCIAL ECONOMY IN STEAM AND OTHER THERMAL POWER-PLANTS as Dependent upon Physical Efficiency, Capital Charges and Working Costs; by Robert H. Smith. A. Constable & Co., Limited, London, 1905.

DEPRECIATION OF PRIME MOVERS. (Editorial.) *Electrical Review and Western Electrician*, v. 54, p. 601 (April 3, 1909). (One and one-half columns.)

DEPRECIATION OF STEAM PLANT. *Electric Railway Review*, v. 19, p. 360 (March 31, 1908). (Opinion of Charles T. Main on life of parts of steam plant; one paragraph.)

——Depreciation of Power Plant Equipment; by Charles T. Main. *Electric Traction Weekly*, v. 4, p. 456 (May 7, 1908).

STEAM POWER—(*Continued*).

STANDARDIZATION OF METHODS FOR DETERMINING AND COMPARING POWER Costs in Steam Plants; by H. G. Stott and W. S. Gorsuch. *Proceedings*, American Institute of Electrical Engineers, v. 32, p. 1097 (May, 1913). (Method of determining costs by groups and individual items and equitable basis of comparing costs of power in different plants and under different conditions.)

——Editorial. *Engineering Record*, v. 67, p. 567 (May 24, 1913).

STEAM POWER PLANT ENGINEERING, p. 624; by G. F. Gebhardt. John Wiley & Sons, New York, 1908. (Contains chapter on finance and economics of power plants including table of rate of depreciation, and one of life of various portions of steam power plant equipments.)

STEAM POWER—UNVERIFIED REFERENCES.

DEPRECIATION OF POWER PLANT EQUIPMENT; by Charles T. Main. *Electric Traction Weekly*, v. 4, p. 456 (May 7, 1908).

STREET AND INTERURBAN RAILROADS—GENERAL.

ACCOUNTING VERSUS STATISTICS. *Electric Railway Journal*, v. 41, p. 803 (May 3, 1913). (Instances where standard classification makes it impossible to compare justly energy production costs and other data of electric railways.)

ACTUAL FIGURES OF EXISTING STREET RAILWAYS; by H. G. Bradlee. *Aera*, v. 1, p. 392 (Dec., 1912). (Includes percentage return on company's investment which must be earned to provide for taxes, depreciation, obsolescence and to attract capital freely to the business; names of companies are not given.)

APPRAISALS OF ELECTRIC RAILWAY PROPERTIES; by D. C. Jackson. *Electric Railway Journal*, v. 32, p. 1233 (Oct. 31, 1908). (Abstract of an address before the New England Street Railway Club; one page.)

CALCULATING DEPRECIATION; by R. W. Western. *Tramway and Railway World*, v. 23, p. 456 (June 4, 1908). (Formula for estimating depreciation in street railways.)

CONSTRUCTION AND DEPRECIATION; by A. S. Atkinson. *Electric Traction Weekly*, v. 5, p. 919 (July 17, 1909). (Refers to street railways.)

THE COST AND SALE OF ELECTRIC POWER; by G. H. Kelsay. *Electric Railway Review*, v. 17, p. 126 (Jan. 26, 1907); *Street Railway Journal*, v. 29, p. 207 (Feb. 2, 1907). (Discusses interest and depreciation; paper read before the Central Electric Railway Association.)

THE COST OF CARRYING A PASSENGER; by C. L. S. Tingley. *Proceedings*, Street Railway Accountants Association, 1905, p. 163. (Table of allowances for depreciation from book by Philip Dawson, and comments on depreciation in street railway property.)

DEPRECIATION. (Editorial.) *Electric Railway Review*, v. 16, p. 452 (Aug., 1906). (Discusses depreciation in relation to street railways.)

DEPRECIATION. (Editorial.) *Electrical Review* (London), v. 61, p. 2 (July 5, 1907). (States that the definite and continued application of some reasonably probable approximation to the average depreciation of tangible assets is wanted in England and America.)

DEPRECIATION. (Editorial.) *Street Railway Journal*, v. 23, p. 760 (May 21, 1904). (A review of European practice.)

DEPRECIATION; by C. N. Duffy. *Electric Railway Journal*, v. 35, p. 184 (Jan. 29, 1910). (Brief abstract of discussion before the Wisconsin Electrical Association on depreciation in street railways.)

DEPRECIATION; by H. E. Weeks. Report of the Seventh Annual Convention, Iowa Street and Interurban Railway Association, p. 59 (1910). (Discusses the subject in general, length of life of property, etc.)

——Abstract. *Electric Railway Journal*, v. 35, p. 782 (April 30, 1910).

——Discussion. *Electric Railway Journal*, v. 35, p. 779 (April 30, 1910).

DEPRECIATION AND PERMANENT RENEWAL FUND. *Street Railway Bulletin*, v. 6, p. 298 (May, 1907). (Depreciation in street railways.)

DEPRECIATION AND PUBLICITY IN IOWA. *Electric Railway Review*, v. 19, p. 523 (May 2, 1908). (Resolution recommending provision of an annual appropriation for a depreciation reserve, separate from the maintenance account.)

STREET AND INTERURBAN RAILROADS—GENERAL—(*Continued*).

DEPRECIATION AND RENEWALS FUND IN RELATION TO TRAMWAYS UNDERtakings; by G. W. Holford. *Electrician*, v. 57, p. 938 (Sept. 28, 1906); *Electric Railway Review*, v. 16, p. 906 (Nov., 1906); *Electrical Engineer* (London), v. 38, p. 441 (Sept. 28, 1906); *Tramway and Railway World*, v. 20, p. 363 (Oct. 4, 1906). (Paper read before the Municipal Tramways Association; contains table showing provision made for depreciation in street railways in sixty cities in Great Britain.)

——Abstract. *Street Railway Journal*, v. 28, p. 529 (Oct. 6, 1906).

——Editorial. *Electric Railway Review*, v. 16, p. 887 (Nov., 1906).

DEPRECIATION AND SINKING FUNDS; by C. A. Smith. *Electric Railway Journal*, v. 40, p. 121 (July 27, 1912). (Refers to depreciation in street railway plants).

——*Canadian Engineer*, v. 23, p. 299 (Aug. 8, 1912).

DEPRECIATION AS APPLICABLE TO ELECTRIC RAILWAYS; by M. Haselmann. *Street Railway Journal*, v. 28, p. 1003 (Nov. 24, 1906). (Depreciation on railways of Continental Europe.)

——Discussion. *Street Railway Journal*, v. 24, p. 830 (Nov. 5, 1904).

DEPRECIATION AS APPLICABLE TO ELECTRIC RAILWAYS; by Robert N. Wallis. *Proceedings*, American Street and Interburban Electric Accountants Association, 1906, p. 168.

——Abstract. *Electric Railway Review*, v. 17, p. 526 (April 20, 1907).

——Editorial. Maintenance and Depreciation. *Electric Railway Review*, v. 17, p. 513 (April 20, 1907).

——Discussion. American Notions on Depreciation. *Electrical Review* (London), v. 60, p. 757 (May 10, 1907). (Discussion of a paper by R. N. Wallis.)

DEPRECIATION FROM A MANAGER'S POINT OF VIEW. *Stone and Webster Public Service Journal*, v. 1, p. 69 (Aug., 1907). (Method of allowing for depreciation in street railways; very brief.)

DEPRECIATION IN ELECTRIC RAILWAY ACCOUNTING; by Daniel Royse. Report of the Fifth Annual Convention, Iowa Street and Interurban Railway Association, p. 30 (1908). (Gives theory and classification of accounts; six pages.)

——Abstract. *Electric Railway Journal*, v. 31, p. 687 (April 25, 1908).

DEPRECIATION OF ELECTRIC RAILWAY EQUIPMENT. *Electric Traction Weekly*, v. 5, p. 736 (July 17, 1909). (Average percentage of first cost of various items of equipment to be set aside as an annual reserve to the depreciation fund for the renewal of these items.)

DEPRECIATION OF ELECTRIC RAILWAYS. (Editorial.) *Electrical Review and Western Electrician*, v. 55, p. 1 (July 3, 1909). (Life and annual percentage of depreciation for buildings, power plant equipment, track and paving; very brief.)

THE DEPRECIATION PROBLEM. (Letter); by H. S. Knowlton. *Street Railway Journal*, v. 24, p. 101 (July 16, 1904). (Considers the necessity of depreciation records.)

THE DEPRECIATION PROBLEM; by William B. Jackson. In "Electric Railway Transportation," p. 31. *Annals*, American Academy of Political and Social Science, v. 37, No. 1 (Jan., 1911). (Refers to depreciation in connection with the valuation of electric railways; eleven pages.)

——*Canadian Engineer*, v. 20, p. 353 (Feb. 23, 1911).

DEPRECIATION, RESERVES AND SINKING FUNDS; by W. O. Strangward. *Electric Railway Journal*, v. 40, p. 123 (July 27, 1912). (Discusses reserves for depreciation, renewals and obsolescence.)

DEPRECIATION, SOME THOUGHTS ON POLICY AND PRACTICE. *Municipal Journal* (London), v. 12, p. 773 (Aug. 28, 1903). (Comparison between Glasgow and Bolton systems of allowing for depreciation in street railroads.)

A DISCUSSION OF THE DEPRECIATION PROBLEM WITH PARTICULAR REFERence to Electric Railways; by William B. Jackson. *Engineering and Contracting*, v. 35, p. 176 (Feb. 8, 1911). (Two pages.)

THE ECONOMICAL LIFE OF CAR MOTORS. (Editorial.) *Electrical Review* (London), v. 63, p. 914 (Nov. 27, 1908). (One-half column.)

ELECTRIC RAILWAY ACCOUNTING; by A. L. Linn. *Electric Railway Journal*, v. 34, pp. 30, 36 (July 3, 1909). (Includes discussion on depreciation; abstract of paper read before the Street Railway Association of the State of New York.)

ELECTRIC RAILWAY APPRAISALS. (Editorial.) *Electric Railway Journal*, v. 30, p. 905 (Nov. 2, 1907). (Discusses object of appraisal, use of records, etc.; one page.)

STREET AND INTERURBAN RAILROADS—GENERAL—(*Continued*).

ELECTRIC RAILWAY APPRAISALS. (Editorial.) *Electric Railway Journal*, v. 31, p. 446 (March 21, 1908). (One column.)

ELECTRIC TRAMWAY ACCOUNTING AND FINANCE. *Electrical Review* (London), v. 61, p. 959 (Dec. 13, 1907). (Contains a brief reference to depreciation allowance.)

ELECTRICAL ENGINEER'S POCKET-BOOK, p. 498; by Horatio A. Foster. Edition 6. D. Van Nostrand Co., New York, 1905. (Contains table on approximate rate of depreciation on electric street railways.)

ENGINEERING AND ELECTRIC TRACTION POCKET-BOOK, p. 914; by Philip Dawson. Edition 4. John Wiley & Sons, New York, 1906. (Gives various tables including durability of railroad ties and approximate life of various parts of plant.)

EQUITABLE CHARGES FOR TRAMWAY SUPPLY; by H. E. Yerbury. *Journal*, Institution of Electrical Engineers, v. 44, p. 576 (1910). (Valuation cost of street railway plants as a basis for rates.)

——*Tramway and Railway World*, v. 27, p. 108 (Feb. 10, 1910).

FOR IMMEDIATE DEPRECIATION ACCOUNTS. (Editorial.) *Electric Railway Review*, v. 18, p 182 (Aug. 17, 1907). (On necessity of depreciation accounts for electric railways; one column.)

HOW SHOULD DEPRECIATION BE ENTERED ON THE BOOKS. (Editorial.) *Street Railway Review*, v. 14, p. 523 (Aug. 20, 1904). (Question as to whether property of street railway company should stand on books forever at the original cost or whether the account should be reduced from year to year to allow for depreciation.)

INTANGIBLE VALUE OF ELECTRIC RAILWAYS AND THEIR DETERMINATION From Accounts; by William J. Hagenah. *Proceedings*, American Electric Railway Accountants' Association, 1912, p. 60. (Elements of reproduction cost, analysis of accounts, economic waste of competition, discount on bonds, unacceptable deficits, and going costs.)

——Abstract. *Electric Railway Journal*, v. 40, pp. 698, 715 (Oct. 9, 1912).

——Editorial. *Stone and Webster Public Service Journal*, v. 11, p. 901 (Nov., 1912).

LOGICAL BASIS FOR VALUATIONS OF INTERURBAN STREET RAILWAYS; by C. G. Young. *Electric Railway Journal*, v. 37, p. 115 (Jan. 21, 1911). (Explains the purpose of valuation, discussing the fair rate of return, and the principal methods used in valuation of properties; three pages.)

——*Electric Traction Weekly*, v. 7, pp. 67, 99 (Jan. 21, 28, 1911).

——*Electrical Review and Western Electrician*, v. 58, p. 180 (Jan. 28, 1911).

——*Engineering News*, v. 65, p. 141 (Feb. 2, 1911).

——Discussion. *Electric Railway Journal*, v. 37, p. 162 (Jan. 28, 1911).

OBSOLESCENCE IN CARS. (Editorial.) *Electric Railway Journal*, v. 40, p. 239 (Aug. 17, 1912). (The effect on valuation of changing from old to new equipment.)

POLICY OF ENGLISH MUNICIPAL TRAMWAYS RESPECTING RENEWALS. *Electric Railway Journal*, v. 38, p. 661 (Oct. 7, 1911). (Abstract of Finance and Policy, by James H. Rodgers; paper read before the Municipal Tramways Association.)

QUESTION BOX OF THE CENTRAL ELECTRIC RAILWAY ACCOUNTANTS ASSOciation. *Electric Railway Journal*, v. 39, p. 742 (May 4, 1912). (How to determine the actual value of stocks and bonds.)

REDUCING THE COST OF DEPRECIATION ON ELECTRIC RAILWAYS; by A. S. Atkinson. *Street Railway Bulletin*, v. 6, p. 80 (Feb., 1907). (One and one-half pages.)

REPORT OF SUB-COMMITTEE ON WHAT CONSTITUTES MAINTENANCE. *Proceedings*, American Electric Railway Engineering Association, 1911, p. 342. (Includes discussion referring to depreciation.)

——Abstract. *Electric Railway Journal*, v. 38, p. 766 (Oct. 12, 1911).

RESOLUTION ON DEPRECIATION AND PUBLICITY. *Street Railway Journal*, v. 31, p. 789 (May 9, 1908). (Resolutions of the Iowa Street and Interurban Association; very brief.)

ROLLING STOCK DEPRECIATION. (Editorial.) *Street Railway Journal*, v. 30, p. 240 (Aug. 17, 1907).

SOME FUNDAMENTAL CONSIDERATIONS IN DEPRECIATION. (Editorial.) *Electric Railway Review*, v. 17, p. 144 (Feb. 2, 1907). (Method of accounting for depreciation.)

STREET AND INTERURBAN RAILROADS—GENERAL—(*Continued*).

SPECIAL REPORTS, STREET AND ELECTRIC RAILWAYS, 1907, p. 165. United States Bureau of the Census. Washington, 1910. (Definition, object and methods allowing for depreciation in electric railway property and estimated per cent. for depreciation allowed by the Chicago Union Traction Co., the Third Avenue R. R. of New York, and the Milwaukee Electric Ry. & Light Co.)

STREET RAILWAY ACCOUNTING; by A. S. Michenner. *Stone and Webster Public Service Journal*, v. 3, p. 92 (Aug., 1908). (Paper read before the Massachusetts Institute of Technology; refers to classification of accounts, including allowance for depreciation.)

A THEORETICAL BASIS FOR DETERMINING FARES ON PROPERTIES HAVING Annual Gross Earnings of from $100 000 to $5 000 000; by C. N. Duffy. *Proceedings*, American Electric Railway Association, 1912, p. 246. (Data on cost of providing the service.)

——Abstract. *Electric Railway Journal*, v. 40, p. 1103 (Nov. 30, 1912).

TRAMWAY DEPRECIATION; by A. J. J. Pfeiffer. *Tramway and Railway World*, v. 28, p. 61 (Aug. 4, 1910). (A discussion of the subject from the viewpoint of conditions in Great Britain; theoretical.)

TRAMWAYS DEPRECIATION. (Editorial.) *Municipal Journal* (London), v. 11, p. 287 (April 4, 1902). (Discussion of necessary allowance for depreciation in street railways.)

TREATMENT OF DEPRECIATION OF STREET RAILWAY PROPERTIES; by Frank R. Ford. *Engineering-Contracting*, v. 38, p. 560 (June 15, 1910). (From a paper read before the American Street and Interurban Railway Association, January, 1910; three pages.)

——*Electric Railway Journal*, v. 35, p. 284 (Feb. 12, 1910).

*UNIFORM CLASSIFICATION OF ACCOUNTS FOR ELECTRIC RAILWAYS, PRE- scribed by the Railroad Commission of Wisconsin, January, 1909. Edition 2. Madison, Wis., 1912. (Includes treatment of reserve accounts, depreciation, sinking fund and amortization.)

VALUATION AND RATES. (Editorial.) *Street Railway Journal*, v. 30, p. 307 (Aug. 31, 1907). (On the similarity of street and steam railroad valuation; one and one-half columns.)

VALUATION OF A SHORT-TERM FRANCHISE. (Editorial.) *Electric Railway Review*, v. 17, p. 313 (March 9, 1907). (Should reconstruction and renewals be charged to capital accounts or provided for out of earnings, etc.)

VALUATION OF INTANGIBLE STREET RAILWAY PROPERTY; by Frank R. Ford. In "Electric Railway Transportation," p. 119. *Annals*, American Academy of Political and Social Science, v. 37, No. 1 (Jan., 1911). (Twenty-two pages.)

WHERE MAINTENANCE ENDS AND DEPRECIATION BEGINS; by J. H. Neal. *Proceedings*, American Street and Interurban Railway Accountants' Association, 1907, p. 195. (Discusses the relation between maintenance and depreciation.)

——*Street Railway Journal*, v. 30, p. 700 (Oct. 19, 1907).

WORK OF VALUATION OF ELECTRIC RAILWAY PROPERTY; by H. R. Ralph Badger. *Electric Traction Weekly*, v. 6, p. 197 (Feb. 19, 1910). (Methods of determining physical and intangible values.)

United States Interstate Commerce Commission.

ACCOUNTING CIRCULAR OF THE INTERSTATE COMMERCE COMMISSION. *Electric Railway Review*, v. 19, p. 266 (Feb. 29, 1908). (Classification of accounts for electric railways, including depreciation accounts, from Circular No. 20 of the U. S. Interstate Commerce Commission.)

ACCOUNTING FOR DEPRECIATION AS PRESCRIBED BY THE INTERSTATE COMmerce Commission. (Editorial.) *Electric Railway Review*, v. 18, p. 32 (July 13, 1907). (Comments on paper by H. J. Davies, who outlined a method of providing for depreciation or renewal reserves for an electric railway.)

CONFERENCE ON STANDARD ACCOUNTS WITH THE INTERSTATE COMMERCE Commission. *Street Railway Journal*, v. 31, p. 860 (May 23, 1908). (Tentative classification of operating expenses of electric railways.)

HEARING ON DEPRECIATION OF EQUIPMENT ACCOUNTS. *Street Railway Bulletin*, v. 7, p. 390 (July, 1908). (Committee of the American Railway Association; hearing before the Interstate Commerce Commission.)

THE INTERSTATE COMMERCE CLASSIFICATION. (Letter); by H. M. Kochersperger. *Street Railway Journal*, v. 31, p. 729 (May 2, 1908). (On the inapplicability of the classification to electric railways.)

INTERSTATE COMMERCE CLASSIFICATION. (Letter); by Thomas Yapp, Assistant Secretary, Minnesota Railroad and Warehouse Commission. *Electric Railway Journal*, v. 32, p. 124 (June 20, 1908). (Contains opinion on depreciation accounts.)

STREET AND INTERURBAN RAILROADS—GENERAL—(*Continued*).

THE INTERSTATE COMMERCE CLASSIFICATION OF ACCOUNTS. (Letter); by W. W. May. *Street Railway Journal*, v. 31, p. 613 (April 11, 1908). (Objections to the system of accounting prescribed in Accounting Circular No. 20, U. S. Interstate Commerce Commission.)

MILWAUKEE ELECTRIC RAILWAY & LIGHT COMPANY'S REPLY TO ACCOUNTing Circular; by C. N. Duffy. *Electric Railway Journal*, v. 19, p. 419 (April 4, 1908). (Reply to Accounting Series Circular No. 20 of the U. S. Interstate Commerce Commission.)

REPORT ON INTERSTATE ACCOUNTING SYSTEM; by H. E. Adams. *Electric Railway Journal*, v. 34, p. 218 (Aug. 7, 1909). (Statement regarding the classification of accounts of electric railways required by the Interstate Commerce Commission with paragraphs on depreciation and valuation.)

REVISED CLASSIFICATION OF ACCOUNTS FOR ELECTRIC RAILWAYS. *Electric Railway Review*, v. 19, p. 624 (May 23, 1908). (Classification of the Inter-State Commerce Commission, effective as of Oct. 1, 1908.)

SUIT AGAINST CLASSIFICATION OF ADDITIONS AND BETTERMENTS OF THE Interstate Commerce Commission. *Electric Railway Journal*, v. 38, p. 1067 (Nov. 18, 1911). (One-half column.)

STREET AND INTERURBAN RAILROADS—SPECIAL CASES.

Augusta-Aiken Ry. & Electric Co.

INSURANCE FUND AND DEPRECIATION RESERVES. (Letter); by John Blair MacAfee. *Street Railway Review*, v. 15, p. 292 (May 15, 1905). (Plans of the Augusta-Aiken Ry. & Electric Co. for taking care of depreciation.)

Boston Elevated Ry.

HEARING ON ELECTRIC RAILWAY MAIL PAY. *Electric Railway Journal*, v. 41, p. 291 (Feb. 15, 1913). (Details of estimated cost of operation of present type of mail car on Boston Elevated Ry.; car, power, track investment, etc.; includes per cent. allowed for depreciation in each case.)

Brooklyn, N. Y.

ALLOWANCE FOR OBSOLESCENCE UPHELD IN FRANCHISE TAX CASE. *Electric Railway Journal*, v. 36, p. 1154 (Dec. 10, 1910). (Decision of New York Supreme Court in favor of Brooklyn Rapid Transit Co.; one-half page.)

APPROXIMATE VALUE PLACED ON PHYSICAL PROPERTY OF BROOKLYN Transit System. *Electric Railway Journal*, v. 34, p. 1261; v. 35, pp. 156, 248 (Dec. 25, 1909; Jan. 22, Feb. 5, 1910). (Testimony of B. J. Arnold and T. S. Williams before New York Public Service Commission.)

HEARING ON VALUATION OF CONEY ISLAND AND BROOKLYN R. R. *Electric Railway Journal*, v. 34, pp. 377, 398, 437, 469, 878, 1108, 1148, 1188, 1263; v. 35, pp. 104, 460 (Sept. 4, 11, 18, 25, Oct. 16, Nov. 27, Dec. 4, 11, 25, 1909; Jan. 15, March 12, 1910). (Hearing before the New York Public Service Commission, First District.)

MAY RESERVE FUND TO RENEW OBSOLETE EQUIPMENT. *Electric Traction Weekly*, v. 6, p. 1473 (Dec. 31, 1910). (Decisions of the Supreme Court at Albany that there may be a deduction for obsolescence as distinguished from depreciation in connection with the valuation of special franchise of the Brooklyn Rapid Transit Co.)

***RE MacREYNOLDS V. BROOKLYN UNION ELEVATED RAILROAD COMPANY** (Case 353). Reports and Decisions of the Public Service Commission, First District of the State of New York, v. 2, p. 246. New York, 1912. (Relation of fares and the valuation of Brooklyn Union Elevated R. R. Co.)

***RE MONHEIMER V. CONEY ISLAND & BROOKLYN RAILROAD COMPANY** (Case 350). Reports and Decisions of the Public Service Commisison, First District of the State of New York, v. 1 p. 705. New York, 1912. (Valuation of the Coney Island & Brooklyn R. R. Co. in relation to fares.)

*——A Ten-cent Fare to Coney Island Upheld by Public Service Commission. *Electric Railway Journal*, v. 35, p. 456 (March 12, 1912). (Decision of Commission after considering the testimony as to the value of the Brooklyn Rapid Transit Co.)

THEORY OF STREET RAILWAY RATE REGULATION AS DEVELOPED IN THE Coney Island Fare Case; by Frank R. Ford. *Proceedings*, American Street and Interurban Railway Association, v. 29, p. 159 (1910). (On valuation; twelve pages.)

——*Electric Railway Journal*, v. 36, pp. 712, 752 (Oct. 12, 1910).

STREET AND INTERURBAN RAILROADS—SPECIAL CASES—(*Continued*).

Buffalo, N. Y.

DEPRECIATION CHARGES OF THE INTERNATIONAL TRACTION COMPANY. (Editorial.) *Electric Railway Review*, v. 19, p. 472 (April 18, 1908). (The definite policy of the International Traction Co. of Buffalo, in accounting currently for depreciation.)

FURTHER TESTIMONY IN BUFFALO REORGANIZATION CASE; by F. A. Sager. *Electric Railway Journal*, v. 39, p. 246 (Feb. 10, 1912). (Reviews methods followed in the inventory of the physical property of the International Traction Co.)

HEARING IN BUFFALO ON INTERNATIONAL TRACTION REORGANIZATION. *Electric Railway Journal*, v. 38, pp. 910, 991 (Oct. 21, Nov. 4, 1911). (An account of the methods used by B. J. Arnold in determining the cost to produce new the physical property of the International Traction Co. of Buffalo.)

——Editorial. Values Claimed by the Buffalo Plan. *Electric Railway Journal*, v. 38, p. 976 (Nov. 4, 1911).

California.

***ORDER OF CALIFORNIA COMMISSION REQUIRING VALUATIONS OF ELECTRIC** Railways. *Electric Railway Journal*, v. 40, p. 1027 (Nov. 16, 1912).

Cardiff, Wales.

CARDIFF TRAMWAYS FINANCE. *Electrical Engineer*, v. 44, p. 879 (Dec. 24, 1909). (Discusses depreciation of electric railway at Cardiff.)

DEPRECIATION, INTERESTING REPORT FROM CARDIFF. *Municipal Journal* (London), v. 16 p. 1083 (Dec. 20, 1907). (Allowance for depreciation considered to represent fair wear and tear.)

DEPRECIATION OF CARDIFF ELECTRIC TRAMWAY AND LIGHTING UNDERTAKings. *Electric Railway Review*, v. 19, p. 16 (Jan. 4, 1908). (Abstract from *Electrical Engineer* (London) giving details of depreciation of equipment.)

DEPRECIATION OF CARDIFF PROPERTIES. *Electric Railway Journal*, v. 36, p. 409 (Sept. 10, 1910). (Brief report on the street railway of Cardiff in relation to depreciation.)

TRACK DEPRECIATION AT CARDIFF; by John Allcock. *Tramway and Railway World*, v. 27, p. 30 (Jan. 6, 1910). (Brief statement.)

Chicago, Ill.

THE BASIS OF VALUATION IN THE CASE OF MUNICIPAL PURCHASE OF STREET Railways; by Sidney Ossoski. *Electric Railway Journal*, v. 36, p. 999 (Nov. 12, 1910). (Discusses methods of valuation using street railways of Chicago and Cleveland as examples; two pages.)

CHICAGO ELEVATED RAILWAY VALUATION. *Electric Railway Journal*, v. 39, p. 1087 (June 22, 1912). (Elements entering into the value of each piece of property in real estate valuation.)

——Abstracts. Reports of Appraisal of the Physical Properties of the Elevated Railways of Chicago. *Engineering and Contracting*, v. 37 (May 15, 1912); The Valuation of the Elevated Railroads of Chicago. *Engineering Record*, v. 65, p. 552 (May 18, 1912).

——Editorial. *Engineering Record*, v. 65, p. 534 (May 18, 1912). (Very brief.)

CHICAGO ELEVATED RAILWAYS, REPORT ON VALUATION OF PHYSICAL Property Including Real Estate and Rights of Way of the South Side Elevated Railroad Company, Metropolitan West Side Elevated Railway Company, Northwestern Elevated Railroad Company and Chicago & Oak Park Elevated Railroad Company, to the Local Transportation Committee of the City Council of Chicago, April 30, 1912, Reprinted May 9, 1912, with the Addition of the Final Figures of the Valuation Commission; by George F. Swain. Chicago, 1912.

CHICAGO ELEVATED RAILWAYS VALUATION. *Electric Railway Journal*, v. 39, p. 919 (June 1, 1912). (Analysis of right-of-way values.)

CHICAGO VALUATIONS — AGREEMENTS TO TERMS BY COMPANIES. *Electric Railway Journal*, v. 28, p. 1164 (Dec. 22, 1906). (Abstract of the report of B. J. Arnold, M. E. Cooley and A. B. du Pont, on valuation of the Chicago City Ry. Co. and the Chicago Union Traction Co.)

DEPRECIATION AND CHICAGO VALUATION FIGURES. (Editorial Correspondence.) *Electric Traction Weekly*, v. 8, p. 584 (May 18, 1912).

DETAILED EXHIBITS OF THE TANGIBLE PROPERTY OF THE CHICAGO CITY Railway Company as of June 30, A. D. 1906, Accompanying the Valuation Report Submitted to the Committee on Local Transportation of the Chicago City Council; by Bion J. Arnold, Mortimer E. Cooley and A. B. du Pont. Chicago, 1906.

STREET AND INTERURBAN RAILROADS—SPECIAL CASES—(*Continued*).

DETAILED EXHIBITS OF THE TANGIBLE PROPERTY OF THE STREET RAILWAY System in the Possession of and Operated by the Receivers of the Chicago Union Traction Company as of June 30, A. D. 1906, Accompanying the Valuation Report Submitted to the Committee on Local Transportation of the Chicago City Council; by Bion J. Arnold, Mortimer E. Cooley and A. B. du Pont. Chicago, 1906.

ELEMENTS OF VALUE IN A STREET RAILWAY. *Railroad Gazette*, v. 41, p. 567 (Dec. 28, 1906). (Valuation of the Chicago street railways by a commission prior to their purchase by the city; one page.)

ELEVATED VALUES IN CHICAGO. (Editorial.) *Electric Railway Journal*, v. 39, p. 817 (May 18, 1912).

ESTIMATED COST OF CABLE RAILWAYS IN CHICAGO. *Engineering and Contracting*, v. 37, p. 338 (March 20, 1912). (Cost of reproducing cable railway new as estimated by Bion J. Arnold.)

ITEMIZED UNIT COSTS OF 98 SPECIAL OVERHEAD LAYOUTS FOR A TROLLEY Railway. *Engineering-Contracting*, v. 34, p. 335 (Oct. 19, 1910). (Inventory made by the Traction Valuation Commission of Chicago.)

MAINTENANCE AND DEPRECIATION CHARGES OF THE CHICAGO UNION TRACtion Company. *Electric Railway Review*, v. 17, p. 247 (Feb. 23, 1907). (The policy of the City of Chicago, in allowing for depreciation in street railway property.)

——Editorial. Amount of Maintenance and Depreciation Charges. *Electric Railway Review*, v. 17, p. 244 (Feb. 23, 1907).

METHODS OF CONDUCTING THE VALUATION OF THE PHYSICAL PROPERTIES of the Chicago Consolidated Traction Co., with Summaries of Costs; by Philip J. Kealy. *Engineering-Contracting*, v. 34, pp. 274, 295 (Sept. 28, Oct. 5, 1910). (The valuation covers only that portion of the system within the city limits; describes methods and costs of track and power-house valuation and data of the electric power distribution.)

OPERATIONS OF THE COMPANIES UNDER THE 1907 ORDINANCES (CHICAGO). *Electric Railway Journal*, v. 40, p. 525 (Oct. 5, 1912). (Comparative values of street railways of Chicago, Commission's and Companies' estimates.)

RENEWALS AS DEFINED BY THE BOARD OF SUPERVISING ENGINEERS, CHIcago Traction. *Electric Railway Journal*, v. 37, p. 374 (March 4, 1911). (Classification of renewals of track, equipment, buildings and bridges.)

REPORT ON THE ENGINEERING AND OPERATING FEATURES OF THE CHICAGO Transportation Problem, Submitted to the Committee on Local Transportation of the Chicago City Council, p. 182; by Bion Joseph Arnold. Chicago, 1902. (Gives unit price estimates, valuation estimates, valuations under expiring grants, and cost of estimates; fifty-five pages.)

REPORT ON THE PHYSICAL PROPERTIES AND INTANGIBLE VALUES OF THE Calumet Electric Street Railway Company and the South Chicago City Railway Company as of February 1, A. D. 1908, Submitted to the Committee on Local Transportation of the Chicago City Council; by Bion J. Arnold. Chicago, 1908. 3 v. (General summary of value of physical property and detailed exhibits.)

STREET RAILWAY APPRAISAL METHODS AT CHICAGO. (Editorial.) *Engineering Record*, v. 62, p. 501 (Oct. 29, 1910). (Four columns.)

TWO REPORTS SUBMITTED TO COUNCIL COMMITTEE ON VALUES OF CHICAGO Elevated Railways. *Electric Railway Journal*, v. 39, p. 797 (May 11, 1912). (Comparison of reports by George F. Swain and the one submitted by the Harbor and Subway Commission.)

UNIT PRICES USED IN THE FIRST APPRAISAL OF ELECTRIC RAILWAYS IN Chicago. *Engineering and Contracting*, v. 37, p. 393 (April 3, 1912). (Detailed estimate of cost of street railway property in Chicago.)

VALUATION OF THE PROPERTY OF THE CHICAGO CONSOLIDATED TRACTION Co.; by B. J. Arnold and George W. Weston. *Engineering News*, v. 64, p. 241 (Sept. 1, 1910). (Short paragraph.)

VALUATION OF TWO STREET RAILWAY POWER PLANTS. *Engineering-Contracting*, v. 34, p. 280 (Sept. 28, 1910). (Part of the property of the Chicago Consolidated Traction Co.; two pages.)

VALUATION REPORTS ON CHICAGO ELEVATED ROADS. (Editorial Correspondence.) *Electric Traction Weekly*, v. 8, p. 556 (May 11, 1912).

VALUATIONS OF CHICAGO ELEVATED RAILWAYS. *Electric Railway Journal*, v. 39, p. 829 (May 18, 1912). (Detail figures and summaries of the explanatory statements made in connection with the two valuations.)

VALUE OF PROPERTY OF THE CHICAGO CONSOLIDATED TRACTION COMpany. *Electric Railway Journal*, v. 36, pp. 309, 374, 1111 (Aug. 20, Sept. 3, Dec. 3, 1910). (Valuation made by Bion J. Arnold and George W. Weston.)

STREET AND INTERURBAN RAILROADS—SPECIAL CASES—(*Continued*).

Cleveland, Ohio.

ARBITRATION OF OPERATING EXPENSE CHARGES IN CLEVELAND. *Electric Railway Journal*, v. 41, p. 925 (May 24, 1913). (Includes brief reference to depreciation of the railway plant and maintenance, renewal and depreciation fund.)

DECISION OF ARBITRATOR IN CLEVELAND CONTROVERSY. *Electric Railway Journal*, v. 34, p. 1237 (Dec. 25, 1909). (Findings of Judge Taylor in the Cleveland Street Railway valuation.)

DECISION OF BOARD OF ARBITRATION IN THE CLEVELAND CASE. *Electric Railway Journal*, v. 41, p. 1159 (June 28, 1913). (Text of the finding, including allowance for maintenance, renewal and depreciation.)

——Editorial. The Arbitrated Result in Cleveland. *Electric Railway Journal*, v. 41, p. 1134 (June 28, 1913).

DEPRECIATION IN CLEVELAND. *Street Railway Journal*, v. 29, p. 743 (April 27, 1907). (On depreciation of track and cars; abstract from report of the Cleveland Electric Ry. Co.)

FINAL TESTIMONY AND ARGUMENTS IN THE CLEVELAND CASE. *Electric Railway Journal*, v. 41, p. 1070 (June 14, 1913). (Depreciation in the value of the property shown by tables submitted by Henry J. Davies.)

MAINTENANCE PROVISIONS OF CLEVELAND ORDINANCE; by H. J. Davies. *Electric Railway Journal*, v. 35, p. 614 (April 2, 1910). (Provisions for maintenance of physical property of Cleveland Ry. Co. determined in granting new franchise ordinance.)

OPERATION OF THE CLEVELAND STREET RAILWAY SYSTEM BY A NEW COMPANY. *Electric Railway Journal*, v. 32, p. 433 (Aug. 8, 1908). (Provisions for maintenance and renewal fund in lease.)

TESTIMONY IN CLEVELAND VALUATION. *Electric Railway Journal*, v. 34, pp. 1024, 1068, 1159 (Nov. 13, 20, Dec. 4, 1909). (Opinions on valuation of the Cleveland Street Railway given by Frank R. Ford, Bion J. Arnold and others before Judge Taylor of the United States Circuit Court.)

VALUATION OF THE CLEVELAND ELECTRIC RAILWAY. *Electric Railway Review*, v. 19, p. 149 (Feb. 1, 1908). (Values of physical property, overhead charges, franchises, etc.; two pages.)

Detroit, Mich.

APPRAISAL OF THE CITY LINES OF THE DETROIT UNITED RAILWAY. *Electric Railway Journal*, v. 41, p. 897 (May 17, 1913). (Methods and summary of valuation.)

REPORT AND APPRAISAL OF THE DETROIT UNITED RAILWAY (CITY LINES), Detroit, Michigan, Oct. 1, 1909; by Frederick T. Barcroft. Detroit, 1910. (Contains brief data on method of making appraisal.)

——Abstract. The Appraisal Value of the Electric Street Railways of Detroit, Mich. *Engineering-Contracting*, v. 34, pp. 16, 35 (July 6, 13, 1910).

——Editorial. Noteworthy Article on Electric Street Railway Appraisal. *Engineering-Contracting*, v. 34, p. 1 (July 6, 1910).

REPORT OF THE COMMITTEE OF FIFTY. *Electric Railway Journal*, v. 36, pp. 111, 142 (July 16, 23, 1910). (Abstract of report of Committee to investigate Detroit Street Railway situation; contains brief references to the appraisal.)

REPORTS ON VALUATION OF DETROIT PROPERTY. *Electric Railway Journal*, v. 34, p. 1077 (Nov. 20, 1909). (Brief comparison of the valuations made by F. T. Barcroft and R. B. Rifenberick.)

RESULTS OF DETROIT INVESTIGATION. *Electric Railway Journal*, v. 34, p. 1276 (Dec. 25, 1909). (Concerning reports received by the Committee of Fifty on the street railway valuation.)

A STATEMENT OF "FACTS" CONCERNING THE SO-CALLED "BARCROFT Appraisal" of the Detroit United Railway Lines in the City of Detroit; by R. B. Rifenberick. Detroit, Mich., 1910. (A criticism of Mr. Barcroft's methods.)

THE VALUATION OF THE DETROIT STREET RAILWAYS. *Engineering News*, v. 64, p. 212 (Aug. 25, 1910). (An explanation of the situation with comparison of valuations made for the City with those for the Company; two pages.)

VALUATION OF THE TRACK OF THE DETROIT STREET RAILWAY SYSTEM. *Engineering News*, v. 64, p. 249 (Sept. 8, 1910). (Explains methods used in track valuation, including estimated value of twenty-one types of rail sections; one page.)

VALUATIONS OF THE DETROIT UNITED RAILWAY. *Electric Railway Journal*, v. 36, pp. 258, 294 (Aug. 13, 20, 1910). (Review of the facts, statement of the position of the Company regarding the Barcroft appraisal, brief abstract of the Barcroft appraisal, and a statement by R. B. Rifenberick.)

STREET AND INTERURBAN RAILROADS—SPECIAL CASES—(*Continued*).

Duluth, Minn.

DECISION OF WISCONSIN COMMISSION IN SUPERIOR CASES. *Electric Railway Journal*, v. 40, p. 1067 (Nov. 23, 1912). (Data on valuation of property of Duluth Street Ry. Co.)

Eastern Ry. & Light Co. See Fond du Lac, Wis.

Europe.

DEPRECIATION AS APPLICABLE TO ELECTRIC RAILWAYS; by Haselmann. *Electric Railway Journal*, v. 28, p. 1003 (Nov. 24, 1906). (Abstract of a paper read before the International Street and Interurban Railway Association giving methods of depreciation accounting in Europe; three pages.)

DEPRECIATION FUNDS IN EUROPE. *Electric Railway Journal*, v. 23, p. 696 (May 7, 1904). (Gives allowances made for depreciation.)

——Editorial. Depreciation. *Electric Railway Journal*, v. 23, p. 760 (May 21, 1904).

Fond du Lac, Wis.

***EXISTING FARES OF WISCONSIN ROAD UPHELD BY COMMISSION AFTER A** Valuation. *Electric Railway Journal*, v. 38, p. 193 (July 9, 1911). (Valuation of electric railway properties and division of valuation between city and interurban systems; decision of the Railroad Commission of Wisconsin in a fare case involving the Eastern Ry. & Light Co. of Fond du Lac.)

Fonda, Johnstown & Gloversville R. R.

LIFE OF RAILWAY PHYSICAL PROPERTY FROM THE ENGINEERING STANDpoint; by F. A. Bagg. *Electric Railway Journal*, v. 38, p. 1205 (Dec. 9, 1911). (Paper read before Street Railway Association of State of New York; discusses life of track and overhead lines and gives data regarding Fonda, Johnstown & Gloversville R. R.; one page.)

——Discussion. *Electric Railway Journal*, v. 38, p. 1210 (Dec. 9, 1911).

Glasgow, Scotland.

DEPRECIATION. (Editorial.) *Electrician*, v. 61, p. 744 (Aug. 28, 1908). (Practice of Glasgow Corporation Tramways.)

GLASGOW AND DEPRECIATION. *Municipal Journal* (London), v. 12, p. 795 (Sept. 4, 1903). (Very brief itemized statement of allowance for depreciation by Glasgow Corporation Tramways.)

GLASGOW TRAMWAYS. *Municipal Journal* (London), v. 14, p. 896 (Aug. 11, 1905). (Analysis of accounts of Glasgow Tramways, including allowance for depreciation.)

TREATMENT OF DEPRECIATION IN GLASGOW. *Electric Railway Journal*, v. 36, p. 362 (Sept. 3, 1910). (Discussion of the treatment of depreciation in accounts in report of the Glasgow Corporation Tramways.)

VALUATION OF GLASGOW TRAMWAYS. *Tramway and Railway World*, v. 27, p. 353 (May 5, 1910). (Decision in the appeal of the Glasgow Corporation Tramways against compulsory valuation.)

Great Britain.

B. E. T. DEPRECIATION. *Municipal Journal* (London), v. 16, p. 449 (May 24, 1907); v. 17, p. 459 (June 5, 1908). (Per cent. allowed for depreciation by sixteen British street railway companies.)

DEPRECIATION AND PERMANENT RENEWAL FUND; by William R. Bowker. *Street Railway Bulletin*, v. 6, p. 298 (May, 1907). (On the amount to be allowed for depreciation in street railroad property, giving cities of Manchester, Glasgow, Leeds, Bolton, and Wolverhampton, as examples.)

POLICY OF ENGLISH MUNICIPAL TRAMWAYS RESPECTING RENEWALS. *Electric Railway Journal*, v. 38, p. 661 (Oct. 7, 1911). (Two pages.)

RULES ON DEPRECIATION IN GREAT BRITAIN. *Electric Railway Journal*, v. 34, p. 476 (Sept. 25, 1909). (Allowances for depreciation in electric railway undertakings; one page.)

Illinois.

REPORT OF THE ILLINOIS TRACTION SYSTEM. (Editorial.) *Electric Railway Journal*, v. 36, p. 353 (Sept. 3, 1910). (Refers to annual allowance for depreciation.)

Kansas City, Mo.

DEPRECIATION CHARGES IN KANSAS CITY. (Editorial.) *Electric Railway Journal*, v. 36, p. 424 (Sept. 17, 1910). (On provision for depreciation made by the Kansas City Ry. & Light Co.; one paragraph.)

REPORT ON STREET RAILWAY SYSTEM OF KANSAS CITY. *Electric Railway Journal*, v. 41, p. 716 (April 19, 1913). (An investigation of the valuation of the property and its apportionment between the different municipalities.)

STREET AND INTERURBAN RAILROADS—SPECIAL CASES—*(Continued)*.

REPORT ON THE VALUE OF THE PROPERTIES OF THE METROPOLITAN STREET Railway System of Kansas City, v. 1; by Bion J. Arnold. Kansas City, Mo., 1913. (Report of Commission to investigate the capital value of the properties, various elements of such value, and how it shall be apportioned between the municipalities in a contract for a new franchise.)

A STREET-RAILWAY VALUATION. *Engineering News*, v. 69, p. 1053 (May 22, 1913). (Valuation of the street railway lines of Kansas City, Mo., by Bion J. Arnold; values found and various elements thereof and comparison with the values computed under four different methods.)

Kokomo, Marion & Western Traction Co.

DEPRECIATION ACCOUNT OF THE KOKOMO, MARION & WESTERN TRACTION Company. *Electric Railway Journal*, v. 38, p. 156 (July 22, 1911). (An arbitrary charge of a certain per cent. against each class or division of the property was adopted, to provide for current replacements and future requirements on account of losses due to age and wear; about the same percentages as are used by the Wisconsin Railroad Commission; one page.)

Lincoln, Nebr.

***TESTIMONY ON DEPRECIATION BEFORE NEBRASKA COMMISSION;** by Edward W. Bemis. *Electric Railway Journal*, v. 35, p. 441 (March 12, 1910). (Testimony in relation to the consolidation of the properties comprising the Lincoln Traction Co.)

London, England.

LONDON TRAMWAY DEPRECIATION ALLOWANCE FOR INCOME TAX. *Electric Railway Journal*, v. 35, p. 274 (Feb. 12, 1910). (Very brief statement.)

Middlesex & Boston Street Ry.

LIABILITIES ON WHICH PROPER RETURNS SHOULD BE ALLOWED. *Electric Railway Journal*, v. 34, p. 464 (Sept. 25, 1909). (Hearing before Massachusetts Board of Railroad Commissioners; discussion of the basis on which the value of the property of the Middlesex & Boston Street Ry. should be computed.)

Milwaukee Electric Ry. & Light Co.

***DECISION IN THE MILWAUKEE FARE CASE.** *Electric Railway Journal*, v. 40, p. 314 (Aug. 31, 1912). (Gives summary of physical valuation, going value, treatment of allowance for depreciation, rate of return, etc., of Milwaukee Light, Heat & Traction Co. and Milwaukee Electric Ry. & Light Co.)

DEPRECIATION AND RESERVE FUNDS IN MILWAUKEE. (Editorial.) *Street Railway Journal*, v. 26, p. 441 (Sept. 23, 1905). (Gives actual figures.)

DEPRECIATION OF PUBLIC UTILITIES PROPERTIES. *Electric Railway Journal*, v. 31, p. 169 (Feb. 1, 1908). (On the subject of depreciation in general, with reference to Milwaukee street railways.)

——Editorial. Depreciation. *Electric Railway Journal*, v. 31, p. 104 (Jan. 25, 1908).

DEPRECIATION RESERVES OF THE MILWAUKEE AND ST. LOUIS RAILWAYS. *Electric Railway Review*, v. 17, p. 319 (March 9, 1907). (Comparison of totals of maintenance and depreciation charges for fiscal year 1906, for street railways in Milwaukee, St. Louis, Chicago, and Glasgow.)

A DISCUSSION OF THE MILWAUKEE FARE DECISION. *Electric Railway Journal*, v. 41, p. 110 (Jan. 18, 1913). (Discusses valuation of Milwaukee street railway.)

THE ELECTRIC RAILWAY SYSTEM OF MILWAUKEE AND EASTERN WISCONSIN. *Street Railway Journal*, v. 15, p. 352 (June, 1899). (Provision of the Milwaukee Electric Ry. & Light Co., for depreciation and other reserves.)

——Editorial. *Street Railway Journal*, v. 15, p. 369 (June, 1899).

***HEARINGS ON MILWAUKEE FARE CASE BY WISCONSIN RAILROAD COM**mission. *Electric Railway Journal*, v. 32, p. 395; v. 33, pp. 419, 464, 499, 554, 640, 683, 729, 766, 955 (Aug. 1, 1908; March 6, 13, 20, 27; April 3, 10, 17, 24; May 22, 1909). (Testimony by many experts on the value of the Milwaukee Electric Ry. & Light Co.'s property, allowances for depreciation, etc.)

——Editorial. *Electric Railway Journal*, v. 33, pp. 452, 536 (March 13, 27, 1909).

THE MILWAUKEE FOUR-CENT FARE DECISION. *Street Railway Journal*, v. 14, p. 397 (July, 1898). (Opinions of William H. Seaman, United States District Judge, in the case of the Milwaukee Electric Ry. & Light Co.; three pages.)

——Editorial. *Street Railway Journal*, v. 14, p. 381 (July, 1898).

STREET AND INTERURBAN RAILROADS—SPECIAL CASES—(*Continued*).

VALUATION OF MILWAUKEE PROPERTIES. *Electric Railway Journal*, v. 38, p. 160 (July 22, 1911). (Details of the values placed on the property of the Milwaukee Electric Ry. & Light Co. by the Railroad Commission of Wisconsin; very brief.)

——Editorial. *Electric Railway Journal*, v. 38, p. 143 (July 22, 1911).

Milwaukee Northern Ry. Co.

***EDWARD J. CHROMASTER VS. MILWAUKEE NORTHERN RAILWAY COMPANY;** Submitted May 15, 1911, Decided March 12, 1912. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 8, p. 734. Madison, Wis., 1912. (Table of total valuation of property of Milwaukee Northern Ry. Co. and apportionment between city and interurban.)

Nebraska.

***PROPOSED DEPRECIATION ACCOUNT IN NEBRASKA.** *Electric Railway Journal*, v. 37, p. 919 (May 27, 1911). (Brief reference to hearing before the State Railway Commission on proposed depreciation account for electric railways.)

***RULE FOR TREATMENT OF DEPRECIATION IN NEBRASKA.** *Electric Railway Journal*, v. 38, p. 990 (Nov. 4, 1911). (Rules adopted by State Railway Commission to govern charges by electric railways, for maintenance, additions and betterments; one-half page.)

New Jersey.

REQUEST FOR LOWER FARES DENIED BY NEW JERSEY COMMISSION. *Electric Railway Journal*, v. 38, p. 1117 (Nov. 25, 1911). (Contains brief reference to the value of street railway property and allowance for maintenance and depreciation.)

STANDARD CLASSIFICATION OF STREET RAILWAY ACCOUNTS IN NEW JERSEY. *Electric Railway Review*, v. 37, p. 273 (Feb. 11, 1911). (The adoption, with two slight changes, of the standards of the American Electric Railway Accountants Association in regard to depreciation.)

New York City.

ANOTHER THIRD AVENUE CHAPTER. (Editorial.) *Electric Railway Journal*, v. 39, p. 230 (Feb. 10, 1912). (The Commission provides a plan for the retirement of excessive capitalization of the property; very brief.)

***APPRAISAL OF THE NEW YORK SURFACE SYSTEMS.** (Editorial.) *Electric Railway Journal*, v. 32, p. 111 (June 20, 1908). (Discussion of the proposed appraisal by the Public Service Commission; one page.)

THE APPRAISAL OF THE THIRD AVENUE STREET RAILROAD SYSTEM, NEW York City. *Engineering and Contracting*, v. 35, p. 666 (June 7, 1911). (Data relating to the appraisal taken from a pamphlet entitled "Opinion Disapproving Plan of Reorganization," July 29, 1910.)

AN ARBITRARY DEPRECIATION REQUIREMENT. (Editorial.) *Railway World*, v. 56, p. 141 (Feb. 16, 1912). (On decision of the New York Public Service Commission on the Third Avenue Ry.)

***LIFE OF ELEMENTS OF SUBWAY PROPERTY.** *Electric Railway Journal*, v. 39, p. 575 (April 6, 1912). (Estimates of E. G. Connette, Transportation Engineer, New York Public Service Commission, First District.)

METROPOLITAN STREET RAILWAY REORGANIZATION. *Electric Railway Journal*, v. 37, pp. 708, 756, 798, 876, 916, 976; v. 38, p. 240 (April 22, 29, May 6, 20, 27, June 3, Aug. 5, 1911). (Hearing before the New York Public Service Commission, First District; testimony in relation to the value of the property.)

***OPINIONS OF COMMISSION IN THIRD AVENUE CASE.** *Electric Railway Journal*, v. 39, p. 237 (Feb. 10, 1912). (Opinions on mortgages and accounting, amortization of discounts and depreciation of the Third Avenue R. R. property.)

PHYSICAL APPRAISAL OF THIRD AVENUE RAILROAD. *Electric Railway Journal*, v. 35, p. 228 (Feb. 5, 1910). (Estimate by Henry Floy of the value of the Third Avenue R. R.; one-half page.)

PLAN FOR REORGANIZATION OF THIRD AVENUE ROAD DISAPPROVED BY Commission. *Electric Railway Journal*, v. 36, p. 262 (Aug. 13, 1910). (Contains statement regarding the value of the property; three pages.)

***RE AMORTIZATION ACCOUNTS OF THE THIRD AVENUE RAILWAY COMPANY** (Case 1181). Reports of Decisions of the Public Service Commission, First District of the State of New York, v. 3, p. 51. New York, 1912. (Amortization of discounts and depreciation.)

***RE BOND ISSUE OF NEW YORK & NORTH SHORE TRACTION COMPANY (CASE** 1398). Reports of Decisions of the Public Service Commission, First District of the State of New York, v. 3, p. 63. New York, 1912. (Discussion of valuation of property of the New York & North Shore Traction Co.)

STREET AND INTERURBAN RAILROADS—SPECIAL CASES—(*Continued*).

***RE METROPOLITAN STREET RAILWAY COMPANY REORGANIZATION (CASE 1305).** Reports of Decisions of the Public Service Commission, First District of the State of New York, v. 3, p. 113. New York, 1912. (Estimates of valuation of property.)

***RE 2ND REORGANIZATION PLAN OF 3RD AVE. R. R. CO. (CASE 1181).** Reports of Decisions of the Public Service Commission, First District of the State of New York, v. 2, p. 390. New York, 1912. (Report on valuation of the property of the Third Avenue R. R. Co.)

***REPORT OF A COMMITTEE OF THE BOARD OF ESTIMATE AND APPORTIONMENT** and of the Public Service Commission for the First District with Relation to Pending Proposals for Rapid Transit Lines (1911). Proceedings, Public Service Commission for the First District, State of New York, v. 6, pp. 378, 399, 488 (June 27, 30, July 21, 1911). New York, 1912. (Estimated value of proposed New York Subway.)

***THE RETURN ON THE INVESTMENT IN THE SUBWAY OF THE INTERBOROUGH** Rapid Transit Company of New York City, Submitted to the Public Service Commission for the First District of the State of New York, Report No. 7, Dec. 31, 1908; by Bion J. Arnold. New York, 1908. (Analysis of earnings and expenses, depreciation, etc.)

***SECOND CONDENSATION OF OPERATING ACCOUNTS FOR NEW YORK ROADS.** *Electric Railway Journal*, v. 33, p. 67 (Jan. 9, 1909). (Classification of accounts made by New York Public Service Commission, First District; includes depreciation and treatment of appreciation.)

TENTATIVE CLASSIFICATION OF ACCOUNTS PREPARED BY NEW YORK PUBLIC Service Commission. *Electric Railway Journal*, v. 32, p. 349 (July 25, 1908). (The classification provides for two accounts to cover depreciation, one under maintenance of way and structures and one under maintenance of equipment.)

TREATMENT OF DEPRECIATION ACCOUNTS BY INTERBOROUGH RAPID TRANSIT Co. *Electric Railway Journal*, v. 38, p. 280 (Aug. 12, 1911). (One page.)

***TREATMENT OF DEPRECIATION AND MAINTENANCE IN GREATER NEW YORK.** *Electric Railway Journal*, v. 39, p. 539 (April 6, 1912). (Table of rates of depreciation adopted by street and electric railway companies in accordance with the uniform system of accounts prescribed by the Public Service Commission of the First District.)

VALUATION OF STREET RAILWAY PROPERTIES. *Electric Railway Journal*, v. 33, p. 1122 (June 19, 1909). (Relates more particularly to the street railways of New York City; two and one-half pages.)

New York State.

***ACCOUNTS PRESCRIBED BY NEW YORK PUBLIC SERVICE COMMISSION,** Second District. *Electric Railway Journal*, v. 32, p. 1373 (Nov. 14, 1908). (Provision is made for the treatment of depreciation in two primary operating expense accounts.)

BRIEF ON ACCOUNTING SCHEME SUBMITTED TO PUBLIC SERVICE COMMISSION, Second District, on Behalf of New York State Association. *Electric Railway Review*, v. 19, p. 591 (May 16, 1908). (Protest against requiring same methods of accounting for steam and electric railways and reasons for the protest).

INQUIRY BY PUBLIC SERVICE COMMISSION CONCERNING DEPRECIATION Accounts. *Electric Railway Journal*, v. 35, p. 793 (April 30, 1910). (Circular letter of inquiry issued to street railroad and electrical corporations, by the New York Public Service Commission, Second District; very brief.)

***JOINT HEARING ON UNIFORM ACCOUNTS FOR NEW YORK ELECTRIC ROADS.** *Electric Railway Journal*, v. 32, p. 439 (Aug. 8, 1908). (Statement of H. J. Pierce, President of the International Ry. Co. of Buffalo, on depreciation, and of Howard Abel, Comptroller of the Brooklyn Rapid Transit System, on classification of accounts.)

RESOLUTIONS OF NEW YORK STATE ASSOCIATION CONCERNING TENTATIVE Classifications. *Electric Railway Review*, v. 19, p. 378 (March 28, 1908). (Relates to classification of the New York Public Service Commission, Second District.)

***SECOND CONDENSATION OF OPERATING EXPENSE ACCOUNTS FOR NEW YORK** Roads. *Electric Railway Journal*, v. 33, p. 67 (Jan. 9, 1909). (Scheme of accounts prescribed by New York Public Service Commission, Second District, for street railroads; three paragraphs relating to depreciation.)

***STATE OF NEW YORK. SECOND ANNUAL REPORT OF THE PUBLIC SERVICE** Commission, Second District, for the Year Ending Dec. 31, 1908; v. 2, Uniform System of Accounts. Albany, 1909. (Classification of accounts for street railroads, gas and electrical corporations; general amortization account including amount estimated for wear, tear and obsolescence of plant.)

STREET AND INTERURBAN RAILROADS—SPECIAL CASES—(*Continued*).

***VALUATION BY EARNINGS;** by Frank W. Stevens. *Public Service Regulation*, v. 1, p. 438 (July, 1912). (Opinion of Chairman, New York Public Service Commission, Second District, in the application of the Westchester Street R. R. Co. for authorization to issue capital stock.)

VALUE OF PROPERTY IN NEW YORK REORGANIZATION CASE. *Electric Railway Journal*, v. 41, p. 381 (March 1, 1913). (Decision of the New York Public Service Commission, Second District, in the case in which the Westchester Street R. R. asked authority to issue capital stock.)

Newcastle, England.

DEPRECIATION AND RESERVES, WARNING TO NEWCASTLE. *Tramway and Railway World*, v. 20, p. 258 (Sept. 6, 1906). (Discussion on the necessity of reserve and renewal funds; statistical.)

Niagara Gorge R. R.

TREATMENT OF DEPRECIATION ACCOUNTS OF NEW YORK PUBLIC SERVICE Commission. *Electric Railway Journal*, v. 34, p. 1073 (Nov. 20, 1909). (Rules adopted by the Niagara Gorge R. R.)

Philadelphia, Pa.

***PENNSYLVANIA STATE RAILROAD COMMISSION IN THE MATTER OF THE** Complaints Against the Philadelphia Rapid Transit Company; Report to the Commission by Ford, Bacon & Davis, March 7, 1911. 2 v. New York, 1911. (Detailed report, comprising a series of tabulated statements, maps and diagrams on the physical valuation of the property of the Philadelphia Rapid Transit Co.)

Puget Sound Electric Ry.

***FIFTH ANNUAL REPORT OF THE RAILROAD COMMISSIONER OF WASHINGTON** to the Governor Covering the Period from January 1 to November 1, 1910, p. 49. Olympia, Wash., 1910. (Refers to valuation of the Puget Sound Electric Ry.)

VALUATION OF THE PUGET SOUND ELECTRIC RAILWAY; by Henry L. Gray. *Engineering-Contracting*, v. 33, p. 482 (May 25, 1910). (Methods and details of valuation of physical property; four pages.)

St. Louis, Mo.

DEPRECIATION FUND IN ST. LOUIS. (Editorial.) *Electric Railway Journal*, v. 35, p. 433 (March 12, 1910). (One paragraph.)

LARGER DEPRECIATION FUND FOR ST. LOUIS. (Editorial.) *Electric Railway Journal*, v. 37, p. 247 (Feb. 11, 1907). (Comments on the policy of the United Railways Co. of St. Louis.)

***REPORT TO THE MUNICIPAL ASSEMBLY ON THE UNITED RAILWAYS COM-**pany of St. Louis by the St. Louis Public Service Commission; by James E. Allison. 2 v. Woodward & Tiernan Printing Co., St. Louis, 1912. (A statement of the principles which in the opinion of the Commission should be the basis of valuation and details of physical valuation of the property; Appendix A contains a discussion by James E. Allison, "Should Public Service Properties be Depreciated to Obtain Fair Value in Rate or Regulation Cases?")

——Abstracts. Report on United Railways of St. Louis. *Electric Railway Journal*, v. 41, p. 248 (Feb. 8, 1913); Finding Fair Value. *Public Service Regulation*, v. 1, p. 716 (Nov., 1912).

San Francisco, Cal.

FINAL REPORT ON SAN FRANCISCO. *Electric Railway Journal*, v. 41, p. 844 (May 10, 1913). (Analysis of value of street railways of San Francisco; report by Bion J. Arnold.)

Savannah, Ga.

DECISION OF COMMISSION UPHOLDING RATES OF FARE IN SAVANAH, GA. *Electric Railway Journal*, v. 39, p. 663 (April 20, 1912). (Relates to value of street railway property.)

Sheboygan, Wis.

***CITY OF SHEBOYGAN VS. SHEBOYGAN RAILWAY AND ELECTRIC COMPANY;** Submitted Oct. 18, 1910, Decided Feb. 3, 1911. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 6, p. 358. Madison, Wis., 1912. (Contains table of valuation of the physical property of the Sheboygan Ry. & Electric Co.)

Spokane & Inland Empire R. R. System.

APPRAISAL OF THE SPOKANE AND INLAND EMPIRE ELECTRIC RAILROAD System; by Henry L. Gray. *Engineering and Contracting*, v. 36, p. 696 (Dec. 27, 1911). (Contains tables of cost of reproduction, depreciation, etc.; deals with methods adopted to determine the correctness of the allegation concerning the insufficiency of present rates.)

STREET AND INTERURBAN RAILROADS—SPECIAL CASES—(*Continued*).

Sunderland, England.

DEPRECIATION AT SUNDERLAND. *Tramway and Railway World*, v. 14, p. 478 (Nov. 12, 1903). (Estimated life and percentage set aside for depreciation of equipment and permanent way of street railway at Sunderland, England.)

Toledo, Ohio.

INVENTORY OF PHYSICAL RAILWAY PROPERTY OF TOLEDO COMPANY GIVEN to City. *Electric Railway Journal*, v. 36, p. 990 (Nov. 12, 1910). (Letter from Ford, Bacon & Davis; gives a list of the work and expense items entering into the construction cost which should be included in an appraisal; one page.)

Wausau, Wis.

*DECISION OF WISCONSIN COMMISSION: CONSIDERS THE RATE OF RETURN. *Electric Railway Journal*, v. 36, p. 404 (Sept. 10, 1910). (Statement in regard to the valuation of the Wausau Street R. R. Co.; one page.)

Wisconsin.

SOME PRINCIPLES ESTABLISHED BY THE WISCONSIN RAILROAD COMMISSION; by Edwin S. Mack. *Electric Railway Journal*, v. 37, p. 164 (Jan. 28, 1911). (Includes valuation; one page.)

*SYSTEM OF ACCOUNTS PRESCRIBED BY WISCONSIN RAILROAD COMMISSION. *Electric Railway Journal*, v. 33, p. 1076 (June 12, 1909). (Includes provision for a depreciation fund; two pages.)

*WISCONSIN CLASSIFICATION OF ACCOUNTS. *Electric Railway Journal*, v. 34, p. 366 (Sept. 4, 1909). (Gives slight changes from list published June 12, 1909, with extracts from introductory letter of the Commission.)

STREET AND INTERURBAN RAILROADS—UNVERIFIED REFERENCES.

ACCOUNTING OF DEPRECIATION BY ELECTRIC RAILWAYS; by Robert N. Wallis. *Journal of Accountancy*, May, 1907. (Discusses methods used and matters to be considered in electric railway accounting.)

ALLOWANCE FOR MAINTENANCE TO COVER DEPRECIATION. *Light Railway and Tramway Journal* (London), v. 21, p. 29 (July 2, 1909). (Details of allowances as agreed between Council of Institute of Municipal Treasurers and Accountants and the Inland Revenue Department for tramway and light railways as well as for municipal corporations.)

CLASSIFICATION OF ELECTRIC RAILWAY EXPENSES; by Willard Hubbard Lawton. *Journal of Accountancy*, v. 6, p. 114 (June, 1908).

COST OF CARRYING A PASSENGER; by C. L. S. Tingley. *Street Railway Bulletin*, v. 4, p. 793 (Nov. 15, 1905). (Abstract.)

DEPRECIATION AND RENEWAL FUNDS IN RELATION TO TRAMWAYS UNDERtakings; by G. W. Holford. *Light Railway and Tramway Journal* (London), v. 15, p. 294 (Oct. 5, 1906). (Abstract of paper read before the Municipal Tramways Association; contains table showing provision made for depreciation by street railways in sixty English cities.)

DEPRECIATION OF TRAMWAYS AND LIGHT RAILWAYS. *Light Railway and Tramway Journal* (London), v. 21, p. 80 (Aug. 6, 1909).

DEPRECIATION PROBLEM OF ELECTRIC STREET RAILWAYS; by W. B. Jackson. *Public Service*, Sept., 1911, p. 71.

LIFE OF DIFFERENT PARTS OF CAR EQUIPMENT, BEFORE AND AFTER USING Recording Wattmeters on Cars at Cape Town. *Journal*, Tramways and Light Railway Association, Sept., 1911, p. 241.

MANAGEMENT OF ELECTRIC TRAMWAYS; by Bowker.

PHYSICAL VALUE SCHEDULES OF THE CLEVELAND ELECTRIC RAILWAY CO. as of January 1, 1908.

REPORT OF THE STREET RAILWAY COMMISSION TO THE DETROIT COMMON Council on the Valuation of the Street Railways of Detroit. Journal of the Common Council, City of Detroit, 1899, p. 346.

REPORTING A STREET RAILWAY EXAMINATION (FROM THE CLIENT'S POINT of View); by W. B. Brockway. *Journal of Accountancy*, v. 4, p. 16 (May, 1907).

STREET RAILWAY COSTS; by M. E. Cooley. *Public Service*, v. 6, p. 117 (April, 1909).

STREET RAILWAY FARES IN LARGE CITIES; by Howard S. Knowlton. *Review of Reviews*, v. 32, p. 80 (July 1905).

STREET RAILWAY SETTLEMENT IN CLEVELAND; by E. W. Bemis. *Quarterly Journal of Economics*, Aug., 1908. (Thirty-three pages.)

STREET AND INTERURBAN RAILROADS—UNVERIFIED REFERENCES—(*Continued*)

TRAMWAY BOOKKEEPING ACCOUNTS; by D. McGall.

VALUATION OF CLEVELAND RAILWAY CO.: LETTER OF DEC. 17, 1909, TO CITY Council of Cleveland, Ohio, by R. W. Taylor, as Arbitrator Between City and Railways. (Copy in files, American Electric Railway Association.)

VALUATION OF PROPERTY OF RAILROADS IN THE DISTRICT OF COLUMBIA. 62d Cong., 2d Sess. Senate Doc. No. 335. (Letter in response to Senate resolution of Feb. 14th, 1912.)

TELEGRAPH AND TELEPHONE.

AN ANALYSIS OF COST OF TELEPHONE SERVICE. *Electrical World*, v. 55, p. 1243 (May 19, 1910). (One page.)

DEPRECIATION AND REPLACEMENT OF GROWING TELEPHONE PLANTS; by Burke Smith. *Journal*, Western Society of Engineers, v. 17, p. 779 (Oct., 1912). (Discusses renewal, life and depreciation of plant.)

——Abstract. Depreciation and Replacement of Telephone Equipment. *Electrical Review and Western Electrician*, v. 60, p. 790 (April 27, 1912). (Very brief.)

THE DEPRECIATION OF UNDERGROUND CABLES; by F. Fernie. *Electrical Review* (London), v. 60, p. 577 (April 5, 1907). (Method of computing depreciation of cables.)

DEPRECIATION OF UNDERGROUND CONDUITS, CABLES AND WIRES. *Electric Railway Journal*, v. 33, p. 881 (May 8, 1909). (Classification of property of the American Telephone & Telegraph Co.; very brief.)

DETERMINATION OF TELEPHONE RATES FOR LARGE EXCHANGES; by William H. Crumb. *Journal*, Western Society of Engineers, v. 12, p. 781 (Dec., 1907). (On depreciation, with a table giving per cent. to be allowed to depreciation account; one-half page.)

PLANT-INVENTORY AND VALUATION. *Electrical World*, v. 55, p. 295 (Feb. 3, 1910). (Abstract of paper by W. R. McGovern before the Wisconsin Electrical Association covering in a general way methods of taking inventories of telephone-exchange plants in Wisconsin.

——Abstract and Discussion. *Electric Railway Journal*, v. 35, p. 184 (Jan. 29, 1910).

TELEPHONE CONSTRUCTION METHODS AND COST. Chicago, 1908. (Contains cost data from the actual records of various telephone companies.)

***UNIFORM SYSTEM OF ACCOUNTS FOR TELEPHONE COMPANIES AS PRE**scribed by the Interstate Commerce Commission, pp. 16, 34, 53, 66, 71, 77. Washington, 1912. (Refers to treatment of depreciation.)

TELEGRAPH AND TELEPHONE—SPECIAL CASES.

Augusta, Wis.

***IN RE APPLICATION OF J. L. BALL FOR AUTHORITY TO INCREASE TELE**phone Rates; Submitted Sept. 10, 1907, Decided Nov. 25, 1907. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 2, p. 105. Madison, Wis., 1909. (Brief reference to physical valuation.)

Boston, Mass.

REPORT TO THE MASSACHUSETTS HIGHWAY COMMISSION ON TELEPHONE Rates for Boston and Suburban District; by D. C. and William B. Jackson. Boston, 1910. (Diagrams, tables and maps; sixty-six pages.)

Chicago, Ill.

THE APPRAISAL OF THE CHICAGO TELEPHONE CO. AND A COMPARISON WITH the Results of Three Similar Appraisals. (Editorial.) *Engineering and Contracting*, v. 36, p. 269 (Sept. 13, 1911). (One column.)

APPRAISAL OF THE CHICAGO TELEPHONE COMPANY AND DETERMINATION of Fair Rates of Charge; by William J. Hagenah. *Engineering-Contracting*, v. 36, pp. 289, 445, 473 (Sept. 13, Oct. 25, Nov. 1, 1911). (Method of arriving at plant value, appraised value and income and operating expenses.)

REPORT ON THE TELEPHONE SITUATION IN THE CITY OF CHICAGO IN RESPECT to Service, Rates, Regulation of Rates, etc., Submitted to the Committee on Gas, Oil and Electric Light of the City Council of the City of Chicago; by a Special Committee, composed of Dugald C. Jackson, William H. Crum, and George W. Wilder, April, 1907. Chicago, 1907. (The Committee states that it has endeavored to obtain data from Bell Telephone Companies of New York and elsewhere, but rates seem to have been dictated by estimates based on experience or the requirements of business expediency.)

TELEGRAPH AND TELEPHONE—SPECIAL CASES—(*Continued*).

Clinton Telephone Co.

***B. B. TIGHE ET AL. VS. CLINTON TELEPHONE COMPANY;** Submitted Oct. 10, 1908, Decided Dec. 2, 1908. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 3, p. 117. Madison, Wis., 1910. (Refers to tentative valuation of physical property.)

Massachusetts.

SIXTEENTH ANNUAL REPORT OF THE MASSACHUSETTS HIGHWAY COMMISSION, for the Fiscal Year ending Nov. 30, 1908, p. 158. Boston, 1909. (Contains report by Dugald C. Jackson on the advisability of making an appraisal of the New England Telephone & Telegraph Co.)

——17th, p. 211. Boston, 1910. (Contains a summary report of the results of the inventory and appraisal of the New England Telephone & Telegraph Co., by D. C. and W. B. Jackson.)

TELEPHONE REPORT TO MASSACHUSETTS HIGHWAY COMMISSION. *Electrical World*, v. 55, p. 984 (April 21, 1910). (Brief reference to report on the New England Telephone & Telegraph Co., by D. C. and W. B. Jackson; states that this report on traffic and operating conditions, together with the appraisal which appeared previously, is the most detailed analysis ever made of telephone rates in an urban area of such scope.)

Michigan.

THE VALUATION AND TAXATION OF TELEPHONE COMPANIES IN MICHIGAN; by W. J. Rice. *Electrical World*, v. 37, p. 196 (Feb. 2, 1901). (Two and one-half pages.)

Portage, Wis.

***IN RE APPLICATION OF THE PORTAGE TELEPHONE COMPANY FOR AUTHORity to Increase Rates;** Submitted May 19, 1908, Decided Aug. 27, 1908. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 2, p. 692. Madison, Wis., 1909. (Contains brief data on valuation.)

Seattle, Wash.

APPRAISAL OF THE PACIFIC TELEPHONE AND TELEGRAPH COMPANY OF Seattle; by Henry L. Gray. *Engineering and Contracting*, v. 36, p. 332 (Sept. 27, 1911). (Gives detailed estimate of cost of reproducing the plant; five pages.)

APPRAISAL OF THE SEATTLE TELEPHONE COMPANIES BY THE RAILROAD Commission of Washington; by Henry L. Gray. *Engineering and Contracting*, v. 35, p. 520 (May 3, 1911). (Describes the work and explains the causes which led to the appraisal.)

STUDY OF THE TELEPHONE SITUATION IN SEATTLE, WASH.: REPORT; by C. H. Judson and F. B. Hall. *Engineering News*, v. 65, p. 652 (June 1, 1911). (On depreciation and valuation; one column.)

Wisconsin Telephone Co.

***E. E. PAYNE ET AL. VS. WISCONSIN TELEPHONE COMPANY;** Decided Aug. 3, 1909. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 4, p. 1. Madison, Wis., 1910. (Intangible values embracing franchise, good will and going value are briefly discussed.)

TELEGRAPH AND TELEPHONE—UNVERIFIED REFERENCES.

DEPRECIATION AND REPLACEMENT OF GROWING TELEPHONE PLANTS; by Burke Smith. *Telephony*, April 27, 1912, p. 1062.

NATIONAL TELEPHONE CO., LIMITED, VS. HIS MAJESTY'S POSTMASTER-General. Great Britain Railway and Canal Commission Court. Judgment, Jan. 13, 1913, pp. 4209-39.

REPORT OF THE INVESTIGATION OF THE CHICAGO TELEPHONE COMPANY, 1911; by William J. Hagenah.

REPORT OF UNFAIR TELEPHONE RATES IN MINNEAPOLIS, TAKES UP ALLOW-ance for Depreciation; by Gordon Steele & Co. *Public Service*, v. 5, p. 106 (Oct., 1908).

TELEPHONE VALUATION, OKLAHOMA. Pioneer Telephone & Telegraph Co. *vs.* E. S. Westenhaver *et al.* and State of Oklahoma. Oklahoma Supreme Court, 1910, p. 1256.

WATER POWER—GENERAL.

AN ANALYSIS OF THE "COMMERCIAL" VALUE OF WATER-POWER PER Horse-power per Annum; by A. F. Nagle. *Transactions*, American Society of Mechanical Engineers, v. 24, p. 286 (1903). (With discussion.)

——Abstract. *Engineering News*, v. 49, p. 83 (Jan. 22, 1903).

WATER POWER—GENERAL—(*Continued*).

THE APPRAISAL OF WATER POWER RIGHTS; by Halbert P. Gillette. *Engineering and Contracting*, v. 38, p. 624 (Dec. 4, 1912). (Discusses seven methods of appraisal: the steam comparison method; the capitalized profit method; the alternative use method; the next available water power method; the public utility factor method; the market value method; and capitalized rental method.)

COMMENTS ON DEVELOPMENT AND OPERATION OF HYDRO-ELECTRIC PLANTS; by Henry L. Doherty. *Proceedings*, American Institute of Electrical Engineers, v. 28, Pt. 2, p. 1362 (1909). (Treat of value of water-power securities, cost of power and depreciation.)

——Abstract. Cost and Depreciation of Steam and Hydro-Electric Installations. *Electrical World*, v. 54, p. 1558 (Dec. 30, 1909).

COMPARATIVE COST OF STEAM AND WATER POWER; by Charles H. Manning. *Transactions*, American Society of Mechanical Engineers, v. 10, p. 499 (1889). (On the value of water power.)

THE COMPARATIVE VALUES OF WATER-POWER AND STEAM POWER; by A. C. Dunham. *Electrical World*, v. 59, p. 38 (Jan. 6, 1912). (Advantages and disadvantages of hydro-electric stations for central-station service compared with steam-driven stations, financial considerations involved.)

——Abstract. The Value of Water Power. *Engineering Record*, v. 65, p. 181 (Feb. 17, 1912).

COMPUTATION OF THE VALUE OF WATER POWERS AND THE DAMAGES Caused by the Diversion of Water Used for Power; by Charles T. Main. *Journal*, New England Water Works Association, v. 21, p. 214 (Sept., 1907). (Contains a table of estimated costs per horse-power of water-power plants.)

——Abstracts. *Engineering-Contracting*, v. 29, p. 73 (Jan. 29, 1908); *Journal of Electricity, Power and Gas*, v. 22, p. 20 (June 30, 1909).

COMPUTATION OF THE VALUES OF WATER POWERS AND THE DAMAGES Caused by the Diversion of Water Used for Power; by Charles T. Main. *Transactions*, American Society of Mechanical Engineers, v. 26, p. 68 (1905). (Gives definitions of value and damage and method of determining value.)

COST OF GENERATING ELECTRIC POWER; by F. A. Griffin. *Street Railway Journal*, v. 26, p. 1142 (Dec. 30, 1905). (Gives diagram of maintenance of generating station and states that the cost of generating power by water can be found from the diagram by eliminating the cost of coal.)

COST OF STEAM AND WATER POWER; by Charles T. Main. *Transactions*, American Society of Mechanical Engineers, v. 11, p. 108 (1889). (On value of water power.)

THE COST OF STEAM POWER; by Charles E. Emery. *Transactions*, American Society of Civil Engineers, v. 12, p. 425 (Paper 266. Nov., 1883). (In a suit respecting the loss of power by the diversion of water, damages were claimed by mill owners based on the cost of purchasing, operating and maintaining at each mill a small engine and a complete independent steam plant.)

DAMAGES CAUSED BY THE DIVERSION OF WATER-POWER; by Clemens Herschel. *Journal*, New England Water Works Association, v. 21, p. 241 (Sept., 1907). (On methods of estimating market value of water power.)

ELECTRIC POWER TRANSMISSION; by Frederick Darlington. *Transactions*, American Institute of Electrical Engineers, v. 25, p. 181 (1906). (Cost of developing and maintaining hydro-electric power utilized in mill work, in comparison with steam power.)

ELECTRIC TRANSMISSION OF WATER-POWER, p. 1; by Alton D. Adams. McGraw Publishing Co., New York, 1906. (On water-power and its utility in electrical supply, relates to the cost of water power; two chapters.)

EVALUATION OF WATER RIGHTS; by Arthur Halsted. *Engineering Record*, v. 61, p. 245 (Feb. 26, 1910). (On methods of valuation; two pages.)

HYDRAULIC DEVELOPMENTS AS RELATED TO ELECTRIC INSTALLATIONS; by William B. Jackson. *Journal*, Western Society of Engineers, v. 8, p. 312 (June, 1903). (Contains a discussion by T. T. Johnson on the economic side of a water-driven electric plant.)

HYDRO-ELECTRIC POWER VERSUS STEAM FOR INDUSTRIAL PURPOSES; by H. von Schon. *Engineering Magazine*, v. 33, pp. 34, 184, 353 (April, May, June, 1907). (A comparison of costs of hydro-electric and steam power in developed and undeveloped plants.)

A METHOD OF ESTIMATING THE LOSS OF WATER POWER IN A STREAM BY Taking Water Therefrom for a City Supply; by L. M. Hastings. *Journal*, New England Water Works Association, v. 7, p. 187 (June, 1893). (Discussion on the value of the water power.)

——Abstract. *Engineering Record*, v. 27, p. 296 (March 11, 1893).

WATER POWER—GENERAL—(*Continued*).

NOTES ON DESIGN OF HYDRO-ELECTRIC POWER STATIONS, WITH REFERENCE to the Influence of Load-Factor; by David B. Rushmore. *Transactions*, American Institute of Electrical Engineers, v. 25, p. 145 (1906). (The discussion of costs is confined to general principles; definite values are not given.)

ON THE VALUE OF A HORSE-POWER; by George I. Rockwood. *Transactions*, American Society of Mechanical Engineers, v. 21, p. 590 (1900). (On the dispute between the city officials of Worcester and the mill owners on the loss of power by the diversion of water for the Worcester Reservoirs.)

THE RELATION OF LOAD-FACTOR TO THE EVALUATION OF HYDRO-ELECTRIC Plants; by S. B. Storer. *Transactions*, American Institute of Electrical Engineers, v. 25, p. 139 (1906). (Contains diagrams giving comparative cost of steam and hydro-electric plants.)

RELATION OF STEAM TO WATER POWER; by James G. Hill. *Transactions*, New England Cotton Manufacturers' Association, v. 65, p. 333 (1898). (Contains a table giving yearly cost of 1 h.p. of water.)

THE SALE AND MEASUREMENT OF ELECTRIC POWER; by S. B. Storer. *Street Railway Journal*, v. 27, p. 1018 (June 30, 1906). (Contains diagrams giving methods of plotting costs and prices per horse-power per year of steam or hydro-electric power.)

STORAGE AND PONDAGE OF WATER; by Joseph P. Frizell. *Transactions*, American Society of Civil Engineers, v. 31, pp. 29, 552 (Papers 688 and 709. Jan., May, 1894). (On the valuation of water power.)

VALUATION OF MANUFACTURING PROPERTY FOR TAXATION; by Charles T. Main. *Transactions*, New England Cotton Manufacturers Association, v. 67, p. 108 (1899). (Contains data on the method of determining the value of water power.)

THE VALUATION OF WATER POWER AND THE ESTIMATION OF STREAM Diversion Damages; by Robert E. Horton. *Proceedings*, American Water Works Association, v. 29, p. 1 (1909). (Twenty-five pages.)

THE VALUE AND DESIGN OF WATER POWER PLANTS AS INFLUENCED BY Load-Factor; by Frederick A. C. Perrine. *Journal*, Franklin Institute, v. 162, p. 269 (Oct., 1906).

THE VALUE OF A WATER POWER; by Charles T. Main. *Transactions*, American Society of Mechanical Engineers, v. 13, p. 140 (1891). (On method of estimating the value of water power with relation to condemnation proceedings.)

THE VALUE OF WATER; by Alton D. Adams. *Municipal Engineer*, v. 37, p. 77 (Aug., 1909). (Decision of the Massachusetts Court as to the general rule of compensation where water is taken under legislative authority for public use.)

——Editorial. Value of Water and Water Power. *Municipal Engineering*, v. 37, p. 102 (Aug., 1909).

THE VALUE OF WATER POWER. (Editorial.) *Engineering Record*, v. 33, p. 597 (May 9, 1896). (Dealing with the general and special conditions and circumstances that should be considered in the condemnation of water supplies for municipal purposes; two columns.)

WATER POWER. In Geological Survey of New Jersey, Final Report, v. 3, Henry B. Kummel, State Geologist. Trenton, N. J., 1894. (Data on the cost of water power.)

WATER RIGHTS; by Richard A. Hale. *Journal*, New England Water Works Association, v. 21, p. 248 (Sept., 1907). (The discussion of this paper relates to the valuation of water power.)

WATER POWER—SPECIAL CASES.

Beloit, Wis.

*CITY OF BELOIT VS. BELOIT WATER, GAS AND ELECTRIC COMPANY; Decided July 19, 1911. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 7, p. 246. Madison, Wis., 1912. (Gives estimates of value of the water power.)

*VALUATION OF WATER POWER. *Engineering Record*, v. 61, p. 153 (Feb. 5, 1910). (Case of the Beloit Water, Gas & Electric Co. before the Wisconsin Railroad Commission; abstracts of testimony.)

Boston, Mass.

BOSTON BELTING COMPANY VS. CITY OF BOSTON. Boston, 1899. (Suit relates to the diversion of water from Stony Brook and the value of the water power; fifty-nine parts.)

WATER POWER—SPECIAL CASES—(*Continued*).

Bronx River.

CALCULATIONS OF THE MEAN HORSE-POWER OF A VARIABLE STREAM AND the Cost of Replacing the Power Lost by a Partial Diversion of the Flow; by William H. Grant. *Transactions*, American Society of Civil Engineers, v. 22, p. 389 (Paper 440. June, 1890). (In regard to the claims of property owners for diversion of part of the waters of the Bronx River.)

Connecticut River Transmission Co.

HEARING ON CONNECTICUT RIVER TRANSMISSION COMPANY'S FRANCHISE. *Electrical World*, v. 53, p. 486 (Feb. 25, 1909). (Brief data on the estimated value of the plant.)

Everett (Wash.) Ry., Light & Power Co.

***THE APPRAISAL OF WATER RIGHTS.** *Engineering and Contracting*, v. 37, p. 429 (April 17, 1912). (Report made by Halbert P. Gillette to the Everett Ry., Light & Water Co. as part of the Company's exhibits in a recent hearing before the Washington Public Service Commission.)

Holyoke, Mass.

HOLYOKE WATER POWER CO. VS. CITY OF HOLYOKE. 20 v. George H. Ellis, Boston, 1899. (Suit in regard to the value of the water power.)

Illinois.

REPORT ON THE WATER POWER OF THE ROCK RIVER AT STERLING AND Rock Falls, Illinois, and the Probable Effect on the Power of the Diversion of Water for Feeding the Illinois and Mississippi Canal; by Daniel W. Mead. The Author, Chicago, 1904. (Gives the value of water power destroyed by diversion of water.)

Kaukauma, Wis.

***IN RE DETERMINING AND FIXING THE JUST COMPENSATION TO BE PAID TO** the Kaukauma Gas, Electric Light & Power Company by the City of Kaukauma, for the Property of Said Company Actually Used and Useful for the Convenience of the Public; Submitted Feb. 6, 1911, Decided Dec. 26, 1911. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 8, p. 417. Madison, Wis., 1912. (On the value of a water-power lease.)

Kennebec River.

WATER-POWER OF CARATUNK FALLS, KENNEBEC RIVER, MAINE; by Samuel McElroy. *Transactions*, American Society of Mechanical Engineers, v. 17, p. 58 (1895-96). (On the relative cost of steam and water power.)

——Abstract. *Engineering News*, v. 34, p. 422 (Dec. 26, 1895).

Nashua River Paper Co.

NASHUA RIVER PAPER COMPANY VS. COMMONWEALTH OF MASSACHUSETTS. 4 v. Wright & Potter Printing Co., Boston, 1901. (On damages to be awarded for drawing off the water flowing by the plaintiff's mills.)

Newton, N. J.

AN IMPORTANT DECISION UPON A MILL OWNER'S SUIT TO COLLECT DAM-ages for the Diversion of Water. (Letter); by Louis L. Tribus. *Engineering News*, v. 43, p. 228 (April 5, 1900). (Gives text of decision in the case at Newton, N. J.)

NOTES ON NEWTON, N. J., WATER WORKS CONSTRUCTION AND LITIGATION; by Louis L. Tribus. *Journal*, New England Water Works Association, v. 23, p. 145 (June, 1909). (Decision of Court as to valuation of water power diverted for Newton, N. J., Water-Works.)

Niagara Falls.

COURT OF APPEALS: THE PEOPLE OF THE STATE OF NEW YORK, EX REL. Niagara Falls Hydraulic Power and Manufacturing Company, Appellant, Against State Board of Tax Commissioners, Respondents; Respondents' Points. Buffalo, 1911. (On valuation of property of the Niagara Falls Hydraulic Power Co.)

COURT OF APPEALS: THE PEOPLE OF THE STATE OF NEW YORK, EX REL. the Niagara Falls Hydraulic Power and Manufacturing Company, Appellant, *versus* the State Board of Tax Commissioners, Respondents, John L. Romer, Counsel for Appellant: Points for Appellant. Buffalo, 1910. (Relates to valuation of property of the Niagara Falls Hydraulic Power Co.)

SUPREME COURT, ERIE COUNTY: THE PEOPLE OF THE STATE OF NEW YORK, *ex rel.* the Niagara Falls Hydraulic Power & Manufacturing Company, against the State Board of Tax Commissioners. no place, no date. (Decision in regard to the valuation of property of the Niagara Falls Hydraulic Power Co.)

WATER POWER AT NIAGARA FALLS; by Samuel McElroy. *Journal*, Association of Engineering Societies, v. 4, p. 395 (Sept., 1885). (Estimation of the value of water power by Commissioners to award damages.)

WATER POWER—SPECIAL CASES—(*Continued*).

Troy, N. Y.

ABSTRACT FROM THE REPORT OF THE WATER COMMISSIONERS, TROY, N. Y., Damages to Mill Powers; by William G. Raymond. *Journal*, New England Water Works Association, v. 13, p. 152 (Dec., 1898). (On the method of estimating value of water power; cost of damages.)

Waltham, Mass.

WATER POWER, ITS MEASUREMENTS AND VALUE, WITH DATA RESPECTING Damages Awarded; by George A. Kimball. *Journal*, Association of Engineering Societies, v. 13, p. 71 (Feb., 1894). (Paper read before the Boston Society of Civil Engineers; some of the facts presented in evidence before the commission to award damages in the City of Waltham, Mass.)

Wausau, Wis.

***FRANK B. L. FULLMER VS. WAUSAU STREET RAILROAD COMPANY;** Decided April 1, 1910. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 5, p. 125. Madison, Wis., 1911. (Gives basis of determining value of water power.)

Worcester, Mass.

KETTLE BROOK AND BLACKSTONE VALLEY MILL OWNERS, PETITIONERS, VS. City of Worcester. 5 v. Worcester, 1899. (Final arguments in a suit on the loss of power from the diversion of water.)

WATER-WORKS—GENERAL.

THE APPRAISAL AND DEPRECIATION OF WATER WORKS AND SIMILAR PROPerties; by William H. Bryan. *Journal*, Association of Engineering Societies, v. 39, p. 336 (Dec., 1907). (Forty-five pages.)

——Abstract. Depreciation Allowances for Various Public-Service Industries. *Engineering News*, v. 59, p. 96 (Jan. 23, 1908).

THE APPRAISAL OF PLANTS FOR PUBLIC SERVICES; by Nicholas S. Hill, Jr. *Engineering Record*, v. 43, p. 546 (June 8, 1901). (On methods of evaluation of water-works, etc., by the city.)

THE APPRAISAL OF WATER WORKS PROPERTIES WITH SPECIAL REFERENCE to the Reproduction Method. *Engineering and Contracting*, v. 39, p. 420 (April 9, 1913). (Paper read by Douglas A. Graham before the Illinois Water Supply Association.)

——*Engineering News*, v. 69, p. 677 (April 3, 1913).

——*Engineering Record*, v. 67, p. 532 (May 10, 1913).

THE ARBITRATION OR APPRAISAL OF THE VALUE OF PUBLIC UTILITIES; by Daniel W. Mead. *Proceedings*, American Water Works Association, v. 22, p. 132 (1902). (On the appointment of boards, duties of appraisers, evidence on the part of the company and of the municipality, and basis of valuation.)

CONSTRUING CERTAIN CLAUSES IN MUNICIPAL FRANCHISES; by John W. Hill. *Proceedings*, American Water Works Association, v. 19, p. 223 (1899). (On the value of water-works plants.)

——Abstract. *Engineering Record*, v. 39, p. 594 (May 27, 1899).

DEPRECIATION; by John W. Alvord. *Proceedings*, American Water Works Association, v. 23, p. 473 (1903). (Takes up the physical depreciation of pumping engines, stand-pipes, boilers, etc.; fifty-one pages.)

DEPRECIATION AS APPLIED TO WATER WORKS PROPERTIES; by Morris Knowles. no place, 1910. (Eighteen pages.)

DEPRECIATION CHARGES. (Letter); by Charles W. Helwick. *Engineering Record*, v. 59, p. 672 (May 29, 1909). (On valuation of water-works; very brief.)

DEPRECIATION IN CAST IRON PIPE. *Municipal Engineering*, v. 41, p. 211 (Sept., 1911). (Estimates for purpose of valuation.)

DEPRECIATION IN WATER WORKS ACCOUNTS, WITH REFERENCE TO UNIform Reports; by Harvey S. Chase. *Journal*, New England Water Works Association, v. 24, p. 305 (June, 1910). (Discusses depreciation in general as well as its relation to accounts; twenty-six pages.)

——Abstract. *Engineering-Contracting*, v. 33, p. 598 (June 29, 1910).

——Editorial. Depreciation and Sinking Fund Accounts. *Municipal Engineering*, v. 39, p. 26 (July, 1910).

DEPRECIATION IN WATER WORKS OPERATION AND ACCOUNTING; by Leonard Metcalf. *Journal*, New England Water Works Association, v. 24, p. 442 (Dec., 1910). (Thirty pages, with diagrams.)

WATER-WORKS—GENERAL—(*Continued*).

——Abstracts. *Engineering News*, v. 64, p. 482 (Nov. 3, 1910); Methods of Computing Depreciation of and Reasonable Assumptions as to Period of Useful Life of Water Works. *Engineering and Contracting*, v. 34, p. 434 (Nov. 16, 1910).

——Discussion. Methods of Making Computations for Depreciation in Public Utility Plants. *Engineering-Contracting*, v. 34, p. 590 (Dec. 28, 1910).

A DISCUSSION OF DEPRECIATION AND A COMPARISON OF RATES AND BOOK-keeping Methods of Municipally and Privately Owned Water Works. *Proceedings*, American Water Works Association, v. 32, p. 325 (1912). (Discusses report of Committee on Depreciation; twenty-two pages.)

——Abstract. Depreciation; by John W. Alvord. *Engineering Record*, v. 65, p. 670 (June 15, 1912).

THE FINANCIAL MANAGEMENT OF WATER-WORKS; by E. Kuichling. *Transactions*, American Society of Civil Engineers, v. 38, p. 1 (Paper 809. Dec., 1897). (Discusses annual expenses of water-works, including depreciation fund, yearly extensions, minor betterments, and future additions.)

THE FINANCIAL MANAGEMENT OF WATER WORKS; by Freeman C. Coffin. *Journal*, New England Water Works Association, v. 11, p. 63 (Sept., 1896). (Gives tables of water-works statistics; original cost, cost of annual maintenance, etc.)

FINANCIAL QUESTIONS IN WATER-WORKS VALUATION; by John W. Alvord. *Proceedings*, American Water Works Association, v. 22, p. 142 (1902). (On the business value, the franchise value and the fair return.)

——Abstracts. *Engineering Record*, v. 46, p. 30 (July 12, 1902); *Engineering News*, v. 47, p. 509 (June 19, 1902).

THE GOING VALUE OF WATER WORKS; by Leonard Metcalf and John W. Alvord. *Transactions*, American Society of Civil Engineers, v. 73, p. 334 (Paper 1199. Sept., 1911). (Sixty-six pages.)

METHOD OF ARBITRATION WITH REFERENCE TO VALUE OF WATER WORKS Plants; by Peter Milne. *Proceedings*, American Water Works Association, v. 17, p. 25 (1897). (On the tangible property and its value, value of franchise, and their relation; two and one-half pages.)

MUNICIPAL WATER SUPPLY REVENUE; by James L. Tighe. *Journal*, New England Water Works Association, v. 18, p. 352 (Dec., 1904). (On taxation; refers to the proper valuation of water-works.)

THE NECESSARY ELEMENTS FOR WATER-WORKS VALUATION; by John W. Alvord. *Engineering News*, v. 63, p. 286 (March 10, 1910). (Paper read before the Indiana Sanitary and Water Supply Association; outlines four methods of valuing public utility property which have been upheld by the Courts, and discusses in detail the valuation by reproduction.)

NOTES ON GOING VALUE AND METHODS FOR ITS COMPUTATION; by John W. Alvord. *Proceedings*, American Water Works Association, v. 29, p. 184 (1909). (Contains data on the valuation of water-works properties; ninety-five pages.)

——Abstract. *Engineering-Contracting*, v. 32, p. 95 (Aug. 4, 1909).

THE PRINCIPLES GOVERNING THE VALUATION FOR RATE FIXING PURPOSES of Water Works Under Private Ownership; by Arthur L. Adams. *Journal*, Association of Engineering Societies, v. 36, p. 37 (Feb., 1906). (On the valuation of water-works by the Government; paper read before the Pacific Coast Engineering Congress.)

——*Engineering Record*, v. 52, p. 153 (Aug. 5, 1905).

RATING OF WATER UNDERTAKINGS; by F. J. Bancroft. *Transactions*, British Association of Waterworks Engineers, v. 5, p. 26 (1900). (Discusses the taxation and valuation of English water-works, with reference to the Valuation (Metropolis) Act, 1869.)

——*Journal of Gas Lighting*, v. 76, p. 24 (July 3, 1900).

SOME FUNDAMENTAL CONSIDERATIONS IN THE DETERMINATION OF A REASON-able Return for Public Fire Hydrant Service; by Metcalf, Kuichling and Hawley. *Proceedings*, American Water Works Association, v. 31, p. 55 (1911). (Contains data on the valuation of water-works.)

TABLE SHOWING LIFE AND DEPRECIATION OF WATER WORKS PLANTS. *Municipal Journal and Engineer*, v. 24, p. 558 (May 6, 1908).

TOWN WATER-WORKS FROM A FINANCIAL STANDPOINT; by W. L. Hedenberg. *Municipal Engineering*, v. 15, p. 341 (Dec., 1898). (On value of a plant after several years' use; theoretical.)

VALUATION OF WATER WORKS; by Alton D. Adams. *Municipal Journal*, v. 32, p. 942 (June 20, 1913). (Cost of reproduction, value of plant site, distribution system, adequateness of plant, depreciation.)

WATER-WORKS—GENERAL—(*Continued*).

VALUATION OF WATER-WORKS PROPERTIES; by Charles E. Burdick. *Engineering-Contracting*, v. 23, p. 238 (Oct. 23, 1907). (On physical value, depreciation, going value and franchise value; abstract of paper read before Wisconsin League of Municipalities; four pages.)

——*Municipal Journal and Engineer*, v. 23, p. 302 (Sept. 11, 1907).

VALUATION OF WATER-WORKS PROPERTY; by Wynkoop Kiersted. *Transactions*, American Society of Civil Engineers, v. 38, p. 115 (Paper 813. Dec., 1897). (100 pages, including discussion.)

WATER-WORKS APPRAISALS; by Burns and McDonnell. *Engineering Record*, v. 59, p. 616 (May 15, 1909). (Gives brief descriptions of appraisals in nine different cities.)

WATER-WORKS MANAGEMENT AND MAINTENANCE; by Winfred D. Hubbard and Wynkoop Kiersted. John Wiley & Sons, New York, 1907. (Contains a chapter on franchise, water rates, and depreciation.)

WATER-WORKS—SPECIAL CASES.

Antigo, Wis.

***GEORGE W. HILL ET AL. VS. ANTIGO WATER COMPANY**; Submitted June 29, 1908, Decided August 3, 1909. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 3, p. 623. Madison, Wis., 1910. (Gives methods of valuation of water-works plant.)

Appleton, Wis.

***CITY OF APPLETON VS. APPLETON WATER WORKS COMPANY**; Decided May 14, 1910. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 5, p. 215. Madison, Wis., 1911. (Discusses the determination of the present value and reproduction of physical property, value of franchises, etc.)

——The Appleton Water-Works Decision. *Engineering Record*, v. 62, p. 158 (Aug. 6, 1910). (Two pages.)

——Decision of the Railroad Commission of Wisconsin in the Appleton Water-Works Case. *Engineering News*, v. 63, p. 697 (June 16, 1910). (Two pages.)

***IN RE DETERMINING AND FIXING A JUST COMPENSATION TO BE PAID TO** the Appleton Water Works Company by the City of Appleton for the Taking of the Property of Said Company; Submitted Oct. 24, 1910, Decided Dec. 7, 1910. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 6, p. 97. Madison, Wis., 1912. (Detailed summary of valuation of physical property of the Appleton Water-Works Co., five-year average, franchise value and going value.)

Ashland Wis.

***CITY OF ASHLAND VS. ASHLAND WATER COMPANY**; Decided Nov. 1, 1909. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 4, p. 273. Madison, Wis., 1910.

Augusta, Me. See Maine.

Baltimore, Md.

A RETROSPECT OF AN ARBITRATION ON THE VALUE OF A WATER WORKS; by Albert H. Wehr. *Proceedings*, American Water Works Association, v. 26, p. 361 (1906). (The Mayor and City Council of Baltimore against the Baltimore County Water & Electric Co.; shows method and principle applied to appraisal of the property.)

——Abstract. Arbitration on the Value of a Water-Works. *Municipal Engineering*, v. 31, p. 135 (Aug., 1906).

Beloit, Wis.

***CITY OF BELOIT VS. BELOIT WATER, GAS AND ELECTRIC COMPANY**; Decided July 19, 1911. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 7, p. 201. Madison, Wis., 1912. (Includes appraisal of the physical property of the Water-Works Department.)

——Fixing Normal Operating Costs; by Frank A. Newton. *Engineering Record*, v. 65, p. 258 (March 9, 1912). (Comments on the decision of the Wisconsin Railroad Commission in the case of the City of Beloit *vs.* the Beloit Water, Gas & Electric Co.)

Birmingham, Ala.

THE MERIDIAN CASE; by W. J. Milner. *Proceedings*, American Water Works Association, v. 16, p. 204 (1896). (Concerning the appraisal of the Birmingham, Ala., Water-Works, on their purchase by the City.)

Brunswick, Me. See Maine.

WATER-WORKS—SPECIAL CASES—(*Continued*).

California.

***UNIFORM CLASSIFICATION OF ACCOUNTS FOR WATER CORPORATIONS PRE**scribed by the Railroad Commission of the State of California; Adopted Oct. 23, 1912; Effective Jan. 1, 1913. Sacramento, 1912.

Chicago, Ill.

THIRTY-FOURTH ANNUAL REPORT OF THE DEPARTMENT OF PUBLIC WORKS to the City Council of the City of Chicago for the Year Ending Dec. 31, 1909, pp. 320, 321. Chicago, 1911. (Gives tables of appraisement of water-works equipment and percentage of depreciation.)

Chippewa Falls, Wis.

***T. J. CUNNINGHAM ET AL. VS. CHIPPEWA FALLS WATER WORKS AND LIGHT**ing Company: In Re Investigation by the Railroad Commission of Wisconsin of Rates Charged by the Chippewa Falls Water Works and Lighting Company; In Re Valuation of the Property of the Chippewa Falls Water Works and Lighting Company; Decided June 14, 1910. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 5, p. 302. Madison, Wis., 1911. (Consideration of factors affecting plant value, going value, working capital and accruing depreciation.)

Contra Costa, Cal.

VALUATION OF THE WORKS OF THE CONTRA COSTA WATER COMPANY. *Engineering Record*, v. 43, p. 516 (June 1, 1901). (Review of a decision in a California Court in which the value of the property of a water-works company is placed at two and one-half times its cost.)

Denver, Colo.

REPORT OF THE BOARD OF APPRAISERS AND ARBITRATORS UPON THE PROPerty of the Denver Union Water Company, March 20, 1909. Denver, 1909. (Report made to the Mayor and City Council, giving estimates on real and personal property; forty-six pages.)

Fond du Lac, Wis.

***IN RE DETERMINING AND FIXING JUST COMPENSATION TO BE PAID TO THE** Fond du Lac Water Company by the City of Fond du Lac for the Property of Said Company Actually Used and Useful for the Convenience of the Public; Submitted April 15, 1910, Decided Aug. 19, 1910. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 5, p. 482. Madison, Wis., 1911. (Discusses the original value of plant depreciation, etc.)

——Valuation of the Fond du Lac Water-works. *Engineering Record*, v. 62, p. 275 (Sept. 2, 1910). (Reviews the principles on which the Railroad Commission of Wisconsin based its findings; two pages.)

Freeport, Ill.

A COMPARATIVE STUDY OF THE FOUR PRINCIPAL METHODS OF APPRAISING the Value of Public Utilities with Special Reference to the Valuation of the Freeport (Ill.), Water Works Properties. *Engineering and Contracting*, v. 38, pp. 368, 396 (Oct. 2, 9, 1912). (The original cost method; the commercial or comparative method; the value of a plant as found by the market value of its securities; and the cost of reproducing the property at the present normal prices of material and labor.)

Gloucester, Mass.

THE APPRAISAL OF THE GLOUCESTER WATER-WORKS. *Engineering Record*, v. 40, p. 264 (Aug. 19, 1898). (A review of the principles adopted by the commissioners appointed to hear testimony and appraise the value of a private water company.)

——Appraisal of the Gloucester Water-Works. *Engineering Record*, v. 44, p. 121 (Aug. 10, 1901). (A decision of the Supreme Judicial Court of the Commonwealth of Massachusetts on the valuation of water-works.)

Great Britain.

THE VALUATION OF WATER-WORKS UNDERTAKINGS ON TRANSFER TO MUnicipal Authorities; by E. J. Silcock. *Surveyor and Municipal and County Engineer*, v. 43, p. 920 (June 13, 1913). (Paper read before the Institution of Water Engineers; general principles on valuation of water-works property in Great Britain.)

Indianapolis, Ind.

REPORT OF THE BOARD OF PUBLIC WORKS, INDIANAPOLIS, 1898, p. 13. Indianapolis, 1898. (Contains report upon the physical condition and value of the property of the Indianapolis Water Co.)

WATER-WORKS—SPECIAL CASES—(*Continued*).

Janesville, Wis.

***CITY OF JANESVILLE VS. JANESVILLE WATER COMPANY;** Decided August 17, 1911. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 7, p. 628. Madison, Wis., 1912. (Contains summary showing value of each class of property in revised valuation of physical property brought down to Jan. 1, 1910.)

Kansas. See Missouri.

Knoxville, Tenn.

THE KNOXVILLE WATER CASE. *Electric Railway Journal*, v. 33, p. 280 (Feb. 13, 1909). (Decision of U. S. Supreme Court; contains material on valuation and depreciation; one and one-half pages.)

——Editorial. Depreciation of Plant and Fair Rates for Public Service. *Engineering Record*, v. 59, p. 197 (Feb. 20, 1909). (Comments on the decisions of the Supreme Court in the Knoxville water case.)

PROVISION FOR DEPRECIATION BY PUBLIC UTILITY CORPORATIONS. (Letter); by W. H. Winslow. *Engineering News*, v. 61, p. 251 (March 4, 1909). (Comment on decision of the Supreme Court in the Knoxville water case.)

SUPREME COURT DECISION IN THE KNOXVILLE WATER CASE. *Electrical World*, v. 53, p. 386 (Feb. 11, 1909). (Two pages.)

VALUATION OF PUBLIC UTILITY PROPERTIES. *Electrical World*, v. 53, pp. 509, 692, 740, 928, 1036 (Feb. 25, March 18, 25, April 15, 29, 1909). (Discussion between W. H. Winslow and F. E. Haskell in relation to the reasoning of the U. S. Supreme Court as to depreciation, in the Knoxville water case.)

Lake Forest, Ill.

OUTLINE OF A CONTRACT BETWEEN A CITY AND A WATER-WORKS COMpany. *Municipal Engineering*, v. 36, p. 247 (April, 1909). (Ordinance rejected by City Council of Lake Forest, Ill.; included provision for valuation of property according to the British plan.)

London, England.

LONDON WATER-WORKS ACQUIREMENT; by R. Price-Williams. *Engineering*, v. 77, p. 544 (April 15, 1904). (Concerning the report of the Court of Arbitration on the valuation of eight water companies acquired by the Water Board.)

Los Angeles, Cal.

ALLOWANCES FOR DEPRECIATION IN THE PIPE SYSTEM OF THE LOS ANgeles Water-Works. *Engineering News*, v. 41, p. 283 (May 4, 1899). (Gives total valuation of the distribution system and details of depreciation established for different varieties of pipe.)

Madison, Wis.

***CHRISTIAN DICK ET AL. VS. BOARD OF WATER COMMISSIONERS OF THE** City of Madison, In Re Valuation of the Plant of the Madison Municipal Water Works; Decided Nov. 11, 1910. In Opinions and Decisions of the Railroad Commission of the State of Wisconsin, v. 5, p. 731. Madison, Wis., 1911. (A valuation of the Madison water plant undertaken by the Engineers of the Commission.)

——The Method of Making Water Rates Ordered in Wisconsin. *Engineering Record*, v. 63, p. 28 (Jan. 7, 1911). (Valuation of the water-works of Madison, Wis., to assist in determining rates.)

Maine.

A COURT RULING ON THE BASIS FOR APPRAISAL OF A WATER-WORKS PLANT. *Engineering News*, v. 49, p. 75 (Jan. 22, 1903). (Contains instructions to the appraisers appointed to fix the price of water-works property at Waterville, Fairfield, Winslow, Benton, and Mt. Vernon, in Maine, to be taken by the Kennebec Water District.)

MAINE WATER DISTRICTS AND APPRAISERS; by Harvey D. Eaton. *Journal*, New England Water Works Association, v. 19, p. 147 (June, 1905). (Provisions of an act providing for the incorporation of the Kennebec Water District and the appraisal of the water-works of Waterville and Augusta, Me.)

NEW FEATURE IN WATER-WORKS APPRAISALS. (Editorial.) *Engineering News*, v. 54, p. 147 (Aug. 10, 1905). (Considers the relation between the Waterville and Augusta appraisals and the quality of the water supply.)

WATER WORKS VALUATION AND FAIR RATES IN THE LIGHT OF THE MAINE Supreme Court Decisions in the Waterville and Brunswick Cases; by Leonard Metcalf. *Transactions*, American Society of Civil Engineers, v. 64, p. 1 (Paper 1105. Sept., 1909). (111 pages, including discussion.)

MEMOIRS OF DECEASED MEMBERS.

BENJAMIN MORGAN HARROD, Past-President, Am. Soc. C. E.*

DIED SEPTEMBER 7TH, 1912.

Benjamin Morgan Harrod was born in New Orleans, La., on February 19th, 1837. His father, Charles Harrod, came to that city in 1809, and made it his home. His mother, Mary Morgan, was a native of Louisiana, and the daughter of Benjamin Morgan who had come from Pennsylvania in the late years of the previous century and engaged in business and planting.

After attending the local schools, he prepared for college at Flushing, N. Y. He afterward entered Harvard University and was graduated in the class of 1856, with a well-formed intention of following a technical or constructive profession.

After a year or more of preparatory study, Mr. Harrod secured employment as Draftsman, in the United States Engineer Office in charge of the construction of forts and light-houses on the Gulf Coast, from the Mississippi River to the Rio Grande River, and subsequently was appointed Assistant Engineer. In 1859 he commenced practice in New Orleans, as an Engineer and Architect.

In April, 1861, he enlisted as a private in the Confederate Army, and was soon commissioned as Lieutenant in an Artillery Regiment, being detailed on engineer duty. He served as Brigade and Division Engineer with the command of Gen. M. L. Smith in the fortification and defense of New Orleans and Vicksburg. When exchanged after the surrender of the latter place, he was commissioned as Captain of Engineer troops in Virginia, was engaged in the defense of Petersburg and Richmond, and followed the fate of that Army to the surrender at Appomattox, in 1865. He then resumed professional practice in New Orleans.

In 1877 Major Harrod was appointed Chief State Engineer of Louisiana, with the late H. B. Richardson and T. S. Hardee, Members, Am. Soc. C. E., as associates, on a board, the principal function of which was the construction of a system of levees to protect the alluvial regions of the State from overflow.

In 1879 he was appointed an Engineer member of the Mississippi River Commission, charged by the United States Government with the survey of the Mississippi River and its tributaries, and the improvement of the main streams from the junction of the Ohio to the head of the Passes, with special reference to confinement and its conservative influence on navigation. The importance of this latter

* Memoir prepared by the following committee: Frank M. Kerr, Sidney F. Lewis, and Arsene Perrilliat, Members, Am. Soc. C. E.

B. McHarrod

part of the work of the Commission was subsequently recognized by the Government, and the repair and building of levees was made mandatory. It has been one of the most beneficent and remunerative works of the age, affecting the reclamation from overflow of 30 000 sq. miles of territory of unsurpassed fertility, and its development in population, agriculture, commerce, and wealth.

From 1888 to 1892 Major Harrod was City Engineer of New Orleans, and, subsequently, Advisory Engineer for the drainage, sewerage, and water-works systems of that city; and from 1897 to 1902, he had charge of the drainage, both designing and constructing.

In 1903 he was appointed, with Gen. C. W. Raymond and John Bogart, Members, Am. Soc. C. E., as the first United States Delegates to the International Congress of Navigation, held that year at Düsseldorf, Germany, but was prevented by business from attending its sessions.

In 1904 he was appointed a Member of the Panama Canal Commission, and served until 1907, when the type of the canal was determined and the charge of the work was transferred to the present Commission. His subsequent work was as a Consulting Engineer in New Orleans.

He married, in 1865, Miss Harriet Shattuck Uhlhorn, and, in 1883, Miss Eugenia Uhlhorn, both of New Orleans, the latter surviving him.

The degree of LL.D. was conferred on him by Tulane University, in 1906, as a

"Graduate of Harvard University fifty years ago; President of the American Society of Civil Engineers; expert specialist and virile all-round man; friend of Tulane University and of all movements to better this City. In deepening a river and now in cutting an isthmus, his work has ever been to bring men closer in commerce, in friendship, and in mutual helpfulness."

Major Harrod was also a Member of the Association of Harvard Engineers, and its Vice-President in 1909, as well as a Member of the Louisiana Engineering Society.

He was a man of sterling qualities and strong individuality, but at all times generous and kind, and the friend of the worthy young aspirant for advancement in the Profession. Recognized, as he was, as a man of letters, of science, and of pronounced artistic taste, and as a high-toned, patriotic, public-spirited, loyal citizen, his loss will long be felt by the many who in life had the privilege of knowing him and in consequence admiring him.

Major Harrod was elected a Member of the American Society of Civil Engineers on April 4th, 1877. He served as Director from 1892 to 1894, as Vice-President in 1895-96, and as President in 1897.

GEORGE EDWARD GRAY, Hon. M. Am. Soc. C. E.*

DIED JANUARY 1ST, 1913.

George Edward Gray, the son of Joel and Betsey R. Gray, was born at Verona, N. Y., on September 12th, 1818.

After receiving a public school education, he studied civil engineering under Pelatiah Rawson, a pioneer in the Profession in this country.

In August, 1839, Mr. Gray was appointed Resident Engineer on the Black River Canal, in New York State, and remained in that position until 1842. He then served as Assistant Engineer, under the late Allan Campbell, M. Am. Soc. C. E., Chief Engineer, and the late A. W. W. Evans, M. Am. Soc. C. E., Resident Engineer, on the New York and Harlem Railroad until 1847, when he returned to the Black River Canal, serving as Assistant Engineer and, later, as Resident Engineer, on that and the Erie Canal.

In the Spring of 1852, he was appointed Chief Engineer of the Utica and Schenectady and the Mohawk Valley Railroads, and, in 1853, when these and other roads were consolidated to form the New York Central Railroad, he was made Chief Engineer of the latter, remaining in that position until May, 1865. It was during his incumbency as Chief Engineer, and under his immediate direction, that the first wrought-iron truss bridges in the United States were built on the line of this railroad. He also acted as Chief Engineer on the construction of the Hudson River Bridge, at Albany, N. Y., from 1860 to May, 1865.

In 1865 Mr. Gray was made Consulting Engineer of the Central Pacific Railroad which, with the Union Pacific Railroad, completed the first transcontinental railroad in the United States. Mr. Gray continued in this position until 1871, when he was employed as Chief Engineer by the Southern Pacific Railroad, and in this capacity had charge of the construction of many miles of that road and of the various other railroads comprising the Southern Pacific System.

In 1885, he retired from railroad work and engaged in consulting practice at his home in Elmwood Park, Berkeley, Cal., until his death on January 1st, 1913.

Mr. Gray was held in affection and respect by all who knew him and his work. He was a member of many technical and scientific associations, including the Institution of Civil Engineers of Great Britain, the California Academy of Sciences, the San Francisco Association of the American Society of Civil Engineers, etc., and served as a Trustee of the Leland Stanford, Jr., University for many years.

Mr. Gray was elected a Member of the American Society of Civil Engineers on July 2d, 1873, and an Honorary Member on June 5th, 1894.

* Memoir prepared by the Secretary from material on file at the Society House.

PETER SUTHER ARCHIBALD, M. Am. Soc. C. E.*

DIED MARCH 16TH, 1913.

Peter Suther Archibald, the son of William and Elizabeth (Blair) Archibald, was born at Truro, Nova Scotia, on March 21st, 1848, and received his education in the Truro Model and Normal Schools.

Mr. Archibald began his professional career as a Rodman on the preliminary surveys for the Intercolonial Railway in September, 1867, under *Sir* Sandford Fleming, M. Am. Soc. C. E., and, during the construction of the road and its subsequent operation, he rose, by sheer ability and application, from one position to another, until, in 1879, he became Chief Engineer of the railroad which, as a boy, he had helped to construct. This position he held until his resignation, in 1898, to take up private practice as a Consulting Engineer.

Mr. Archibald was Consulting Engineer of the St. John Cantilever Bridge and Railway Extension Company, by special permission of the Minister of Railways. In 1894 he was appointed a member of the Royal Commission to inquire into freight rates in Manitoba and the Northwest Territories.

In 1902 he was made Chairman of an Arbitration Tribunal between Contractor Reid and the Newfoundland Government, which involved a $2 000 000 claim; and, later, he was Chairman of the Arbitration Board to settle the question of the Newfoundland telegraph lines. He was also employed as an expert in disputed matters between the Clergue Syndicate and its contractors on railway construction.

In 1905 Mr. Archibald was Contractor's Engineer for Mr. A. E. Trites, on the construction of the Northern Maine Seaport Railroad, now a part of the Bangor and Aroostook Railroad. In 1907 he was appointed a member of the Conciliation Board *re* the Cumberland Coal and Railway Company, under the Industrial Disputes Act, and in 1908 he was made a Commissioner by the New Brunswick Government to manage the New Brunswick Central Railway.

Mr. Archibald's capabilities as a Consulting Engineer were so widely recognized that, after taking up private practice, his services and advice were frequently sought in cases of special importance, as well as in many smaller projects for railways, bridges, and water supplies.

Mr. Archibald was a wide reader; a man of calm, even temperament, a true friend, and a gentleman who possessed the confidence and respect of those who had the pleasure of his acquaintance. By his

*Memoir prepared by William B. MacKenzie, Esq., Right-of-Way and Lease Agent, Intercolonial Railway of Canada, Moncton, N. B., Canada.

ever-ready desire to assist those in need, he secured not only the respect of his professional brethren, but the admiration and loyalty of his subordinates.

In April, 1874, Mr. Archibald was married to Miss Clara G. Lindsay, the daughter of Mr. F. S. Lindsay, of Rockland, Me.

He was a Member and Councillor of the Canadian Society of Civil Engineers, and a Lieutenant in the 73d Volunteer Battalion.

Mr. Archibald was elected a Member of the American Society of Civil Engineers on January 7th, 1885.

THOMAS CHALKLEY JAMES BAILY, JR., M. Am. Soc. C. E.*

DIED DECEMBER 6TH, 1912.

Thomas Chalkley James Baily, Jr., was born in Boston, Mass., on December 20th, 1867. His father, Major Thomas Chalkley James Baily, U. S. A., served throughout the Civil War, being commissioned First Lieutenant on May 14th, 1861, and retiring with the rank of Major, on August 18th, 1865. His mother, Carrie E. Todd, a native of Augusta, Me., was of Puritan ancestry, and descended from the earliest New England settlers.

After attending the local schools, Mr. Baily prepared for college at the Newark School, Newark, Del. He afterward entered Lehigh University, and was graduated in the Class of 1890, with high honors, and with the degree of Civil Engineer.

For two years after his graduation, he was a member of the Engineer Corps of the Erie Railroad, stationed at New Castle, Pa., resigning to accept a position on the Mississippi River improvement, where he was engaged in examinations and surveys of the mouth of the Mississippi. In 1893, he entered the Engineer Department of the District of Columbia, first as Draftsman and then as Assistant Engineer in the Highway Division. In 1908, he was appointed Principal Assistant Engineer in the Sewer Department of the District of Columbia; two years later he was made Assistant Engineer in charge of Street Extensions; and, in 1910, he was appointed Engineer of Bridges for the District of Columbia.

Mr. Baily was in charge of the construction of the Anacostia River Bridge, and, as Engineer of Bridges, he designed and built a number of important structures, among them the Cedar Street Subway at Takoma Park, D. C., and the Belmont Street Improvement. At the time of his death, he had just completed the plans and specifications for the Q Street Viaduct, crossing Rock Creek Valley at Washington.

He assisted in the design and construction of the Edmonton Avenue Bridge at Baltimore, Md., and collaborated with W. J. Douglas, M. Am. Soc. C. E., in writing the chapters on Masonry and Timber Structures for the "American Civil Engineers' Pocket Book," edited by Mansfield Merriman, M. Am. Soc. C. E.

At the time of his death, Mr. Baily was making investigations of the Harbor of Progresso, Yucatan, for Barclay Parsons and Klapp, Consulting Engineers. He died suddenly in the City of Mexico, on December 6th, 1912.

* Memoir prepared by Asa E. Phillips, M. Am. Soc. C. E.

In 1894, he was married to Miss Mary Rodgers, of Orange, N. J., who, with one daughter and one son, survives him.

Mr. Baily was a thorough and painstaking engineer, and an exceptionally devoted student of his Profession. He had a kind and genial nature, and was esteemed and admired by all who knew him. He was a devoted father, a faithful friend, and a good citizen.

Mr. Baily was elected a Member of the American Society of Civil Engineers on October 4th, 1905.

ANDREW BELL, M. Am. Soc. C. E.*

DIED OCTOBER 22D, 1912.

Andrew Bell was born at Toronto, Ont., Canada, on December 21st, 1835. His father, the late Rev. Andrew Bell, was the eldest son of the Rev. William Bell, the pioneer clergyman of Perth, Ont., and the surrounding country. His mother was the eldest daughter of the late Col. E. W. Thomson, of Toronto, a cousin of Baron Sydenham, who was Governor of Upper Canada at the time of consolidation of the provinces.

Mr. Bell was educated at Queen's College, from which he was graduated in 1853 with the degree of B. A. Immediately after his graduation he was articled to Mr. William Syles as a student of Civil Engineering.

In February, 1854, he was appointed Rodman on the survey of the Brockville and Ottawa Railway (now a part of the Canadian Pacific Railway) from Smith's Falls to Carleton Place, and to Perth. This work was discontinued in 1855, and Mr. Bell was engaged in making surveys, under K. Tully, Esq., for the proposed canal from Toronto to Georgian Bay.

In July, 1856, he was appointed Resident Engineer on the Brockville and Ottawa Railway, which position he retained until 1859, having been engaged in the following work: In 1856 he surveyed and located the line from Brockville to Smith's Falls; in October of the same year, he was sent to Almonte, Ont., and placed in charge of the construction, under the late Alphonse Brooks, from Carleton Place to Pakenham; and from 1857 to 1859, he was in charge of the surveys from Sand Point to Pembroke and of the completion of the construction between Carleton Place and Almonte.

Between 1864 and 1869, Mr. Bell had charge of the construction of the large woolen mills at Almonte and Cornwall, Ont., being engaged, at the same time, in general private practice. In 1869 he made a hydraulic survey between Lake Superior and Lake Winnipeg for the Dominion Government.

In June, 1870, he was appointed Resident Engineer on the enlargement of the Grenville Canal, remaining in this position until June, 1872, when he became Resident Engineer on the construction of the Carillon Canal Dam and Slide. After the completion of this work, in 1886, Mr. Bell removed to Almonte, Ont., where, until his death, he was engaged in private practice as a Civil Engineer, Land Surveyor, and Architect. While engaged on a survey of the country east of

* Memoir prepared by the Secretary from information on file at the Society House.

Cochrane, on the Grand Trunk Pacific Railway, he was taken ill and was forced to return to his home in Almonte, where he died on October 22d, 1912.

In 1858, Mr. Bell was married to Miss Marion Rosamond, eldest daughter of the late James Rosamond, of Almonte, who, with five children survives him.

Mr. Bell was elected a Member of the American Society of Civil Engineers on September 5th, 1883. He was also a Member of the Canadian Society of Civil Engineers, and many other technical associations.

DANIEL SEYMOUR BRINSMADE, M. Am. Soc. C. E.*

DIED SEPTEMBER 7TH, 1912.

Daniel Seymour Brinsmade was born at Trumbull, Conn., on February 17th, 1845. He was the youngest son of Daniel Stiles Brinsmade and Catherine Mallette Brinsmade, his family having resided continually for more than 250 years within the limits of the original town of Stratford, Conn.

Mr. Brinsmade received his early education in the public schools of Trumbull and at the Gunnery at Washington, Conn. He then entered the Sheffield Scientific School of Yale University, from which he was graduated in 1870.

Immediately after his graduation, Mr. Brinsmade was appointed Assistant Engineer on the construction of the dam across the Housatonic River at Huntington, Conn., for the Ousatonic Water Company. In 1871, he was made Chief Engineer of the project, and afterward served successively as Secretary and Treasurer. In 1900, he was made President of the Company, which position he held until his death, at Shelton, Conn., after an illness of nearly two years. In 1891, the old dam was destroyed, and Mr. Brinsmade had to rebuild the structures and add many new features in order to meet the conditions which obtained at that time.

He made hydraulic engineering his life study, and, being an authority on the subject, was continually engaged in the construction of water-supply and water-power projects. He was widely known as a Consulting Engineer throughout New England and New York State, and served as a member of a commission appointed by the State of Maine to consider the question of water-power development in that State.

Mr. Brinsmade was a genial, cultured gentleman, whose advice was eagerly sought in business as well as in private life, and whose salient characteristics were honesty and truth. He took great pride in the betterment of his home town, Shelton, Conn., and was closely connected with all phases of activity within the community. He served the Borough in nearly every elective position in its gift. He was also elected to the General Assembly as Representative and State Senator, and, although a staunch Republican, he did his duty in these positions regardless of party.

Mr. Brinsmade was a Director of the Shelton Water Company, a Trustee of the Griffen Hospital, President of the Shelton School Board for nearly twenty-eight years, President of the Plumb Memorial Library Directorate, and a Trustee of the Riverside Cemetery Association, all

* Memoir prepared by the Secretary from information on file at the Society House.

of which institutions he was largely interested in establishing and maintaining. He was also Vice-President of the Home Trust Company, of Derby, Conn., and a Director of the Birmingham National Bank. He was a Member of the Congregational Church, of Shelton, and also prominent as a Mason and an Odd Fellow.

Mr. Brinsmade was elected a Member of the American Society of Civil Engineers on February 1st, 1888. He was also a Charter Member of the Connecticut Society of Civil Engineers and served as its President in 1907.

ALFRED ELLSWORTH CARTER, M. Am. Soc. C. E.*

DIED JUNE 11TH, 1912.

Alfred Ellsworth Carter was born at Blair, Nebr., on April 19th, 1867, of American parents, his ancestry dating back through several generations of pioneer stock. His early education was obtained at the public schools of his home town, and, later, at the University of Nebraska, from which he received the degree of Bachelor of Science, in 1900. In 1902 he entered Columbia University, New York City, and was graduated in 1904 with the degree of Civil Engineer.

Mr. Carter's early experience was gained while earning his way through college. In the the early Nineties he was in the employ of the Chicago and Northwestern Railway Company, in Fremont, Elkhorn and Missouri Valley Railroad activities, holding successively the positions of Chainman, Rodman, and Transitman, on miscellaneous surveys in Nebraska and the Black Hills of South Dakota. From August, 1897, to March, 1899, he was Assistant Engineer on the construction of a hydro-electric power dam at Divide, Mont., an impounding reservoir dam adjacent to Butte, Mont., and one of the first wood stave and riveted steel pipe lines for the Montana Power Company.

Following the Spanish-American War, from October, 1900, to October, 1902, Mr. Carter was Assistant Engineer in charge of detailed designing of sewers and pumping stations for two sections of the marginal sewer system of Havana, Cuba, being associated with Samuel M. Gray, M. Am. Soc. C. E., Consulting Engineer, the work being done by the Department of Sewers, under Military Government, William M. Black, M. Am. Soc. C. E., Colonel, Corps of Engineers, U. S. A., being in general charge at Havana.

From January, 1905, to the time of his death, Mr. Carter was in the employ of the Rapid Transit Subway Construction Company, Contractors, of New York City, as Assistant Engineer, until 1908, in charge of tunnel alignment, check surveys, track-laying, and driving reinforced concrete piles, on the construction of the East River Tunnel of the Rapid Transit Railroad; then Resident Engineer in charge of construction of the Bowling Green Shuttle Station, and the Subway station extensions at the Fulton Street, Wall Street, Bowling Green, Borough Hall, and Atlantic Avenue Stations of the Interborough Rapid Transit Company. He was also engaged in reporting on extra claims of the Sub-contractor on the East River Tunnel.

At the time Mr. Carter became engaged on the work of the East River Tunnel, the Brooklyn tubes were just entering the river sec-

* Memoir prepared by George H. Pegram, M. Am. Soc. C. E.

tion and the Manhattan tubes had not emerged from the rock. He was employed continuously on this work until its completion in January, 1908. It has been described as one of the most difficult pieces of engineering work ever accomplished. Mr. Carter's position as Assistant Engineer imposed great responsibilities on him. He was in charge of the delicate operations of sinking piles through the bottom of the tubes to rock. The character of the work and the financial failure of the Sub-contractor, during the construction of the tunnel, made the accounting unusually complicated. The patience and fidelity with which Mr. Carter worked in checking the claims of the Sub-contractor and the skill and judgment evinced in his reports are remarkable. It was a work of great labor and uncongenial to an Engineer, but his familiarity with the construction forced it on him. His engineering work had been above criticism, but this work was almost above praise.

Subsequently, Mr. Carter was put in charge, as Resident Engineer, of the construction of Bowling Green Shuttle Station and the lengthening of the Subway stations from Fulton Street, Manhattan, to Atlantic Avenue, Brooklyn. Like his East River Tunnel experience, this work was of the most difficult character. The continuous operation of trains, the congested street traffic, the numerous sub-surface structures which interfered with the work, such as sewers, water pipes, electric subways, and the foundations of buildings, made it always a delicate task.

The work of extending the Borough Hall Station in Brooklyn, for which Mr. Carter designed the shoring and directed the work for the Construction Company, was especially difficult. This station was built of reinforced concrete which was exceptionally difficult to remove. At this point there are three tracks in the Subway, with cross-overs, and on the surface of the street there is a junction of two tracks in Court Street and two tracks in Fulton Street. Both side-walls of the Subway, for a length of 135 ft., were entirely removed, and its roof with 7 ft. of cover, together with street structures, etc., was supported on timber. Three columns of the Elevated Railroad in Brooklyn were temporarily supported over the work and the foundations renewed; the cast-iron pipes and the gate-chambers of the high-pressure water mains were supported and reconstructed at an especial hazard to the work. In addition, the portico of the County Court House, weighing more than 1 000 tons, a structure with four large granite columns, thus having little transverse stiffness, was temporarily supported, and the foundations were carried 12 ft. deeper by masonry underpinning. This was done without the slightest show of crack or any measurable settlement of the portico. All this work was in sand and Mr. Carter was continually obliged to render it safe against the breakage of water pipes or the unusual flood of storm-water.

This work was about completed at the time of his death, which occurred suddenly at his home in New York City on June 11th, 1912, from cerebral hemorrhage.

Mr. Carter was a man of sterling integrity, with the ability for doing hard work well, and accepting and fulfilling growing responsibilities with quietness and efficiency; the consideration he gave to all matters, large or small, entrusted to his care, had won for him the respect of his associates and those who worked under his direction.

In 1904 Mr. Carter was married to Miss Ida C. Messer, of Cleveland, Ohio, who survives him. She is a lady of unusual educational attainments and was able to assist him in his professional work.

He was a Member of Columbia Chapter (Kappa) of the Society of the Sigma Xi, and a Member of Washington Lodge No. 21, F. & A. M., of Blair, Nebr.

Mr. Carter was elected an Associate Member of the American Society of Civil Engineers, on June 4th, 1902, and a Member on April 4th, 1911.

PHILIP HENRY COOMBS, M. Am. Soc. C. E.*

DIED MARCH 6TH, 1913.

Philip Henry Coombs, the son of P. H. and Sarah Forbes (Woodhull) Coombs, was born at Bangor, Me., on December 24th, 1856. He was educated in the public schools of that place, and in 1875 entered the office of his uncle, the late Frederick H. Coombs, who was then City Engineer of Bangor, as his Principal Assistant, remaining in this position until 1883.

In November, 1883, Mr. Coombs was elected City Engineer and Superintendent of Sewers of Bangor, which office he held continuously until March, 1893. He occupied the same office in 1894, 1899, and from 1901 to 1905, inclusive. He also served as City Engineer for Brewer, Me. During his incumbency as City Engineer, Mr. Coombs had charge of the construction of many miles of sewers, and thereby became an authority on the plan of the City of Bangor, its streets, and sewerage system, a knowledge which proved of great value during his long period of service as a public official.

As City Engineer, he also made the plans, specifications, and contracts, and had direct charge of the construction of the masonry pier and abutments for Kenduskeag Bridge in 1884 and 1889, and of the masonry pier for the Franklin Street Bridge, in 1885, this latter work having been done jointly by the United States Government and the City of Bangor. He also supervised the erection of the new steel bridge between Bangor and Brewer; the reconstruction and extension of the Bangor Water-Works; and the erection of the Eastern Maine Insane Hospital, as well as the construction of roads and the design of the landscape work.

In addition to the work done for the City of Bangor, Mr. Coombs made surveys and plans for water-works and sewerage systems in many other towns in Maine, including Dexter, Dover, Foxcroft, Newport, and Brewer.

In 1887, he formed a partnership with Thomas W. Baldwin, M. Am. Soc. C. E., under the firm name of Baldwin and Coombs. The firm was engaged in general engineering practice until 1892, when Mr. Baldwin removed from Bangor, and the business was taken over by Mr. Coombs.

Mr. Coombs was widely known as a Consulting Engineer, and had charge of the construction of many large industrial plants, including the pulp mills of the Penobscot Chemical Fibre Company, at Great Works, Me., in 1881-83; the paper and pulp mills of the Eastern Manufacturing Company, at Brewer, in 1889; the Orono Pulp and

* Memoir prepared by the Secretary from material on file at the Society House.

Paper Company, at Basin Mills, Orono, Me.; and the Webster Paper Company, at Orono, Me., in 1890.

In 1888, he had charge of laying out the Bangor Street Railway, the first electric road built in Maine, and one of the first to be operated successfully in the United States. He was also engaged as Engineer on the survey and construction of railroads of several companies centering in Bangor, from 1888 until his death.

In 1901, Mr. Coombs was one of two Commissioners, authorized by the Maine Legislature and appointed by the Penobscot Log Driving Company, on a survey of the West Branch water-shed of the Penobscot River to investigate and determine the present storage, and need of increased storage for log-driving, manufacturing, and other purposes. He remained in the service of the Penobscot Log Driving Company until his death, being engaged chiefly on hydraulic work.

Mr. Coombs was also employed at various times as Engineer in charge of the construction of Chapin Park, Broadway Park, and Summ', Park, for the City of Bangor, and for a number of years he was also, as Engineer, in charge of the designs, plans, specifications, etc., of fishways for the Maine Fisheries Commission.

In January, 1883, Mr. Coombs was married to Miss Millie M. Field, of Bangor, Me., who, with two daughters, survives him.

On July 3d, 1911, he was suddenly stricken with what at first was thought to be sunstroke, but which later proved to be paralysis. He had partly recovered his health, and was able to attend to business, but on March 2d, 1913, he had an attack of acute indigestion, from which he died.

Mr. Coombs was a man of pleasant, genial disposition and had a wide circle of friends. He was especially prominent in Masonic affairs, and was also a member of the Order of Odd Fellows.

Mr. Coombs was elected a Member of the American Society of Civil Engineers on March 7th, 1906.

SAMUEL LISPENARD COOPER, M. Am. Soc. C. E.*

DIED MAY 8TH, 1913.

Samuel Lispenard Cooper was born in the City of New York on January 16th, 1858. His father, Samuel Hawes Cooper, was a nephew of Peter Cooper; his mother, Helen Sophia Lispenard was of French Huguenot descent. Mr. Cooper received his early education in the public schools of New York City and then studied at the College of the City of New York and at New York University. He was graduated from the latter institution in 1878 with the degree of Civil Engineer.

For the first five years of his professional career, Mr. Cooper was engaged on the surveys and preliminary work for the New Croton Aqueduct and Reservoirs, and was then placed in charge of the maintenance of the Old Croton Aqueduct, as Resident Engineer. In 1889 he entered the service of the Finance Department of the City of New York, as Supervising Engineer, and continued in this position for the next four years, gaining valuable experience in many directions. When the Department of Public Works of the City of Yonkers was organized, in 1893, Mr. Cooper was placed at its head as Commissioner, and continued in this position for 14 years until Yonkers became a second-class city, in 1908, when, under the reorganization that took place, he was appointed City Engineer, a position he filled until his death.

During 20 years of uninterrupted service with the City of Yonkers, first as Commissioner, and then as City Engineer, Mr. Cooper was responsible for the entire street system of the City. The City Pier and Recreation Pavilion were constructed according to his plans, and the City Hall Building was erected under his supervision. He also had much to do with making plans for the parks, and acted as Consulting Engineer to the Bronx Valley Sewer Commission and in connection with other enterprises.

In 1885, Mr. Cooper was married to Elizabeth Underhill, daughter of the Rev. George H. Goodsell, D.D., and niece of Bishop Daniel A. Goodsell, of the Methodist Episcopal Church, who with three children, Samuel G. Cooper, of Portland, Ore., Mrs. Raymond C. Rose, and Mary L. Cooper, survive him.

Mr. Cooper was an engineer of high ability, a man of sterling character and of indefatigable industry. Performing his duties with absolute honesty, he could not avoid making enemies, but he won the esteem of all good citizens.

During the last two years of his life Mr. Cooper suffered from an incurable disease. He bore this misfortune with great fortitude, and attended faithfully to his official duties to the last, even when scarcely able to leave his home.

* Memoir prepared by Edward Wegmann, M. Am. Soc. C. E.

On May 8th, 1913, he was relieved from his suffering. His funeral was attended by the Mayor, Aldermen, and other City officials, past and present, of Yonkers, and by a large number of citizens who showed by their presence the high esteem in which they held their former City Engineer.

Mr. Cooper was a member of the New York University Alumni Association, Delta Upsilon Fraternity, a Director of the Hollywood Inn, a member of the Nepperhan Lodge of Free Masons, Terrace City Chapter of Royal Arch Masons, of the Elks, of the City Club, and of the Central Methodist Episcopal Church of Yonkers.

Mr. Cooper was elected a Member of the American Society of Civil Engineers on February 6th, 1889.

GEORGE BLINN FRANCIS, M. Am. Soc. C. E.*

DIED JUNE 9TH, 1913.

George Blinn Francis, the son of Blinn and Lucy (Hart) Francis, was born at West Hartford, Conn., on January 31st, 1857. He received his early education in the public schools of his native town and at the Hartford High School, from which he was graduated at the age of 17.

On April 6th, 1874, he entered the employ of the Providence, R. I., Water-Works, as a student, and served for a period of three years in the Engineering Corps, during the construction of the Pettaconset Pumping Station. In March, 1877, he was transferred to the City Engineer's Department, which had just been consolidated with the Water-Works, where he served for the next 4½ years as Assistant Engineer, being assigned to the corps in charge of the "Brook Street District" improvements, and, on the completion of that work, to the Water Department.

In 1881 he joined the Engineering Department of the New York, West Shore and Buffalo Railroad and was assigned to the Ulster Division, in charge of a Hydrographic Corps between Fort Montgomery—at the southern entrance to the Highlands—and Poughkeepsie; later, he was made Assistant Engineer in charge of 4 miles of construction on this Division.

Early in 1883 Mr. Francis went to the Pacific Coast with a party selected to make surveys for a relocation of the Oregon Railway and Navigation Company's line between Portland and The Dalles, through the Cascade Mountains. In the spring of that year he was transferred to Portland as Assistant Engineer in charge of the construction of a large freight terminal, for the Northern Pacific Terminal Company, on the Willamette River, opposite Portland, including the construction of the car-ferry inclines, in connection with the transfer of passengers, for cars across the river, which were to be built in thirty days in order to be in readiness for the transfer of the famous "Gold Spike" party over the Northern Pacific Railway, in September, 1883.

On the completion of this work he returned East and for the next two years was employed on general railroad work—design, construction, and maintenance—including the preparation of plans for harbor works under the direction of the late James B. Eads, M. Am. Soc. C. E., in connection with his scheme for a ship railroad at Tehuantepec, and as Assistant Engineer, on the Hudson River Division (Weehawken to Albany), of the New York, West Shore and Buffalo Railroad, on maintenance of way.

* Memoir prepared by John F. Wallace, Past-President, Am. Soc. C. E., and John W. Ellis, M. Am. Soc. C. E.

In the fall of 1884, Mr. Francis resigned the latter position to accept that of Engineer of the Portland Construction Company, and as such had charge of the design of warehouses, docks, floating pile-driver, coal-pockets, bridges, floating dry-dock, etc. Subsequently, he became Resident Engineer on the construction of the Yakima Division of the Northern Pacific Railroad, returning East on the completion of this work. For the next three years he served in various positions on general railroad work, both design and construction, as follows: In the Engineer Corps on the Blue Mountain and Kittatinny Mountain Tunnels, on the South Pennsylvania Railroad, at Roxbury, Pa.; with the New Jersey Junction Railway, on field location from Weehawken to Bayonne, afterward having charge of the location and construction through Jersey City; and as Division Engineer on general railroad work on the Western Division of the New York Central and Hudson River Railroad, with headquarters at Rochester, N. Y.

On May 1st, 1887, he returned to Providence, R. I., as Principal Assistant Engineer of the New York, Providence and Boston Railroad, remaining in that position until March, 1892, when he was appointed Resident Engineer of the New York, Providence and Boston and Old Colony Railroad Terminal Company (subsequently controlled through lease by the New York, New Haven and Hartford Railroad Company), designing and constructing the Providence Terminal.

On July 1st, 1896, he became Resident and Acting Chief Engineer of the Boston Terminal Company, designing and constructing the South Terminal Station, in Boston, one of the largest passenger terminals in the world. With such care, foresight, and skill were the details of this intricate problem worked out that no important change has ever been made in the layout. The study and experience derived from the successful solution of these two important engineering works led Mr. Francis to specialize in this branch of the Profession, in which field he was recognized subsequently as a leading authority.

In the spring of 1899 he designed and supervised the construction of the foundations of the Kingsbridge Power Station of the Third Avenue Railroad, in New York City.

On the completion of the Boston Terminal, he became Chief Engineer of the Providence Street Railway System, and from February, 1900, to June, 1902, served during a very active period of construction and reconstruction of the Company's urban and interurban lines, building a new generating station, repair shops, car barns, etc.

Mr. Francis resigned to accept a position as head of the Civil Engineering Department of Westinghouse, Church, Kerr and Company, which Company had been retained as Engineers in connection with the new Pennsylvania Terminal in Manhattan, and, during the next eight years, the important civil engineering features of this work were under his supervision.

Some other terminal problems which received his attention are: The proposed Union Station at Toronto, Ontario; the proposed passenger and freight terminal, at Chicago, for the Chicago and Western Indiana Railroad; the Winnipeg Terminal, Grand Trunk Pacific Railway; Vancouver, B. C., Terminal, Canadian Pacific Railway; the proposed freight terminal, Canadian Pacific Railway, at Toronto; the proposed passenger terminal for the City of Buffalo; the rearrangement of the track layout, St. Louis Terminal; and many smaller terminals, both for passengers and freight, in the United States and Canada. As a member of the Railroad Committee of the Merchants Association of New York City, he rendered valuable assistance in the preparation of its report on "The West Side Improvements," relating to railroad and terminal facilities. He thrice visited Europe for observation and study of the large terminals in England and on the Continent.

Some of the many engineering problems which engaged his attention during his connection with Westinghouse, Church, Kerr and Company, were as follows:

Supervision of the construction of two high-speed interurban electric roads, one in the Lackawanna Valley, between Scranton and Wilkes-Barre, Pa., and the other in the Ohio Valley between Beaver, Pa., and Steubenville, Ohio; general supervision of the reconnaissance, location, and plans for a proposed high-speed electric road between Paterson, N. J., and Times Square, New York City; a proposed electric road between Rochester and Syracuse, N. Y., and a proposed line between Baltimore, Frederick, and Hagerstown, Md.; Consulting Engineer on hydro-electric development for the Atlanta Water and Electric Power Company; Consulting Engineer, Shut-off Dam, Charles River Basin; Consulting Engineer, deep foundations, Providence Journal Building; Consulting Engineer, East Side Easy Grade Street, Providence, R. I.; Associate Consulting Engineer with Gustav Lindenthal, M. Am. Soc. C. E., on reconstruction of Locust Point Pier for the Baltimore and Ohio Railroad, at Baltimore, Md.; Consulting Engineer, heavy reinforced concrete bridge, designed for Bush and Gunpowder River Bridges, Pennsylvania Railroad; and investigations and reports on various water-power and irrigation projects in the South and West.

Mr. Francis was a member of the Institution of Civil Engineers of Great Britain; the Boston Society of Civil Engineers; the Canadian Society of Civil Engineers; the New York Railroad Club; and the Boston Engineers' Club. He was very active in the affairs of the Boston Society of Civil Engineers, having been the first non-resident member to be honored with the Presidency, which office he filled from March 17th, 1910, to March 16th, 1911.

He was Past-Master of What Cheer Lodge No. 21; Member of the Providence Royal Arch Chapter No. 1; Providence Council No. 1, R. and S. M.; Calvary Commandery No. 13, K. T., and of Rhode Island Consistory, A. A. S. Rite, N. M. J.

He was a frequent contributor to the technical press and to the publications of various engineering societies. In 1906, with W. F. Dennis, M. Am. Soc. C. E., he was awarded the Thomas Fitch Rowland Prize by the Society, for the paper entitled "The Scranton Tunnel of the Lackawanna and Wyoming Valley Railroad."* Other papers contributed to the Society by Mr. Francis are: "The South Terminal Station, Boston, Mass.," "Electric Railways in the Ohio Valley between Steubenville, Ohio, and Vanport, Pennsylvania," and "The New York Tunnel Extension of the Pennsylvania Railroad. Certain Engineering Structures of the New York Terminal Area."†

He was awarded a gold medal at the Paris Universal Exposition in 1900, in connection with the exhibit of the Boston Terminal Company; and in 1906, he received the Honorary Degree of A. M. from Brown University.

Mr. Francis was a man of keen perception, retentive memory, and rare judgment. He was quick to grasp the essentials of a problem, and brought to its solution a trained mind and a wide and varied experience. His genial disposition, democratic spirit, and kindly courtesy won for him the unfailing loyalty, unfeigned affection, and unwavering devotion of all who ever worked for or with him. His death is keenly felt by a host of friends and business acquaintances, and is a distinct loss to the Profession which he loved, in which his life found its expression, and for which he zealously labored.

In April, 1882, Mr. Francis was married to Florence Louise Greene, of Providence, R. I., who, with one son, George B. Francis, Jr., survives him.

Mr. Francis was elected a Junior of the American Society of Civil Engineers on September 5th, 1883, and a Member on November 7th, 1888. He had also served for two years as a Member of the Nominating Committee.

† Joint author with Joseph H. O'Brien, M. Am. Soc. C. E.

CHARLES LEWIS HARRISON, M. Am. Soc. C. E.*

DIED SEPTEMBER 14TH, 1912.

Charles Lewis Harrison was born on his father's farm at Auxvasse, in Callaway County, Missouri, on March 5th, 1857, and was one of a family of twelve, having seven sisters and four brothers. He was descended from the families of Harrison and Crockett, of Virginia, his grandfather, Major John Harrison, emigrating to Missouri in 1817, and being one of the earliest American settlers in Callaway County. His parents were Thomas Harrison and Catherine (Maddox) Harrison. Thomas Harrison was born in Virginia, and moved with the family to Missouri when he was less than a year old; he served as a volunteer during the war with Mexico; tried mining in Michigan for several years in the Thirties; went to California in 1849, but returned to Auxvasse in a few years and passed the remainder of his life in Callaway County, where he became a prosperous farmer and a man of wide influence in the community, exhibiting those qualities of helpfulness and thought of others so strongly marked in his son Charles.

Mr. Harrison's early education was acquired in the public schools, from which, in 1876, he entered the University of Missouri, receiving the degree of T. E. in 1879 and the degree of C. E. in 1880. During the first two years of his course he was a working student, his father refusing to help him until, as he expressed it, he found out "what the boy was made of" and what he wanted to do. In college he exhibited those qualities for thoroughness, ready debate, and argument, which were so marked throughout his life.

After being graduated from the University, he entered the service of the Mississippi River Commission as a Rodman, and assisted in measuring the discharge of the Mississippi at Fulton, Tenn., until August, 1880, when he was transferred to Grafton, Ill., with the grade of Recorder, continuing in the work of discharge measurements until October, 1881. He was then transferred to Lake Providence, La., as Assistant on hydrographical and topographical surveys. He was obliged to give up this work in June, 1882, on account of malaria, but was offered employment under the Corps of Engineers of the Army, and from June to December, 1882, was Transitman on a topographical survey of the Missouri River from Fort Pierre to Fort Randall, Dak.; from December, 1882, to September, 1883, he was Instrumentman on a topographical survey of the Red River of the North.

The construction of reservoirs at the head-waters of the Mississippi was then in progress, under the direction of the Army Engineers, and Mr. Harrison was engaged as Assistant in the construction of a dam across that river at Pokegama Falls, Minn., from September,

* Memoir prepared by Alfred Noble, Past-President, Am. Soc. C. E., and J. Waldo Smith, M. Am. Soc. C. E.

1883, to July, 1884, and as Engineer in charge of the completion of a dam at the outlet of Lake Winnebigoshish, Minn., during the remainder of the year. During the five years ensuing he was with an uncle in Chicago, in the live stock commission business.

From July, 1890, to May, 1891, Mr. Harrison took part as Assistant Engineer in hydrographical surveys and investigations for the Sanitary District of Chicago; he then went to Northern Michigan as Engineer in charge of the improvement of Carp River and of the construction of a sewerage system for the City of Ishpeming, returning in February, 1892, to the Sanitary District to take charge of surveys for the location of the Chicago Drainage Canal, and from August, 1892, to August, 1897, was Division Engineer in charge of construction of Sections 5 to 15, embracing excavation of various kinds on a large scale and much concrete and structural work, including, with other important features, the regulating works at Lockport, Ill. While with the Sanitary District, Mr. Harrison served under Lyman E. Cooley and Isham Randolph, Members, Am. Soc. C. E., successively Chief Engineers. This was the first opportunity afforded to show to the Engineering Profession his ability as an engineer and an executive, and his work gave him a high standing.

In the summer of 1897, the United States Board of Engineers on Deep Waterways was organized to make surveys and estimates for a deep waterway from the Great Lakes to tide-water, and Mr. Harrison was the first engineer engaged. As Division Engineer he had charge of two sections, one being the Niagara Ship Canal route, from Lake Erie to Lake Ontario, the other extending from Troy to Lake Champlain. On the completion of this work at the end of 1900, he went to Panama for the Isthmian Canal Commission, where he made surveys to verify the work of the engineers of the French Company and also made borings at the site of the Bohio Dam and at other points. From June, 1900, to May, 1902, he was Chief Engineer for the Denver Union Water Company, and designed and built the Lake Cheesman Dam, notable as sustaining a greater head of water than any other structure then existing, and without any leakage.

At the end of May, 1902, Mr. Harrison accepted the position of Principal Assistant Engineer of the East River Division of the New York Terminal of the Pennsylvania Railroad. The division included four tunnels under the East River, built in compressed air, this class of work continuing nearly three years. In April, 1908, he suffered an injury of the heart from too long a stay under pressure, from which he never recovered. The work was then so nearly completed that if he could have endured for another day, he would not have incurred any further risk. He attempted to resume professional work in April, 1909, as Deputy Chief Engineer for the Board of Water Supply of the City of New York, but after a year's trial was compelled to give it up, and from that time limited himself to consultations. He passed

the winter of 1910-11 in Southern California; in the winter of 1911-12 he was in Havana and was greatly interested in the raising of the battleship *Maine*, then in progress. In March, 1912, he visited the Panama Canal.

In the latter part of August, 1912, he contracted a slight cold which did not take a serious form until two or three days before his death. He was buried in the family plot in the churchyard of the Presbyterian Church at Auxvasse.

Mr. Harrison's engineering experience embraced a wide range of successful work. To every new problem he gave the most thorough study, from the first step to the completion, and his judgment thus founded and trained was seldom or never erroneous. During his many years of participation in important work, he trained and developed a large number of young engineers from whom he required the same thoughtfulness and thoroughness, and nothing was more certain to incur his criticism than lack of care or misdirected energy, but it was given so kindly that no bitterness followed, and he possessed the friendship and loyalty of his assistants to a remarkable degree.

His work at three important industrial centers—Chicago, Denver, and New York—had made him well known throughout the United States as a capable engineer, an executive of rare ability, and as a man of the highest integrity. That his further career would have been most distinguished, if his health had permitted, is evidenced by the large number of engagements he was obliged to decline.

He loved the truth in all things, and hated any form of deceit or misrepresentation; he was generous to a fault, but for the hypocrite or professionally impecunious he had no consideration. His patience and perseverance, as well as his thoughtfulness for, and kindliness to, those associated with him, was particularly marked, and he was always a most loyal friend.

His recreation and hobby was a most unusual one, in that he was the only engineer, or one among a few, who owned a racing stable. His stable, although small, was chosen with the same good judgment and attention to detail shown in his engineering work, so that his colors were often in the lead on the principal tracks of the country, and his percentage of winners was greater than in the stables of the wealthy owners.

Mr. Harrison was elected a Member of the American Society of Civil Engineers on March 2d, 1898, and was a Director from 1908 to 1910. He was a frequent contributor to the discussions on papers before the Society; in 1905, the Thomas Fitch Rowland Prize was awarded to him and S. H. Woodard, M. Am. Soc. C. E., as joint authors, for their paper entitled "Lake Cheesman Dam and Reservoir."*

He was also a member of the Western Society of Engineers, and of the University and Engineers' Clubs of New York City.

* *Transactions*, Am. Soc. C. E., Vol. LIII, p. 89.

HORACE EBENEZER HORTON, M. Am. Soc. C. E.*

DIED JULY 29TH, 1912.

Horace Ebenezer Horton was born near Norway, Herkimer County, N. Y., on December 20th, 1843. Four years before the Civil War, when he was 13 years of age, his parents moved from Norway, N. Y., to Rochester, a small town in the southeastern part of Minnesota, at that time a frontier country. Here he was a pioneer, at an age susceptible to all the moving influences of a new country. Consideration of his after life leads to the belief that, as a western boy, he acquired those qualities of thoughtful planning, of initiative, and of self-reliance, for which he was distinguished in his manhood. With a fine mind, a splendid physique, and a natural fund of energy, this pioneer life was a good foundation for a working life characterized by ability, activity, and usefulness.

Mr. Horton's education in the schools was limited, as the schools were limited. At that time it may be said that engineering was not even a Profession, and engineering schools were almost unknown. At best, only an elementary engineering education could be offered in the schools of this country. Mr. Horton, doubtless, enjoyed such school training as was then obtainable. As a boy he attended school in Rochester, and later, for two years, at Fairfield Seminary in Herkimer County, N. Y., and was probably 19 or 20 years old at the completion of his course in that institution.

Considering the schools which he attended, and the proficiency which he displayed afterward in his Profession, it is fair to designate him as a self-educated man, and, like all true engineers, he continued to educate himself to the end of his life.

The timber bridge, at Oronoco, Minn., of 186 ft. span, 60 ft. above the water, was designed and built in 1866-67 by Mr. Horton, at the age of twenty-three. That a mere youth should combine the technical skill, the address to convince the authorities that the design was adequate, procure financial assistance, and have the business capacity to execute such a work, point out a man of very unusual powers and qualities.

One must remember that in 1866 Minnesota was a remote part of the world; that "Trautwine's Civil Engineer's Pocket-Book" was not published until six years later, and that the mass of technical literature we now have was not then dreamt of.

The fact recalls Smiles' "Lives of the Engineers," those wonderful men, with little education, nearly all coming from the strip of north country across England, who gave us The Highway, The Canal, The

* Memoir prepared by the following committee: Onward Bates, Past-President, Am. Soc. C. E., Hugh L. Cooper, and Arthur J. Mason, Members, Am. Soc. C. E.

Railroad, and The Extended Use of the Steam Engine in Modern Industry.

It is probably not a mere coincidence that the first Horton to land in America, in the seventeenth century, came also from Lancashire. One can readily believe that, running through the seven generations from the first Horton settled on Long Island, the constructive instinct persisted.

Horace E. Horton's father, a carpenter and builder, seventy years ago, in his wanderings between New York State and the far West, happened on some town in Ohio where a church had to be moved. The job frightened local talent, but Horton, Senior, undertook the work, succeeded, and, in his own words, "It paid handsome."

Here we have the Engineer's instinct strong in Horace E. Horton; a physical difficulty becomes a challenge or dare to overcome it.

Mr. Horton's career is of chief interest to us because he was one of the first group of engineers, fast disappearing, who grew up with the art; whose feeling for all kinds of material, structures, action, was the result of contact with them, and, therefore, became incorporated with his five senses, and instinctive.

A generation later, the Engineer's approach to knowledge in his work had become a literary one.

Horace E. Horton began his work with timber—the material of the country—and changed as the times changed. At his death his work was wholly in steel. He was always youthful in view point, always learning, never losing a sort of strong horse-sense.

Older members of the Society will recall his great impressive head, towering above the common run of men in any gathering.

Engineers are proud of the fact that the constructive quality seems ever to be accompanied with a certain robust force of character and probity. George Stephenson, the father of railways, a man who taught himself to read at the age of nineteen, was at home in the House of Lords, or any company, by reason of this mixture of sagacity, directness, and probity. Mr. Choate, in his address at the opening of the present Society House, traced these qualities to the fact that service and performance are the sole tests of the Engineer's work—not an appeal to taste, as so largely in other professions. From Horace E. Horton there seemed at all times to emanate an atmosphere of these very qualities—sagacity, directness, and probity. To this fact is due his success in the world.

Mr. Cooper joined Mr. Horton's staff in boyhood, and remained in his service for many years. He describes one side of the man as follows:

"Those who knew Mr. Horton intimately, and as an employer, realized his possession of a mind of unusual endowments, and specially gifted in creative analysis and quick comprehension.

HORACE E. HORTON.

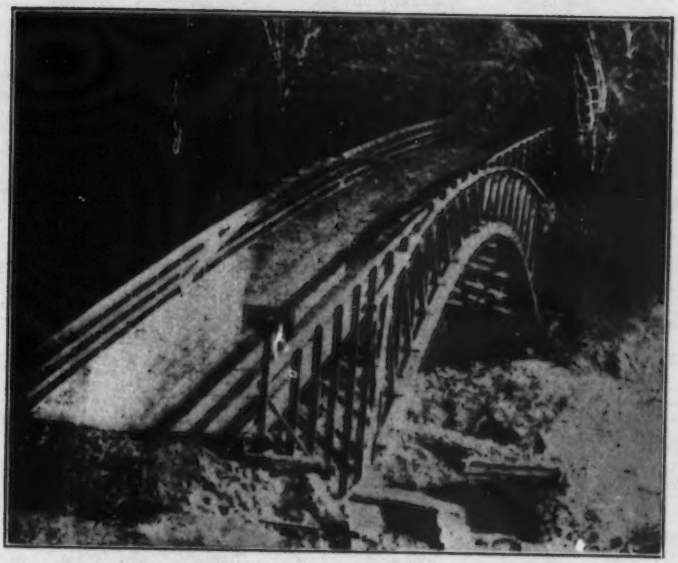
"The subject might be engineering, which he dearly loved as a Profession, or it might be politics, history, genealogy, the Bible, or civic life. The rapidity of his understanding and general comprehension sometimes naturally led to little expressions of impatience with those of lesser equipment.

"One of his striking qualities in his engineering practice was his universal refusal in middle life to accept anything he had previously designed as a standard for the future. Every new contract for a bridge, and they were many, required an entirely new set of drawings to bring out new ideas of main and detailed designs, and in this sort of work he seemed to find great pleasure. The fact that in his later life he originated and perfected to a fine success the water-tank with the hemispherical bottom, that is now so generally used, and that he maintained this design as a standard over a term of years, during which time he built some twenty-four hundred of these tanks, was a great surprise to those who knew him between 1890 and 1900.

"He was a man who possessed the courage of his convictions to a striking degree, and having once settled a problem, either as related to a design or a method of construc[illegible]ng it, his mind seemed absolutely at rest and to forget the elemer[illegible] responsibility as usually defined. Precedents in methods of construction were tossed aside whenever opportunity for original and bold treatment was presented, and his really interested originality always came through to a successful conclusion.

"In general, his manner toward his employees was given to brusqueness, but they soon came to understand that this attitude was a shield for a nature overly kind when properly appealed to.

"One of Mr. Horton's personal characteristics, that was very rare among men of his ability and always in evidence with him, was his great patience with a student employee who was trying to better his condition through special studies after hours and through special hard work during working hours. To such he was never known to deny all the time the student asked for, and it frequently resulted in the student getting more time given him than he in his unwisdom thought he needed. His pride in the advancement of his 'young men,' as he called them, never came to the attention of the student, except when stories of their progress were told by Mr. Horton to third parties.



"His notions of charity followed most strictly the biblical inhibition about giving. He gave generously and freely to the needy, but always in a manner that successfully precluded the possibility of even minute public knowledge. During his residence in Chicago he listened to a very strong appeal from the pulpit for funds with which to purchase a pipe organ for the church. A day or two afterward he met the pastor and told him that he would give a certain sum toward the purchase of the organ, which amount happened to be 75% of the total cost, provided he would never breathe a word about the contribution to a soul. The pastor took the subscription, gave the exacted promise, and then went to another member of Mr. Horton's immediate family, stated that he had secured 75% of the necessary amount, asked for further aid, received 15% of the necessary amount, and gave the same promise about secrecy. The pastor knew from previous experience how to proceed, and was a skilled solicitor; at the first oppor-

tunity he appealed to yet another member of Mr. Horton's family, and obtained the remaining 10% for the organ, on the execution of the same promise regarding secrecy. It is believed that the family do not to this day know how that church got that organ, but the truthfulness of this story is vouched for, and is only related to evidence a trait of character beautiful and none too common.

"The possessor of great physical and mental strength, it is difficult to realize that he could so quickly succumb, and his going away will long be foundation for sadness in the minds of those he befriended."

As a bridge builder, his contracts were obtained by competitive bids, usually on plans prepared under his direction. These plans were required to conform to specifications and meet the approval of the engineer representing the purchaser. The successful bridge contractor had to design a structure meeting all requirements, and be the lowest bidder, as well. Success depended on the skill of the designer in producing the most economical structure to manufacture and erect. It was the custom for bidders to assemble at the time and place set for letting the contract, and the occasion was one in which competitors met in a friendly rivalry, although sometimes it was not so friendly. Competition was very keen, and, if by any chance a bidder lost his opportunity to bid, he was rather the butt of the jokes of the other bidders than an object of sympathy with them.

Mr. Horton was always a generous rival. He would encourage competition instead of suppressing it. It seemed as if he entered into the spirit of the game, on the principle that "the more the merrier," and that, if he won, his success was greater with many than with few to bid against. An instance of this is related by Mr. Bates, on the occasion of the letting of the superstructure for the high bridge at St. Paul. The bridge contracting company which Bates represented had arranged that the bidder's bond required by the city should be furnished to him through a local bank in St. Paul. On the morning of the letting of the contract, and perhaps two hours before the bids were to be opened, he called at the bank with full assurance that the bond would be passed over the counter to him. To his surprise and dismay, he was informed that some hitch, in the arrangement with the Philadelphia bank which was to guarantee the bond, prevented the St. Paul Bank from furnishing it. The decision was final, as it was impossible to make other arrangements in the limited time. Coming out of the bank, Bates paused on the steps of the building, reflecting on his position and wondering if anything could be done to save his bid. Just then Mr. Horton appeared, and, looking up, asked, "What is the matter? Why are you looking so sorrowful this morning?" He was informed of the dilemma of his competitor. Then Horton's fine instinct came to the rescue. He took Bates by the arm and said: "This will never do. We must get you a bond at once." Going to the nearest office build-

TIMBER BRIDGE, ORONOCO, MINN., 1866-67.

ing, they scanned the list of tenants, found the name of a lawyer and proceeded to his office. The lawyer was instructed to draw up the bond at once. Horton remarked: "The amount of this bond is so large that I cannot qualify for the whole of it myself, and we must get another bondsman." They proceeded from the building and on reaching the street, the first man who passed was seized by Horton and told that he must come in at once and sign Bates' bond, not even giving the newcomer an opportunity for argument. The matter was satisfactorily concluded. Bates' bid was considered, and when the decision on the bids was made known, the contract was Horton's as the lowest bidder.

Mr. Bates states that he never was so pleased at the success of a rival, and that a man who could show the spirit that Mr. Horton did under the conditions, was worth his lasting friendship.

Returning to Rochester, Minn., from his studies at Fairfield Academy, about twenty years of age, the next few years were devoted to whatever seemed to offer—farm work, surveying, railroad location—until we find him engaged on the Oronoco Bridge, described at the opening of this memoir.

With this as his starting-point, he was duly launched on his life work. For the following twenty-three years he had his headquarters at Rochester, and built up an extended business in the designing and erection of highway bridges throughout a considerable area of the Northwest. During this time he also developed some skill as an architect, designing a number of public buildings, as well as private residences.

A paper* entitled "Bridge Legislation," by Mr. Horton, is a delicious sample of the mixture of wit, clear-headedness, technical skill, and force of character of the man. Members will recall an occasion, years ago, when an effort was made to obtain acts of State Legislatures providing that highway bridges in the country should be under the supervision of some State officer or engineer, much as buildings are under the superintendent of buildings in cities.

Mr. Horton believed that this movement implied a failure to understand and appreciate the very remarkable ingenuity, skill, energy, and economy which had been shown by the men building highway bridges in the West, with funds seeming to us now humorously insufficient, in places remote, and under circumstances of extraordinary variety and difficulty.

Mr. Horton states a case which we venture to insert as a clean-cut sample of his logic and astonishing economy of design and execution.

"A congressional township (six miles square) with an assessed valuation of $38,000, had a stream running through it requiring a 200-ft. bridge; at medium low water the stream could be forded, but with a rise of one foot it was dangerous.

*_Journal_, Association of Engineering Societies, Vol. XI, p. 54 (February, 1892)

"Within ten years preceding the building of the bridge, three people had been drowned (one each, on three separate occasions) in attempting to ford the stream.

"With all available funds, and all ability for contracting a debt, the township was able to apply $1,800 for this work. It seemed to be best to build the bridge in one span.

"The abutments cost $500. A 200-ft. span was built for $1,300 (with profit to the builder), which has served eight years, with every prospect of use for a long term of years in the future.

"The thought comes to me: What would the engineers of legislation have done with a case like this. Would they have insisted on this community continuing to take chances on the ford, or have taken themselves out of the way, and allowed a man, with knowledge of how to do it, to build a bridge?"

Again, he says in the same paper:

"Have the committee been careless in their statements or shall I (having built thousands of highway bridges, and never having occasion to apologize for a failure either in design or execution) thank God for his mercy (being myself incompetent) * * * that these works have developed into bridges instead of hetchels."

Like most strong men, sure of themselves, he loved a "scrap."

Up to 1889 he had conducted his business, as a bridge contractor, independently of any shop. He had begun in the days of timber bridges, had passed through the combination stage, and had seen the metal bridge become the universal one. In 1889, recognizing that he must either become a manufacturer or lose his identity in the business, he moved to Chicago, and in conjunction with others started the Chicago Bridge and Iron Company, of which he was the President and Manager until the destruction of the plant by fire in 1897. At that time Mr. Horton purchased all the outside stock in the company, rebuilt the plant, and operated it thereafter in his own name, as the Proprietor of the Chicago Bridge and Iron Works.

Mr. Horton's great ability was as an engineer and as a contractor, rather than as a manufacturer. The interminable detail work of the latter annoyed him, and it was a great pleasure to him in later years to turn over much of this to his eldest son.

As an engineer, Mr. Horton was always progressive. When the combination of wood and iron became economical, he was prepared to use them to produce rational designs therewith. When the virtue of cantilever constructions for certain conditions was pointed out, he was ready to make use of them. A man of the most thorough commonsense, he utilized this in the design of his structures, which were proportioned to the service they were expected to give, rather than to some letter of a specification. At a time, twenty-five years ago, when communicating bridges were in demand by cities located on the banks of the Upper Mississippi River, where the conditions necessitated long

and high structures, with only a very limited amount of money available, he designed and built bridges which were strictly adapted to their service and have continued all these years properly to take care of the business. They were very light, and relatively inexpensive, structures, but they showed the skill of the designer, and the adaptation of means to ends. There was no metal wasted; every pound was used to the best advantage.

Perhaps Mr. Horton was best known to many people through his improvements in elevated water-tank design and construction. In 1894 he brought out a design for a steel water-tank supported on steel columns, the tank having a hemispherical bottom, and the columns connecting directly to the sides of the tank. Of this, his son, George T. Horton, M. Am. Soc. C. E., writes:

"He brought out these two essential elements which made the steel tank commercial with not over a half hour's study. The more I think of this one thing, the more remarkable it seems."

Prior to this, though the steel tank on steel columns had been used quite extensively, its general adoption had been prevented by the expense incident to the method of construction. The tanks had generally been flat-bottomed, supported on the columns by heavy floor-beams and closely-spaced joists, though there had been some instances of tanks with conical bottoms, and also with segmental bottoms, both these forms necessitating materially more metal, as well as more expensive shop work, than did the full hemispherical bottom produced by Mr. Horton. The method he adopted, too, for dishing these bottom plates, was novel and inexpensive. The result of these improvements, as well as of the energy and skill with which the sale of the structures was promoted by him, has been the general adoption of this form of elevated tank, and examples thereof are to be found in all portions of America, and the world generally, many of which are the product of his shop.

Mr. Horton's skill and courage as a contractor fully equalled and perhaps surpassed his ability as an engineer. In his case, the engineer and contractor were one. Being satisfied that a certain thing was feasible, he had the courage and skill, both as an engineer and as a contractor, to carry it out. If the state of the art did not provide the tools and facilities to suit him, he promptly devised them. He had a great deal of ingenuity, amounting to the true inventive instinct, and his shops contain many evidences thereof. So far as known, however, he never patented any improvement he made.

Mr. Cooper vouches for the following, which is worth telling as characteristic of the man, and goes to show that the same person may be at once shrewd and a money maker, and withal a generous man:

"Along about 1891 a strong competitor of Horton's was forced into the hands of a receiver. I happened to be in the office the next morn-

ing after the failure, and Horton, seeing the notice of the failure in the morning's paper, ordered me to bring him his check book, and he thereupon drew a check for $5,000 to the order of the President of that company and sent it to him with a brief note, stating that he undoubtedly needed a little household money and asked him to accept the check with his best compliments. As far as I know, and I think I am correctly advised, this check was never repaid, and was never expected to be repaid by Horton."

The foregoing incident seems to his biographers to be especially typical of the man, who, throughout his life, was large minded enough to act outside and above conventionality. He was probably influenced in this case, strange as it may seem, by the very reason that he was neither the same kind of a man nor an intimate friend.

Mr. Horton was married in 1871 to Miss Emma Babcock, of Waupun, Wis. She survives him, with their five children, George T. Horton, Mrs. K. Koessler, and Horace B. Horton, of Chicago; Mrs. R. H. Murray, and Hiram T. Horton, of Greenville, Pa.

He died at his home in Chicago on July 29th, 1912, aged 69, and was buried at Rochester, Minn.

Mr. Horton had a long list of friends who admired his personal qualities and who recognized his professional talent by electing him as President of the Western Society of Engineers, and as a Director of the American Society of Civil Engineers.

Mr. Horton contributed to the *Transactions* of this Society discussions on the following subjects: "The Halsted Street Lift Bridge," "Elevated Railroads," "Safe Stresses in Steel Columns," and "Tests of Large Steel Columns." He was the author of the following papers in the *Journal* of the Association of Engineering Societies: "Bridge Legislation" and "The Compressive Member." Mr. Horton's "Address," as President of the Western Society of Engineers may be found in the first volume of the *Journal* of that society, to which he also contributed discussions on: "Specifications for Steel Railroad Bridges," "Northern Pacific Standard Bridge Plans," "Specifications for Steel Structures," "Modern Practice in Bridge Shop Work," and "Curious Lattice Trusses."

Each of these papers and discussions will be found interesting, even to the layman, from the ability shown to discuss the most complex questions, in simple language, and comparatively free from formulas.

Isham Randolph, M. Am. Soc. C. E., in a letter to the writers, but voices, we believe, the judgment of the Engineering fraternity:

"Often we come in contact with men of heroic stature, whose only claim to consideration is a physical appeal to the eye; from within the human effigy there comes forth to fellow-man nothing helpful, nothing to be admired.

"How different it was with Horace E. Horton. There was a man of commanding stature, manifestly of great physical strength, but with

no faint suggestion of brute force. His noble head towered above his broad shoulders, and his whole appearance was but 'the outward and visible sign' of a great personality, dominated by a bigness of mind and of heart that made him both a leader and friend of his fellow-man, and won for him not alone the esteem, but the love of those with whom he came in contact in the varied relations of a life lived on a broad plan of usefulness.

"These are my epitomized thoughts of a man whom I admired and whose friendship I valued."

Horace E. Horton was elected a Member of the American Society of Civil Engineers on September 6th, 1882, and served as a Director during 1907-08-09.

WILLIAM BELL WHITE HOWE, M. Am. Soc. C. E.*

DIED FEBRUARY 11TH, 1912.

William Bell White Howe was the eldest child of William Bell White Howe who was originally from Claremont, N. H., and who, after studying for the ministry, went to South Carolina in his early manhood and became Bishop of the Episcopal Diocese of that State.

William Bell White Howe, Jr., was born in Charleston, S. C., on November 2d, 1851. After graduation at Charleston College he applied himself to the Civil Engineering Profession, and, after some preliminary experience on railroad surveys in Texas, was employed as Assistant Engineer on the harbor improvements at Charleston under the United States Engineer Corps. From 1876 to 1879 he was a member of the firm of Simons and Howe, Civil Engineers and Architects, in Charleston, and was Architect of the William Enston Home, in that city, as well as Chief Engineer of the Charleston Bridge Company.

Mr. Howe then became associated, as Assistant Engineer and afterward as Chief Engineer, with the system of railroads extending from Charleston into Georgia, Florida, and Alabama, popularly known as "The Plant System." He was instrumental in the substitution of iron bridges for wooden ones throughout the system, and also in the planning and construction of terminal stations and docks at Charleston, S. C., and at Savannah and Brunswick, Ga. As this system of railways was extended in the several States above mentioned, he was Chief Engineer of construction as well.

His ability as an engineer was made evident in the design and construction of the terminal station at Jacksonville, Fla., and more especially in the great work accomplished at Port Tampa, where a deep-water harbor was established on a shoal nearly a mile from shore in Tampa Bay. This harbor and system of docks afforded the best facilities for ocean traffic on the entire west coast of the Gulf of Mexico, and was made memorable as the base of operations against Cuba during the Spanish-American War. As an auxiliary enterprise to "The Plant System", Mr. Howe converted the street railway system in Jacksonville, Fla., into an electric railway, and built a power-house. He also planned the enlargement of the commercial docks at Key West, Fla., and the ocean pier at Palm Beach. Later, he withdrew from the more active pursuit of his Profession, and resided at Spartanburg, S. C., where he interested himself in architectural work and in water-power projects.

* Memoir prepared by H. S. Haines, M. Am. Soc. C. E.

Mr. Howe was of that turn of mind which is particularly adapted to a career of civil engineering. With considerable general culture, he was a close student of every branch of the Profession in which he was engaged. His early training as an architect was of advantage in planning important terminal structures, and, in connection with the works at Port Tampa and the Jacksonville Street Railway, he became well qualified as an electrical engineer. His researches into the properties of cement were recognized in his appointment as a member of the Special Committee on Uniform Tests of Cement of the American Society of Civil Engineers in 1897.

Only as occasion called for it was Mr. Howe's innate ability made manifest, for a reserve due to modesty screened his attainments from the observation of those who did not know him well; but, by reason of his conscientious discharge of duty and his unvarying kindness of demeanor, his more intimate acquaintances became warmly attached to him; and no one appreciated his personal qualities more than the writer of this memorial, with whom he was closely associated for many years. In the spring of 1911, his failing health caused him to retire to his summer home at Flat Rock, N. C., where he died from cerebral hemorrhage on February 11th, 1912, in the sixty-second year of his age.

Mr. Howe married Miss Louisa Preston King, granddaughter of the Hon. Mitchell King, of the South Carolina bar, who survives him. He is also survived by an only son, Dr. William B. W. Howe, of Hendersonville, N. C.

Mr. Howe was elected a Member of the American Society of Civil Engineers on March 1st, 1893.

THOMAS MOORE JACKSON, M. Am. Soc. C. E.*

DIED FEBRUARY 3D, 1912.

Thomas Moore Jackson, son of James Madison and Caroline Moore Jackson, was born at Clarksburg, W. Va., on June 22d, 1852. He received his early education at the public schools and at the Northwest Academy, of Clarksburg, and at Bethany College. He afterward entered Washington and Lee University where he took a special course in civil and constructive engineering, and from which he was graduated in June, 1873, with high honors, with the degree of Civil Engineer.

From 1874 to 1875, Mr. Jackson served as Chief Engineer of the Middle Island Railroad, in West Virginia, and from 1875 to 1879, he was Chief Engineer of the Weston and West Fork Railroad. In 1879, he was appointed First Assistant Engineer of the Iron Valley and Morgantown Railroad, later becoming Chief Engineer.

Mr. Jackson resigned this position to accept that of Chief Engineer of the Tunnelton and Kingwood Railroad, in West Virginia, where he remained until 1881, when he was appointed Engineer in Charge of mines at Wilsonburg, Clarksburg, Flemington, and Gaston, W. Va. Mr. Jackson had been engaged in mining engineering in various parts of West Virginia and Pennsylvania since 1875, and in co-operation with I. C. White, State Geologist, he opened and developed many of the coal, oil, and gas territories in various sections of West Virginia, being one of the pioneers in this field.

In 1882, Mr. Jackson was appointed Chief Engineer of the West Virginia and Pennsylvania Railroad. He held this position until 1885, when he resigned. He was retained, however, by the Company as Consulting Engineer for many years.

In 1887, he was made Assistant Engineer of the Clarksburg Water-Works and was also Engineer in Charge of geological maps of West Virginia and Pennsylvania, working on the coal fields of these States. In 1888, he was engaged in building coke plants at Wilsonburg, Clements, and Clarksburg, W. Va., and, in 1889, he went to Morgantown, W. Va., as Chief Engineer of the water-works and natural gas plant at that place.

In 1889 the Chair of Civil and Mining Engineering was established at the West Virginia State University, and Mr. Jackson was placed at the head of that Department. He remained in this position until 1891, when, the School of Engineering having been firmly established, he resigned against the protests of the Board of Regents and the Faculty of the University, to take up the active practice of his Profession.

After leaving the University, Mr. Jackson served as Chief Engineer of several railroads, among which was the narrow-gauge road from

* Memoir prepared by the Secretary from papers on file at the Society House.

Clarksburg to Weston, afterward known as the West Virginia and Pittsburg Branch of the Baltimore and Ohio Railroad.

Being prominent in the development of the coal, oil, and gas industries of that section of West Virginia about Clarksburg, and realizing the importance of a more direct route to the Ohio River from the latter place for the transportation of these products, Mr. Jackson undertook and was directly responsible for the building of the West Virginia Short Line Railroad, from Clarksburg to New Martinsville, which was completed and opened to traffic in 1901. He was President of this road until its purchase by the Baltimore and Ohio Railroad.

In 1910, Mr. Jackson organized and was made President of a company to build the Clarksburg and Northern Railroad to extend from New Martinsville, by way of Middlebourne and Salem, to Clarksburg, W. Va. Construction work on this road was begun in 1912, and the grading completed between New Martinsville and Middlebourne. Mr. Jackson had just returned to Clarksburg from New Martinsville, where he had been on business in connection with the new road, when he was seized with a severe attack of heart trouble which caused his death on February 3d, 1912, after a short illness.

In 1884, he was married to Miss Emma Lewis, daughter of Judge and Mrs. C. S. Lewis, who, with one daughter, survives him.

Mr. Jackson was a courteous and cultured gentleman, friendly and companionable on all occasions, who was esteemed and admired by all who knew him. He was one of the most prominent and progressive citizens of Clarksburg and was well known among business and professional men throughout the State. Practically his entire life was spent in his home town, and he did much toward its development as an industrial center. His ability as a civil engineer and his great knowledge of geology enabled him to realize the importance of the vast gas, oil, and coal areas in and around his home section and also the necessity of developing them for the establishment of manufacturing industries. It was through his efforts that the Jackson Iron and Tinplate Mills, now the Phillips Sheet and Iron Mills, which is one of the most valuable industrial plants in West Virginia, was established in Clarksburg.

He was President of the Traders National Bank of Clarksburg until its merger with the People's Banking and Trust Company into the Union National Bank, and was one of the chief promoters of the Traders Hotel, the building of which gave the city an up-to-date hotel.

The degrees of Mining Engineer, Doctor of Science, and Civil Engineer had been conferred on him by Washington and Lee University and by the West Virginia State University, respectively, and, as a member of Governor Fleming's staff, he had received the honorary title of Colonel.

Mr. Jackson was elected a Member of the American Society of Civil Engineers on June 9th, 1891.

WILLIAM FREDERICK LOCKWOOD, M. Am. Soc. C. E.*

DIED AUGUST 22D, 1912.

William Frederick Lockwood was born in New York City on July 4th, 1867, and, after attending the public schools, learned the trade of steam fitter. He entered the Engineering Department of what is now the Suburban Branch of the Third Avenue Elevated Railway during its construction in August, 1888, and on its absorption by the Manhattan Railway Company, in 1891, was taken into the Chief Engineer's Office, serving successively as Draftsman and Assistant Engineer until September 16th, 1900, when he was appointed Road Engineer, the duties of which office were the maintenance of the elevated railway structures.

While working as a Draftsman, Mr. Lockwood realized the limitations of his early education, and attended Cooper Institute in his spare time, receiving the degree of Bachelor of Science in 1894.

He was appointed Engineer of Maintenance of Way of the Interborough Rapid Transit Company on October 1st, 1905. His continuous term of service on the elevated roads covered twenty-four years, or practically his entire working life. During this time the roads were being extended, and improvements were being adopted, thus making the conditions of maintenance very burdensome, on account of the deeper foundations of buildings and numerous sub-surface structures, such as subways, conduit lines, high-pressure water mains, etc., which required the reconstruction of numerous foundations for the railway and the constant shoring of the structure at various points.

The adoption of electric motive power, requiring the reinforcement of the structure, was in itself a great task, and the constantly increasing street traffic rendered all such work more and more difficult. It is easily seen that such conditions would tend to keep a man of Mr. Lockwood's conscientious temperament very busy.

During all this time he had the care of his mother's family as well as his own. Time for study and almost for recreation was practically denied him.

His personality was somewhat unique, in that it was so fine. Of clear intellect, inflexible integrity, tireless industry, great patience, and a charming presence, he was a power for influence and accomplishment.

Mr. Lockwood died after a short illness following an operation for appendicitis. He is survived by his widow and three children, Ruth, Blanche, and Constance, and four sisters.

Mr. Lockwood was elected a Member of the American Society of Civil Engineers on October 4th, 1910.

* Memoir prepared by George H. Pegram, M. Am. Soc. C. E.

EDWARD MOHUN, M. Am. Soc. C. E.*

DIED OCTOBER 23D, 1912.

Edward Mohun, was born at Chigwell, England, on September 3d, 1838. In 1863, he came to Victoria, B. C., Canada, and during 1863 and 1864 was engaged as Assistant to the Surveyor General.

From 1864 to 1871, he was employed mainly on official surveys: laying out roads, etc., extending from Comox to Sooke, Nicola, South Thompson, and Bonaparte Valleys; surveying the Lower Fraser from Chilliwack to its mouth, Burrard Inlet, Squamish River, etc.; exploring Queen Charlotte Islands south; and making surveys for a waterworks system for Victoria and for the Wellington and Departure Bay Railway.

In 1871 and 1872, Mr. Mohun was engaged as Divisional Engineer on the Eagle Pass and Yellowhead Pass surveys for the Canadian Pacific Railroad. He also drove the first stake and made the first survey for this road on the Pacific Coast. In 1873, he explored the north end of Vancouver Island, and in 1875-76 was engaged in Government Surveys on that island and on the Lower Fraser River.

In 1876, he received the appointment of Surveyor to the Dominion and Provincial Joint Indian Commission, serving as Chief of the Survey from 1877 to 1884.

In 1885 Mr. Mohun was engaged on the reclamation and diking of 7 000 acres on the Lower Fraser River. While on this work he invented the sluice-box which was adopted by the Government and has been in use for more than 15 years, effecting the saving of many thousands of dollars.

In 1886, he made a test of the woods of British Columbia for which he received his proudest possession, a certificate signed "Albert Edward" and a medal. These tests agreed with similar tests made by the United States Government some twenty years later, and are the basis on which all strains in bridges built by the British Columbia Government are supposed to be calculated.

In 1887, Mr. Mohun designed and constructed the first portion of the sewerage system of Vancouver, B. C., the second portion being built under his supervision in 1889 and 1890.

In a competition for the design of a sewerage system for Victoria, B. C., in 1890, he was awarded the premium over eight competitors from Eastern Canada, the United States, and England, and was appointed Chief Engineer on its construction. As a result of the installation of this system, the death rate of Victoria was reduced 25% in three years.

* Memoir prepared by the Secretary from information on file at the Society House.

From 1893 to 1895, Mr. Mohun was employed as Provincial Government Railway Inspector, and, in 1895, he was appointed Engineer in Charge of the Pitt Meadows Dikes.

In 1898, he made a report to the Government on the sanitary condition of Rossland, Trail, Nelson, Kaslo, Revelstoke, Kamloops, New Westminster, Cumberland, Wellington, and Nanaimo. In the same year he entered the office of the Engineer of Public Works, and, in 1908, was gazetted as First Assistant Engineer. During this time he was engaged in the design of various public works, and since 1896 he had also acted as Consulting Engineer to the Provincial Board of Health, to which, in 1892, he had reported on the "Bacterial Treatment of Sewage." His conclusions on this subject were practically confirmed a few years later by the British Royal Commission on Sewage Disposal.

Mr. Mohun was the author of many engineering papers and of tables which are in constant use on the Pacific Coast. He was a Member of the Canadian Society of Civil Engineers, a Gzowski Medallist, and was also at one time Member of the Council of the Society. He was also a Member of the Royal Sanitary Institute, and for fifteen years was a Justice of the Peace for the Province.

Mr. Mohun was elected a Member of the American Society of Civil Engineers on April 6th, 1892.

WILLIAM HASELTON PUFFER, M. Am. Soc. C. E.*

DIED MARCH 17TH, 1912.

William Haselton Puffer, the son of the Reverend John M. and Anna Haselton Puffer, was born on May 3d, 1861, in Essex, N. Y. He attended the village schools until his fifteenth year, when, on the death of his father, the family moved to Chelsea, Vt., where he took up the management of a farm and the support of the family.

Mr. Puffer was not able to resume his schooling until he was 22 years of age. He then attended the Bradford Academy and later the St. Johnsbury Academy where he was prepared for college. He entered Dartmouth College in 1887 and the Thayer School of Civil Engineering in 1890, and was graduated from the latter in 1892. His struggles to obtain an education took him past the usual age for graduation from an engineering school, but the time was not lost. His early experience with adversity strengthened his will, broadened his character, and supplied him with a stock of common sense and practical experience which was of great value in his engineering work.

After his graduation, Mr. Puffer was employed on general railroad work with the Atchison, Topeka and Santa Fé Railroad until late in 1893, when he became Assistant Engineer in charge of construction for the Mexico, Cuernavaca and Pacific Railroad. In the summer of 1895 he served as Engineer for Sooysmith and Company, in charge of the foundations for the Cathedral of St. John the Divine, New York City. He returned to railroad work and, until 1897, was in charge of a party on the relocation of center lines for the Boston and Maine Railroad.

In the summer of 1897 Mr. Puffer again entered the employ of Sooysmith and Company and was engaged on the construction of the foundations for the Empire Building in New York City. In the fall of 1897 he entered the service of Joseph W. Cody and Company, as Engineer on shoring and deep foundations. During 1898 he had charge of concrete work for the U. S. Government at Fort Hamilton, and for the next two years he was Chief Constructor for the New York Zoological Society.

In 1901 he was employed by John W. Ferguson as Superintendent on construction of the plant for the Alsen Portland Cement Company, at Alsen, N. Y. After 1902, he was engaged in many mining enterprises in Mexico. He was Manager of the La Tula Mining Company, at Guanajuato, Mexico, from 1906 to 1912, and one of the Directors of the Company from its incorporation. He was also Manager of the Guanajuato Amalgamated Gold Mines Company, in 1909 and 1910.

* Memoir prepared by Arthur W. French, M. Am. Soc. C. E.

While on his way to Carlsbad, N. Mex., Mr. Puffer was stricken with cerebro meningitis, and died, after an illness of two days, in Pecos, Tex., on March 17th, 1912.

In September, 1892, he was married to Helen R. Davis, of Troy, Vt., who, with three children, survives him.

Throughout his life Mr. Puffer impressed friends, employers, and employees with his sterling uprightness of character, his kindness, his ability and good judgment, and his loyalty to duty.

Mr. Puffer was elected a Member of the American Society of Civil Engineers on May 3d, 1905.

JAMES DIX SCHUYLER, M. Am. Soc. C. E.*

DIED SEPTEMBER 13TH, 1912.

James Dix Schuyler was born at Ithaca, N. Y., on May 11th, 1849. He was the son of Philip Church and Lucy M. (Dix) Schuyler.

He received his early education at Friends' College which he attended from 1863 to 1868. He owed his high attainments in his Profession, and his versatility, very largely to subsequent study, a broad range of reading, and personal experience. As a young man he joined a railroad surveying party in Colorado, where he was stationed from 1869 to 1873, and, once imbued with the spirit of the West, he kept on to California where he made his home.

Mr. Schuyler began the practice of his Profession as Assistant Engineer on the location and construction of the Kansas Pacific Railway, in Western Kansas and Colorado, and was Resident Engineer on the last division of the road, remaining on this work until its completion in 1870. He was then appointed Resident Engineer on the Denver and Rio Grande Railroad, from Colorado Springs to Denver, and made the first survey of Colorado Springs. On arriving in California, in 1873, he was made Division Engineer of the North Pacific Coast Railroad from Ross Valley to San Rafael. In 1874 he was appointed Chief Engineer of the Stockton and Ione Railroad, and on the financial collapse of that project, he worked temporarily as a writer for the *Stockton Daily Independent*. In 1877 he was made Chief Assistant State Engineer, in the State Engineering Department of California, and was placed in charge of the irrigation investigations being conducted by that Department in the Great Central Valley of California.

Mr. Schuyler remained with the State Engineering Department until 1882, when he resigned to accept the position of Chief Engineer and General Superintendent of the Sinaloa and Durango Railroad in Mexico. In 1884 he returned to California, and was engaged for a time as a Contractor in the construction of a section of the sea-wall on the water-front of San Francisco. During the following year he was placed in charge of raising and completing the Sweetwater Dam, and the work which he did there assured his standing in the Engineering Profession, his rise to prominence thereafter being rapid.

Mr. Schuyler was called into conference and was placed in charge of important work in various parts of the United States and in Mexico. From 1891 to 1895 he was Consulting Engineer to the Lake Hemet Water Company, and designed and supervised the construction of the

* Memoir prepared by Stephen E. Kieffer, C. E. Grunsky, and J. B. Lippincott, Members, Am. Soc. C. E.

Hemet Dam, one of the highest masonry dams in Western America. He was engaged on the construction of water-works at Portland, Ore., and at Denver, Colo., on the Bear River Canal, in Utah, on the Ogden, Utah, Water-Works, and on irrigation works at various places in the West. He was one of the Board of Consulting Engineers to pass on the feasibility of the Owens River water-supply project, for Los Angeles, Cal., and was appointed by President Roosevelt as a member of the second Commission of Consulting Engineers which passed on the feasibility of the Gatun Locks, the Gatun Dam, and related structures for the Panama Canal.

His activities as a Consulting Engineer extended across the ocean to Japan, and as far south as Brazil. He was Consulting Engineer to the Territorial Government of Hawaii on the construction of the Nuuanu Dam; to the Monterey Water-Works and Sewer Company, Limited, of Mexico; to the Kobe Syndicate on an extensive power project in Japan, involving the construction of a very high dam; to the Mexican Light and Power Company, Limited, on the building of four large dams for power development in Mexico; to the Vancouver Power Company, Limited, on the building of a dam at Coquitlam Lake; to the Arrowhead Reservoir Company; the American Beet Sugar Company; and the Sweetwater Water Company.

Mr. Schuyler not only did much in a constructive way that will endure, but he had the happy faculty of imparting, through his writings, the results of his work and experience to other members of his Profession. Among engineers he was recognized as being unusually resourceful, and as having an unusual grasp on the experience of other members of the Profession, which he understood how to apply.

In writing of Mr. Schuyler and his work, Dr. George Wharton James says:

"His unfailing good humor, ready acquiescence in every experience, cheerful bearing of hardship, inconvenience, and annoyance, his uniform kindness, urbanity and courtesy, his gentle consideration for his associates, his companions, and the employees and helpers with whom he came in contact, his ready and quick response to every human and humane feeling and sentiment, his kinship with every living thing, whether of animal or plant life, his keen powers of observation and far-reaching grasp of reflection, his tenacity of memory, and thorough conscientiousness in getting hold of every fact that would aid him in his decisions, his persistent questioning and careful recording of the results obtained, his joy in recognizing the possibilities of a great project, his ready acknowledgments of errors in judgment based upon imperfect knowledge, his eloquent and forceful presentation of facts as he saw them, the brilliant keenness of his intellect in dealing with knotty problems of his Profession, the far-seeing scope of his fine and trained imagination, his loyalty to his friends, his kind toleration of those who harshly differed from him, his open devotion, sincere

admiration, and genuine affection for his wife, his brothers, his sisters, his family generally—these and a score of other traits clearly manifest in our association endeared him to me in a manner peculiarly potent.

"Physically, he was a large man, a man of impressive appearance, yet he was larger and more impressive mentally and spiritually than he was physically. A man of the keenest spiritual perceptions, he was yet a man among men, without a trace of the egotist or prig. His smile was an outward expression of a kindly, genial, humane nature. He wore no celluloid smile, formed by facial control. When his face beamed upon you it was the spontaneous, natural, ready response to the smile of his soul, warming you to trust, confidence, belief. He called forth the best of every man with whom he came in contact. He was a mental and spiritual dynamo, generating and radiating activity, peace, and good will to men.

"In his Profession he ranked with the highest and best, and at his funeral in Ocean Park, in September, every prominent member of the engineering and cognate professions of Southern California was present in person or by representative, and the expressions of the sense of loss were intimate and personal. The world has too few such men; would there were more."

In July, 1889, Mr. Schuyler was married to Mrs. Mary Ingalls Tulliper, of San Diego, Cal., who survives him.

He was a member of the Institution of Civil Engineers of Great Britain, the American Geographical Society, the Franklin Institute, the Technical Society of the Pacific Coast, and the Union League. He contributed extensively to various technical and scientific journals and Society publications, his best-known work being his book entitled, "Reservoirs for Irrigation, Water Power, and Domestic Water Supply," which was first published in 1901, a second edition having been issued in 1908. He was twice winner of the Thomas Fitch Rowland Prize given by this Society for the best paper presented during the year, the first in 1889 for the paper "The Construction of the Sweetwater Dam,"* and the second in 1907 for his paper "Recent Practice in Hydraulic-Fill Dam Construction."†

Mr. Schuyler was elected a Member of the American Society of Civil Engineers on December 6th, 1882. He also served as Vice-President in 1903-04, and as a Director in 1892, and from 1899 to 1901.

* *Transactions*, Am. Soc. C. E., Vol. XIX, p. 201.
† *Transactions*, Am. Soc. C. E., Vol. LVIII, p. 196.

FRANK SOULÉ, M. Am. Soc. C. E.*

DIED FEBRUARY 14TH, 1913.

Frank Soulé was born at Woodville, Miss., on August 6th, 1845. He came from New England ancestry, being a descendant of the Mayflower Pilgrims, and tracing his lineage directly to John Alden, Priscilla Mullins, and George Soulé. His father, Frank Soulé, went to California in May, 1849, where, later, he was well known as a journalist and as one of the authors of the "Annals of San Francisco."

Professor Soulé received his early education at Bridge Hampton, N. Y., and at the San Francisco High School. In 1862 he was appointed to the United States Military Academy at West Point, from which he was graduated in 1866. Immediately thereafter, he was assigned to duty as Assistant Ordnance Officer. In 1868 he was ordered to West Point as Instructor in Ordnance and Gunnery, and also performed the duties of Assistant Professor of Mathematics.

In 1870 he resigned from the Army to join the Faculty of the University of California, as Assistant Professor of Mathematics. In 1872 the Board of Regents established the Department of Civil Engineering by creating a chair for that subject; and on the appointment of Professor Soulé to that chair, they added Astronomy to his responsibilities.

The records of the University of California for the period ending with 1880 will show how prominent was the work of Professor Soulé in those early days. He not only gave his time to Mathematics, Astronomy, and Engineering, but also organized the Military Department. In 1886 the Students' Astronomical Observatory was designed and built by him with special State appropriations. In the next ten years, under his direction and with the co-operation of the late Professor George Davidson, Hon. M. Am. Soc. C. E., many important geodetic studies were maintained and measurements made. He inaugurated the Weather Bureau Record, which later was distributed by the Department of Astronomy, and now is reported by the Department of Geography. In 1890, the exacting demands of the rapidly growing Civil Engineering College forced Professor Soulé to relinquish his interests in astronomical work, although he retained the title of Professor of Astronomy with that of Civil Engineering for several years afterward. In the early Nineties, after a visit to prominent Eastern and European schools, he built and equipped a testing laboratory which from a modest beginning has grown into the present Experiment Station of the Civil Engineering Department.

Professor Soulé continued in the active service of the University as Professor of Civil Engineering and as Dean of the College of

* Memoir prepared by C. Derleth, Jr., M. Am. Soc. C. E.

Civil Engineering until the summer of 1907, a period of 38 years. In 1907 he spent a sabbatical year in foreign travel, visiting Egypt and most of the countries of Europe. On his return to California in 1908, he was retired on the Carnegie Foundation, becoming Professor Emeritus of Civil Engineering. Although his active work had ceased, he still retained a deep interest in the welfare and rapid growth of the College which he had organized. It is given to few men to serve an institution for a span of 44 years and in such varied capacities.

He was a man of multifarious tasks and of many-sided usefulness. No one was in closer touch with the students than he, both by virtue of his one-time office as Commandant of the Cadets and by the nature of his own interests. He was a military man in bearing and in thought, and believed in discipline and in authority. He laid upon himself the heavy hand of self-control, but was always kindly toward and thoughtful of others, and, above all things, was a man of unfailing courtesy.

During the last ten years of his service, it was his deserved pleasure to witness the great expansion of the Engineering Colleges of the University. From 1870 to 1900 his school, like San Francisco, developed slowly. It was about 1895 that, as a University, California began to grow with leaps and bounds. In his immediate Civil Engineering College a Department of Irrigation was established; courses relating to Forestry and Public Health were planned; and the relations between Agriculture and Engineering were defined. Sanitary studies formed a vital part of the curriculum, and instructors in Municipal and Sanitary Engineering were called to co-operate with the Medical Department in Bacteriology, Animal Industry, and Hygiene. In Civil Engineering there is now close contact between the sanitary instructors and the interests of the University known as Domestic Science. The Professors of Sanitation and Irrigation are concerned with the practical Agricultural School at Davis. The Structural Departments are associated with Architecture, no less than with Engineering. The Testing Laboratory is in touch with State problems. Surveying courses lead to instruction in Geodesy, through which channel the students are brought in contact with the Department of Astronomy. Through railroad work they deal with Economics; by the writing of contracts and specifications they lean on the Law; in the design of buildings they become interested in fire-proof construction, fire protection, and prevention, and are led to commune with the Departments of Economics and Insurance. All these relationships now exist, are daily developing, and are bringing Civil Engineering into closer sympathy and bond with the University. Professor Soulé served his University for 44 years; he saw it start from the humblest beginning, and witnessed its growth into one of the most powerful institutions in the country, a University which, in 1913, is second in numbers in the United States. More-

over, as an Instructor in Engineering he lived through those eventful years in the development of Engineering Education—from the pioneer days of instruction in Applied Science to the present decade of great promise.

Professor Soulé was always interested in the public affairs of the community in which he lived. Whenever a movement looking to a betterment in politics and community life developed in California in recent years, that movement found in him a ready helper. In earlier days his active interest was in Oakland; later, this was transferred to Berkeley, where he was a member of the Committee which framed the now famous New Charter for that city. He was an active member of the City Club of Berkeley, and often presided and spoke at citizens' meetings.

As Professor Soulé gave much of his energy and life to community interests and problems, it was only natural that he should be associated with many societies. He was a member of the Association of Graduates of the U. S. Military Academy, and of the Loyal Legion, U. S. A.; Colonel in the National Guard; life member of the Geographical Society of the Pacific; member of the Society of Mayflower Descendants; and life member of the Society of California Pioneers. For many years he was a member of the Athenæan Club, of Oakland, and of the University Club and the Bohemian Club of San Francisco.

Professor Soulé did not practice continuously his Profession as a Designing and Consulting Engineer; he was too busy with educational and social tasks, as already stated. Nevertheless, for thirty years he was a force in Engineering circles in the State of California, often serving in an advisory capacity or as a Consulting Engineer. He was a judge of materials and their tests, and frequently reported on road, street, sewer, and water supply projects for Berkeley, Oakland, and other growing towns and cities. Perhaps his most important reports were those which related to irrigation studies in the San Joaquin Valley and to the difficult foundation problems for the Ferry Building and adjoining docks in San Francisco.

He is survived by his widow, Mrs. Adelaide S. Soulé, and two sons.

Professor Soulé was elected a Member of the American Society of Civil Engineers on March 1st, 1905.

EBENEZER SMITH WHEELER, M. Am. Soc. C. E.*

DIED JANUARY 5TH, 1913.

Ebenezer Smith Wheeler was born at Buckingham, Wayne Co., Pa., on August 27th, 1839. In 1844, he moved with his parents to Noble County, Indiana, and it was there that he received his early training preparatory to entering the University of Michigan. He was graduated from that University in the Class of 1867, with the degree of Civil Engineer. Later, in 1897, on account of his many engineering achievements and general culture, his Alma Mater conferred on him the honorary degree of Master of Science.

Mr. Wheeler's entire engineering work was performed in the service of the United States, and mainly in connection with projects for the improvement of navigation on the Great Lakes. He has left many enduring monuments which will continue to make navigation safer and reduce the cost of transportation; these bear testimony more clearly than words as to his engineering ability. He first entered the service of the United States under the U. S. Lake Survey in 1863 as Assistant Engineer, and continued in that work until 1882. While in this position, Mr. Wheeler had much to do with the early triangulation of the Great Lakes, and to the accuracy of his work is due largely the reliability of the charts and maps used as guides by navigators. To his care was entrusted the delicate work of determining the lengths of the primary base lines in the Great Lakes triangulation system, on which all extensions of this system were founded. While engaged on this work, Mr. Wheeler devised the method of using a metal bar in melting ice as a means of standardizing steel tapes and base-measuring apparatus. This method of standardization was afterward adopted and generally used by others in this branch of engineering.

In 1882, Mr. Wheeler entered the service of the U. S. Engineer Corps under the officer stationed at Detroit, Mich. From that time until 1897, he was stationed at Sault Ste. Marie, Mich., in immediate charge of all Government work in that vicinity. Under his direct supervision were constructed the Poe Lock, the widening and deepening of the St. Marys Falls Canal, the Hay Lake Channel, the 20 to 21-ft. channel through St. Marys River, and many minor improvements to navigation.

In 1897, Mr. Wheeler was designated by the authorities at Washington to supervise the making of a preliminary survey for the Nicaragua Canal project in Central America. During 1897, he had direct charge of all field parties in Nicaragua, and during 1898, he was in Washington preparing his report and plans for submission to

* Memoir prepared by Charles Y. Dixon, M. Am. Soc. C. E.

the Nicaragua Canal Commission. Mr. Wheeler's report was so complete that there was no doubt that the Nicaragua Canal was a feasible engineering project, but this route was afterward abandoned for the Panama Canal. While engaged on his work in Nicaragua, Mr. Wheeler contracted a fever from the effects of which he never fully recovered, although, up to that time, his had been a most rigorous constitution.

On his return from work with the Nicaragua Canal Commission, in 1898, Mr. Wheeler was assigned to duty in the U. S. Engineer Office at Detroit, Mich., as Chief Assistant Engineer, and he continued in that position until his death. During this period, he had direct charge of the construction of the new St. Clair Flats Canal and of the breakwater at Mackinac Island. His engineering experience was also found to be invaluable when acting in an advisory way in connection with all other important works of the District.

While stationed at Detroit, Mr. Wheeler found time to make many investigations of value along lines indirectly connected with his work. The most important of these led to his invention of the Wheeler bathometer. This device has been placed on a number of freight vessels on the Great Lakes to give warning when in shoal water. It has been operated successfully for several seasons, and is destined to be the means of saving life and property on the Great Lakes.

A mere recital of the works with which Mr. Wheeler was connected is ample evidence of his engineering ability; but he was much more than an able engineer; he was well informed on many subjects, about which knowledge would be expected to be obtained by technical training only. He was, withal, a modest, unobtrusive, cultured gentleman. He was gifted with a keen sense of humor, and had that rare and happy faculty which enabled him to solve the difficulties of others and to illustrate his own thoughts with a good story well told. He was a most delightful companion, whom it was a genuine privilege to have known, and no one could know him well without being the better for it.

In 1874, Mr. Wheeler married Miss Clara P. Fuller who, with one daughter and one son, survives him. To his family the sympathy of a host of friends is extended, for truly all who knew him were his friends.

He was a member of many technical and fraternal societies, including the Michigan Engineering Society, the Detroit Engineering Society, the Detroit University Club, and the Masonic fraternity.

Mr. Wheeler was elected a Member of the American Society of Civil Engineers on November 7th, 1883.

HENRY FISHER WHITE, M. Am. Soc. C. E.*

DIED OCTOBER 28TH, 1912.

Henry Fisher White, son of J. Avery and Jane Elizabeth (Fisher) White, was born at Boston, Mass., on October 14th, 1851.

On the completion of his education, Mr. White, in 1870, entered the office of Messrs. Buttrick and Wheeler, at Worcester, Mass., which firm was engaged in general city and county practice. He also began his career as a railroad engineer about this time as Transitman on the Fitchburg Railroad.

In 1872, Mr. White was appointed Assistant to the Division Engineer of the Cairo and Vincennes Railroad on the construction of tunnels and heavy trestles on that road. He remained in this position until March, 1873, when he was employed as Transitman on a preliminary survey for a local company between Brookfield and Kansas City, Mo.

In June, 1873, Mr. White accepted the position of Division Engineer on the Ware Branch of the Boston and Albany Railroad, in charge of track-laying and ballasting on old grades. In 1874 and 1875, he was again engaged on general engineering work for Messrs. Buttrick and Wheeler, and on surveys for, and the construction of, minor roads. In September, 1875, he was employed as Transitman on location, and, in February, 1876, as Resident Engineer in charge of construction, of the Dayton and Southeastern Railway in Ohio.

In June, 1876, Mr. White was appointed Assistant to the Chief Engineer of the Burlington, Cedar Rapids and Northern Railway, with headquarters at Cedar Rapids, Iowa. In November, 1881, he was made Chief Engineer, which position he held until the road was made part of the Rock Island System. During his incumbency as Chief Engineer, the Burlington, Cedar Rapids and Northern Railway grew from 700 to 1 300 miles of splendidly built and equipped road.

When, in 1902, this road was absorbed by and became part of the Rock Island System, Mr. White was appointed Engineer of Maintenance of Way of the latter company, with headquarters at Chicago, Ill. He remained in this position until February, 1908, when he retired from active work. His later years were spent between his home in Chicago and his ranch near Montrose, Colo., where he died from an attack of heart failure.

On April 14th, 1880, Mr. White was married to Miss Anna McConnell, of Cedar Rapids, Iowa, who, with two daughters, survives him.

Mr. White was elected a Member of the American Society of Civil Engineers on January 2d, 1890. He was also a Member of the Western Society of Engineers and of the American Railway Engineering Association.

* Memoir prepared by the Secretary from information on file at the Society House.

CHARLES DE LA PLANE ATTERBURY, Assoc. M. Am. Soc. C. E.*

DIED JUNE 3D, 1912.

Charles De La Plane Atterbury was born at Howard City, Mich., on June 3d, 1878. His earlier years were spent in Utah, where he received instruction in private schools, and, for a short time, at the University of Utah.

He took up work as a telegraph operator at Murray, Utah, for the Rio Grande Western, and later was employed in the same capacity and as Agent on various roads and in various places in Oregon, Washington, and Idaho.

Mr. Atterbury began his technical education when he entered Leland Stanford, Jr., University, as a freshman in 1901. His sophomore year was spent at the University of Oregon, and his junior year at the Colorado School of Mines. Practical experience in mining engineering in Colorado was later found to be of considerable benefit to him in his chosen work. He again entered Stanford University as a senior in 1904, and it was here that the writer met and worked with him in various courses during the year, learning all the while the many sterling and admirable qualities of a character best known only to those in close association with him.

Before graduation, in the spring of 1905, he passed the examination for Engineering Aid in the Reclamation Service, with such standing as to merit immediate appointment. He was assigned to duty on the irrigation project at Hazen, Nev., for a short time on office work; later, he had charge of a party in the field. His ambition was not satisfied with the slower chances for advancement in Government work, so he resigned to enter the employ of a large corporation engaged in Alaska railroad development. On leaving this service he returned to Tacoma, Wash., and entered the employ of the Oregon-Washington Railroad as Division Engineer on a branch road near Centralia, Wash. After the completion of the road, he opened an office in Centralia, making a specialty of mine surveys in the coal region there, his previous experience fitting him for success in that work.

In the spring of 1908 Mr. Atterbury was appointed Assistant City Engineer of Centralia under Mr. Bullard, then City Engineer, and, on the resignation of the latter, some months later, was appointed to fill the vacancy. Many substantial improvements were made in Centralia and the neighboring city, Chehalis, during his term of office as City Engineer, for the success of which he was in large measure responsible.

A change in the form of government and personnel of city officers induced Mr. Atterbury to resign in the spring of 1912, dispose of his

*Memoir prepared by H. B. Langille, Esq.

home, and return to California. He immediately entered the employ of a large contracting firm in San Francisco, and was engaged in special construction, the requirements of which necessitated work in the tule bottom lands along the Sacramento River. During the excessively warm weather of 1912 his party suffered much from heat and lack of good water, Mr. Atterbury being much more affected than the others, due to his having come so recently from the cooler northern State. On the Friday preceding his death, which occurred on June 3d, 1912, he was partly overcome by the heat, but quickly recovered and made light of the occurrence. His wife, however, induced him to come to San Francisco for Saturday and Sunday, with the intention of giving up that work altogether. His characteristic conscientiousness and sense of duty to his employers' interests compelled him to return to the work, it being his intention to remain only Monday and Tuesday.

Work was prevented by the heat on Monday, but it was resumed on Tuesday, which, however, proved to be the hottest day of the year. In the tule rushes, which are 10 or 12 ft. high, the air does not move near the ground, hence is excessively moist and warm. The party started to return in the middle of the afternoon, two of the stronger men being sent ahead for water. On their return, while cautiously making their way through the tules to avoid being seen, they were observed by the others, and, as is usual in such cases when help arrives, Mr. Atterbury succumbed and fell. Some water and much rough handling brought him to his feet again, but for a short time only, when he fell once more and died before he could be carried to the nearest shelter. Two others of the party were overcome also, but were revived.

This was another instance of that quality of devotion to duty so frequently found in the Engineering Profession, and so strongly manifested in Mr. Atterbury. His was a character at once lovable, quiet, and unassuming; he was devoted to his family, loyal to his friends, purposeful, resourceful, and with high ideals of personality and profession; a clean, manly man whose passing is a distinct loss to his Profession and to the community in which he lived.

In May, 1907, Mr. Atterbury was married to Miss Ida Small, whom he met while at Stanford, and who, with two children, survives him.

Mr. Atterbury was elected an Associate Member of the American Society of Civil Engineers on November 8th, 1909.

ARTHUR GARFIELD CRYSLER, Assoc. M. Am. Soc. C. E.*

DIED OCTOBER 22D, 1912.

Arthur Garfield Crysler, the son of George and Harriet (Safford) Crysler, was born at Syracuse, N. Y., on April 24th, 1880. After going through the graded schools and the Syracuse High School, he entered Syracuse University in 1900, and was graduated in 1904, with the degree of C. E.

Immediately after his graduation, Mr. Crysler entered the service of New York State as Rodman in the Department of the State Engineer and Surveyor. He was assigned to work on the preliminary surveys, plans, and estimates of Contract No. 12, of the Barge Canal. In 1907 he was made Assistant Engineer and placed temporarily in charge of that portion of Contract No. 12 between Brewerton and Three Rivers, on the Oneida River, 12 miles of heavy work, including one lock. He did so well that the temporary appointment was made permanent, and he was in charge of the work at the time of his death.

On June 26th, 1906, Mr. Crysler was married to Miss Pearl LaShier, of Ithaca, N. Y., who, with three children, survives him.

Mr. Crysler was elected Associate Member of the American Society of Civil Engineers on August 31st, 1909. He was also a member of the Technology Club of Syracuse, N. Y.

*Memoir prepared by Guy Moulton, M. Am. Soc. C. E.

JOHN HAWKESWORTH, Assoc. M. Am. Soc. C. E.*

DIED DECEMBER 10TH, 1912.

John Hawkesworth, the son of James A. and Ella Zebley Hawkesworth, was born in New York City, on May 18th, 1883. He prepared for college at the Cutler School, and, in 1900, entered Columbia University, from which he was graduated in 1904, with the degree of C. E.

In May, 1904, Mr. Hawkesworth entered the employ of Raymond F. Almirall, M. Am. Soc. C. E., as Assistant Engineer, and was engaged on the design and superintendence of construction of various reinforced concrete buildings and structures in and around New York City. From 1906 to 1908, he served as Business Manager for Mr. Almirall and had general supervision of the work of the office.

Mr. Hawkesworth was one of the first engineers to engage in structural tests of reinforced concrete, and the results of his experiments were published in 1904 in "Cements, Mortars, and Concretes," by Myron S. Falk, M. Am. Soc. C. E. Other articles on this subject were written by Mr. Hawkesworth and published in *Engineering News* in 1905. He was also the author of a "Graphical Handbook for Reinforced Concrete Design," which was issued in 1906, and of various other technical books and papers, one of the latter being entitled "Precarious Expedients in Engineering Practice," presented before this Society on February 16th, 1910.†

From 1908 to 1912, Mr. Hawkesworth spent part of his time in travel abroad and part in consulting engineering practice in this country. He was also engaged in investigating corporations desirous of increasing their capital. Shortly before his death he organized The Carleton Company, Engineers and Contractors, of New York City, of which he was President and also a Director.

Mr. Hawkesworth was married, on November 25th, 1911, to Miss Marion Everett Barling, who survives him.

He was a member of the Lotus Club, the Columbia University Club, the Westchester Country Club, the Municipal Art Society, and of Psi Upsilon.

Mr. Hawkesworth was elected a Junior of the American Society of Civil Engineers on September 6th, 1904, and an Associate Member on November 4th, 1908.

---

* Memoir prepared by Milton L. Cornell, Esq.

† *Transactions*, Am. Soc. C. E., Vol. LXVII, p. 32.

WILLIAM MADISON MYERS, Assoc. M. Am. Soc. C. E.*

DIED APRIL 4TH, 1912.

William Madison Myers, son of William H. and Mary Jane (Harman) Myers, was born near Winchester, Va., on April 4th, 1873. His parents, who lived on a fine farm in the Shenandoah Valley, perceiving that the son had a fondness for books and study, and realizing the value of education, determined to fit him for a professional life. After availing himself of all the advantages of the country schools, Mr. Myers entered the Winchester High School, from which he was graduated in 1891. In the fall of the same year he entered Washington and Lee University, and was graduated from that institution in 1895, with the degree of Civil Engineer.

For some time after his graduation, he taught in the Graded Schools of Frederick County, Virginia, being engaged occasionally on local surveying and engineering work. In 1897 and 1898, he was in charge of road improvements between Leesburg and Harper's Ferry, Va., under Frank Conrad, Civil Engineer.

In 1898, Mr. Myers accepted an offer from the late Lewis Kingman, M. Am. Soc. C. E., then Chief Engineer of the Mexican Central Railway, to go to Mexico as Transitman on the location of the Tampico Division of that railway, being also at times in charge of a party locating reservoir sites, etc. In 1900 he was appointed Assistant, under Mr. W. C. Harris, on the construction of the Parral Extension of the same road, and, in 1901 and 1902, he was with Mr. O. G. Bunsen, as Transitman and Topographical Draftsman, on the location of the Colima Extension.

From 1902 to 1904, Mr. Myers was employed as Division Engineer on the construction of the San Pedro Extension of the Mexican Central Railway, and, while in this position, had charge of the construction of 50 km. of the road, as well as of all the Division yards and buildings. He remained in this position until the work was completed, when he returned to Virginia to visit his old home. After seven years' service on the Mexican Central Railway, under Mr. Kingman, the latter wrote of him:

"Mr. Myers is a gentleman and an educated engineer, and has done all his work, while under my jurisdiction, with credit to himself and to the entire satisfaction of the Railway Company. I take pleasure in recommending Mr. Myers. He is honest, truthful, and considerate. He is industrious, temperate, and careful in his work. He understands the classification of material, and has always done the right thing with the contractors and the Railway Company."

* Memoir prepared by Mrs. Bessie B. McCann.

In 1904, Mr. Myers was appointed Transitman and Topographical Draftsman on the Florida East Coast Railway, but in less than a year, because of the climatic conditions, was compelled to resign this position and return to his home to recuperate.

In 1905, he went back to Mexico, as Division Engineer, under Mr. Kingman, on the construction of the Colima Extension of the Mexican Central Railway from Tuxpan to Colima. This work was very heavy and included the construction of three tunnels in a distance of 7 km. In 1906, Mr. Myers accepted a position with Pierson and Sons, of the Puebla Tramway, Light and Power Company, at Puebla, Mexico, his work consisting of city surveys, and surveys and estimates for water-works, hydro-electric plants, electric lines, etc. Of him and his work at this place, Mr. Pierson has written:

"I consider him an able and experienced railway and general engineer, competent to take charge of important work. * * * As to Mr. Myers' character, I have the highest opinion of him. He is of good family, sober, reliable, and conscious of the dignity of his Profession."

After spending three years in Mexico, Mr. Myers returned to his home in Virginia and was again engaged in local engineering around Winchester. In 1910, he entered the employ of the Virginia State Highway Commission, under Mr. P. St. J. Wilson, having been located at Buena Vista, Big Stone Gap, and Fairfax, Va. While engaged at the latter place, in January, 1912, he was taken ill with typhoid fever and removed to the Georgetown University Hospital, where he remained under treatment for two months. Failing to improve, he was removed to his home in Winchester, where he died on April 4th, 1912.

Mr. Myers was always a student, and surrounded himself with the latest works on all branches of engineering. He was painstaking, and all his work and papers show that great care and precision were his marked characteristics. He was a member of the Presbyterian Church, and carried his love of God and man in his work, always living his religion.

Mr. Myers was elected an Associate Member of the American Society of Civil Engineers on October 3d, 1906.

CHARLES HARRY TISDALE, Assoc. M. Am. Soc. C. E.*

DIED APRIL 30TH, 1913.

Charles Harry Tisdale, the youngest child of Benjamin F. and Eliza H. Tisdale, was born in New Orleans, La., on May 30th, 1874, but after living there only a short time the family removed to the country just outside of Baton Rouge, La., where his early boyhood was passed. He attended the small country schools, but learned principally from his mother's tuition. The family afterward removed into the City of Baton Rouge, where he attended the public schools. He then entered Louisiana State University, from which he was graduated in 1895 with the degree of B. S.

His first work was to teach school at Brusle' Landing, West Baton Rouge Parish, La., where he met the young lady who afterward became his wife.

He taught school only one term, and then accepted a position under Col. George McC. Derby, M. Am. Soc. C. E., who then had charge of the Fourth Mississippi River District, with headquarters in New Orleans. Mr. Tisdale was in that office only a short time, being employed in the Drafting Department; afterward he went into the field as Inspector of levee construction.

In 1902 he was transferred to the Mobile, Ala., District, where he worked in the Drafting Department for about a year. He was then sent into the field and served successively as Recorder, Inspector, and Junior Engineer, in connection with the building of locks and dams on the Alabama and Tombigbee Rivers, Ala.

In the early part of 1906, Col. H. C. Newcomer, who was then in charge of the Chattanooga, Tenn., District, sought a capable man to place in local charge of the projected lock and dam at Hales Bar on the Tennessee River. Mr. Tisdale was selected for the position, was appointed Junior Engineer on February 1st, 1906, and placed in charge of the work. He was there when ground was broken, and remained in charge until his death. There he had his greatest sorrow, his young wife being called away without a moment's warning. His only consolation seemed to be his work, in which he absorbed himself. He saw it growing toward completion after many difficulties had been overcome, and yet he was not spared to see it completed. He knew every inch of the construction and every man connected with it in any way. When finished it will be an enduring monument to him. As the mighty Tennessee rolls onward past the dam, between the mountains standing like sentinels over it, as the turbines whirl in the current and manu-

* Memoir prepared by Robert R. Tisdale, Esq.

facture light and power for distant Chattanooga, they will bear witness to the faithfulness of the one who wrought so earnestly and yet did not live to see the completion of the great project.

Faithful to friends, loving toward his family, and zealous in the performance of his duty, he is mourned by many.

Charles Harry Tisdale was elected an Associate Member of the American Society of Civil Engineers on October 31st, 1911.

JAMES HUGH WISE, Assoc. M. Am. Soc. C. E.*

DIED SEPTEMBER 16TH, 1912.

James Hugh Wise was born in Denver, Colo., on February 27th, 1880. As his father was engaged in mining, the young man spent the first ten years of his life in various parts of New Mexico; he was then brought to San Francisco, Cal. During the next five years he attended the schools of that city and Alameda, and then entered the California School of Mechanical Arts, in San Francisco, from which he was graduated in June, 1899. In that year he entered the University of California, and received his degree from the College of Mines in June, 1903.

During the following year Mr. Wise taught mathematics at the California School of Mechanical Arts, resigning in June, 1904, to enter the employ of the California Gas and Electric Corporation, now the Pacific Gas and Electric Company. His rise to responsibility was strikingly rapid. He continued with the Corporation until February, 1910, when he resigned to become a partner in F. G. Baum and Company, Consulting Engineers. In July, 1911, Mr. Wise again entered the employ of the Pacific Gas and Electric Company, this time as Assistant General Manager, which position he held at the time of his accidental and tragic death. He was on an inspection of the Los Angeles Aqueduct by automobile. While in the southern end of the San Joaquin Valley, it was found that the gasoline tank was leaking, and a stop for repairs was made at a garage. While assisting to empty the tank, it accidentally fell, and Mr. Wise was saturated with the liquid. The day was exceedingly hot, and the gasoline vapor was ignited by a torch burning in a distant part of the garage. Before the flames could be extinguished, Mr. Wise was burned so severely that he died in Oakland the following day.

In his relatively short career, he had held a number of distinctly responsible positions. Among his earlier works may be mentioned the reconstruction of the Centerville Plant of the Pacific Gas and Electric Company, which consisted of the enlargement of the conduits, the rebuilding of the power station, and the installation of a turbine operating a 5 000-kw. generator under a 600-ft. head. Later, he had charge of the erection of a 5 000-kw. generator at Colgate, and of similar work for the Deer Creek Plant of the Pacific Gas and Electric Company. In 1909, the Lake Arthur Dam was constructed under his supervision.

At the time of his death, Mr. Wise was in direct charge of the design and construction of a large hydro-electric power plant for

* Memoir prepared by J. D. Galloway, M. Am. Soc. C. E., and B. A. Etcheverry and H. C. Vensano, Associate Members, Am. Soc. C. E.

his Company. This work included a masonry dam, more than 300 ft. high, to store the waters of Lake Spalding. The conduits, pipe lines, buildings, machinery, and steel tower transmission line of the plant were proportioned to generate 40 000 kw.

Mr. Wise, on account of his kindly nature, was uniformly liked by all who met him. He had exquisite tact, most courteous manners, and, in a very high degree, the power to command loyal service and friendship from others. The writers, speaking for themselves and for many who knew him, remarked with pleasure his rapid rise to a responsible position, and they take this occasion to express their deep respect for the noble character of a friend whose death is a cause for profound sorrow and regret. He was a Mason, was unmarried, and is survived by his mother who lives in Berkeley, Cal.

Mr. Wise was elected an Associate Member of the American Society of Civil Engineers, on February 6th, 1907, and, at the time of his death, was Vice-President of the San Francisco Association of the Society.

STEPHEN HOLMAN, F. Am. Soc. C. E.*

DIED OCTOBER 13TH, 1912.

Stephen Holman was born at Royalston, Mass., on December 28th, 1820. He was the son of Stephen and Hannah (Fuller) Holman whose ancestors settled at Newburyport, Mass., early in the Eighteenth Century, several having served in the War of the Revolution.

On the death of his father in 1832, the boy went to live with his half-brother at Saugus, Mass. After attending school at Saugus Centre, he entered the Lynn Academy where he prepared for college. He was graduated from Williams College in the Class of 1840. Afterward, he studied law and was admitted to the bar, but never practiced that profession to any extent, preferring that of teaching. For a number of years he served as principal of high schools and academies at Winchester, N. H., Gardner, Athol, Phillipston, Fitchburg, and Holyoke, Mass.

While in the latter city Mr. Holman was employed as Paymaster at the Lyman Mills, and, in 1860, bought a controlling interest in the Holyoke Paper Company, which he managed with conspicuous ability. In 1865 he sold his interest in that Company and established the Holyoke Machine Company, and, later, a branch of the same company at Worcester, Mass. He also founded the Deane Steam Pump Company, of Holyoke, and became interested in a number of cotton mills and also in the American Telephone Company.

Mr. Holman was very successful in business, and this success was due in part to his power of initiation. He was the originator of many new methods of reducing business to a scientific basis, and was the first to establish the present methods of cost-keeping in paper mills. An example of his original methods was the establishment of a testing flume at the works of the Deane Steam Pump Company, at Holyoke, by which every water-wheel manufactured at the plant could be tested, as to head and power, under actual service conditions, thereby guaranteeing them to purchasers. This flume was also placed at the disposal of any manufacturer who cared to make use of it for testing.

Mr. Holman retained his physical and mental vigor until his death, keeping in close touch with his business interests. He was a student and an accomplished linguist, never losing touch with his college studies, especially that of the German language and literature of which he was particularly fond. At the age of ninety he gave a reading from Schiller's plays before a German association.

He was a brilliant conversationalist, and, having a wonderful range of general knowledge, could entertain others no matter what their

* Memoir prepared by the Secretary from information supplied by C. J. H. Woodbury, M. Am. Soc. C. E.

tastes and experiences in life had been. He was tenacious in his friendships, particularly with men, his cultured mind and strength of intellect making him a dominating figure in personal associations and in business life.

Fondness for Nature was one of Mr. Holman's strong characteristics, which was gratified by extensive travel in this country and in Europe. He had just returned from a European trip when he was seized with a sudden attack of neuralgia of the heart which caused his death at Swampscott, Mass.

On April 12th, 1853, Mr. Holman was married to Miss Hannah A. Richardson, of Lowell, Mass., who died in 1894. He is survived by a son and a daughter.

He was a Member of the Mt. Tom Lodge, A. F. and A. M., and of many other organizations. At the time of his death he was the oldest Alumnus of the Lynn Academy and of Williams College. He was also the Senior Mason and the Senior Member of the Massachusetts bar.

Mr. Holman was elected a Fellow of the American Society of Civil Engineers on June 29th, 1872.
